18-6. 閏 Spectroscopic data for the indicators thymol blue (TB), semithymol blue (STB), and methylthymol blue (MTB) are shown in the table. A solution of TB, STB, and MTB in a $1.000-\mathrm{cm}$ cuvet had absorbances of 0.412 at $455 \mathrm{~nm}, 0.350$ at 485 nm , and 0.632 at 545 nm . Modify the spreadsheet in Figure 18-5 to handle three simultaneous equations and find $[\mathrm{TB}],[\mathrm{STB}]$, and $[\mathrm{MTB}]$ in the mixture.

|  | $\varepsilon\left(\mathrm{M}^{-1} \mathrm{~cm}^{-1}\right)$ |  |  |
| :--- | :---: | :---: | ---: |
| $\lambda(\mathrm{nm})$ | TB | STB | MTB |
| 455 | 4800 | 11100 | 18900 |
| 485 | 7350 | 11200 | 11800 |
| 545 | 36400 | 13900 | 4450 |

source: S. Kiciak, H. Gontarz, and E. Krzyżanowska, "Monitoring the Synthesis of Semimethylthymol Blue and Methylthymol Blue," Talanta 1995, 42, 1245.

18-7. The spreadsheet gives the product $\varepsilon b$ for four pure compounds and a mixture at infrared wavelengths. Modify Figure 18-5 to solve four equations and find the concentration of each compound. You can treat the coefficient matrix as if it were molar absorptivity because the pathlength was constant (but unknown) for all measurements.

| Wavelength <br> $(\mu \mathrm{m})$ | Coefficient matrix ( $\mathrm{\varepsilon b})$ |  |  |  | Absorbance <br> of unknown |
| :---: | ---: | ---: | ---: | ---: | ---: |
|  | $p$-xylene | $m$-xylene | o-xylene | ethylbenzene |  |
| 12.5 | 1.5020 | 0.0514 | 0 | 0.0408 | 0.09943 |
| 13.0 | 0.0261 | 1.1516 | 0 | 0.0820 | 0.09 |
| 13.4 | 0.0342 | 0.0355 | 2.532 | 0.2933 | 0.2194 |
| 14.3 | 0.0340 | 0.0684 | 0 | 0.3470 | 0.03396 |

source: Z. Zdravkovski, "Mathcad in Chemistry Calculations. II. Arrays," J. Chem. Ed. 1992, 69, 242A.
18-8. A solution was prepared by mixing 25.00 mL of 0.0800 M aniline, 25.00 mL of 0.0600 M sulfanilic acid, and 1.00 mL of $1.23 \times 10^{-4} \mathrm{M}$ HIn and then diluting to 100.0 mL . (HIn stands for protonated indicator.)

Anilinium ion $\mathrm{p} K_{\mathrm{a}}=4.601$

$$
\begin{array}{cc}
\boldsymbol{H I n} \rightleftharpoons & \mathrm{H}^{+}+\mathrm{In}^{-} \\
\nearrow & \\
\varepsilon_{325}=2.45 \times 10^{4} \mathrm{M}^{-1} \mathrm{~cm}^{-1} & \varepsilon_{325}=4.39 \times 10^{3} \mathrm{M}^{-1} \mathrm{~cm}^{-1} \\
\varepsilon_{550}=2.26 \times 10^{4} \mathrm{M}^{-1} \mathrm{~cm}^{-1} & \varepsilon_{550}=1.53 \times 10^{4} \mathrm{M}^{-1} \mathrm{~cm}^{-1}
\end{array}
$$

The absorbance measured at 550 nm in a $5.00-\mathrm{cm}$ cell was 0.110 . Find the concentrations of HIn and $\mathrm{In}^{-}$and $\mathrm{p} K_{\mathrm{a}}$ for HIn.

18-9. Chemical equilibrium and analysis of a mixture. (Warning! This is a long problem.) A remote optical sensor for $\mathrm{CO}_{2}$ in the ocean was designed to operate without the need for calibration. ${ }^{31}$

The sensor compartment is separated from seawater by a silicone membrane through which $\mathrm{CO}_{2}$, but not dissolved ions, can diffuse. Inside the sensor, $\mathrm{CO}_{2}$ equilibrates with $\mathrm{HCO}_{3}^{-}$and $\mathrm{CO}_{3}^{2-}$. For each measurement, the sensor is flushed with fresh solution containing $50.0 \mu \mathrm{M}$ bromothymol blue indicator ( NaHIn ) and $42.0 \mu \mathrm{M} \mathrm{NaOH}$. All indicator is in the form $\mathrm{HIn}^{-}$or $\mathrm{In}^{2-}$ near neutral pH , so we can write two mass balances: (1) $\left[\mathrm{HIn}^{-}\right]+\left[\mathrm{In}^{2-}\right]=\mathrm{F}_{\text {In }}=50.0 \mu \mathrm{M}$ and (2) $\left[\mathrm{Na}^{+}\right]=\mathrm{F}_{\mathrm{Na}}=50.0 \mu \mathrm{M}+42.0 \mu \mathrm{M}=92.0 \mu \mathrm{M}$. $\mathrm{HIn}^{-}$has an absorbance maximum at 434 nm and $\mathrm{In}^{2-}$ has a maximum at 620 nm . The sensor measures the absorbance ratio $R_{\mathrm{A}}=A_{620} / A_{434}$ reproducibly without need for calibration. From this ratio, we can find $\left[\mathrm{CO}_{2}(\mathrm{aq})\right]$ in the seawater as outlined here:
(a) From Beer's law for the mixture, write equations for $\left[\mathrm{HIn}^{-}\right]$and $\left[\mathrm{In}^{2-}\right.$ ] in terms of the absorbances at 620 and $434 \mathrm{~nm}\left(A_{620}\right.$ and $A_{434}$ ). Then show that

$$
\begin{equation*}
\frac{\left[\mathrm{In}^{2-}\right]}{\left[\mathrm{HIn}^{-}\right]}=\frac{R_{\mathrm{A}} \varepsilon_{434}^{\mathrm{HIn}^{-}}-\varepsilon_{620}^{\mathrm{HIn}}}{\varepsilon_{620}^{\mathrm{In}^{2-}}-R_{\mathrm{A}} \varepsilon_{434}^{\mathrm{In}^{2-}}} \equiv R_{\mathrm{In}} \tag{A}
\end{equation*}
$$

(b) From the mass balance (1) and the acid dissociation constant $K_{\text {In }}$, show that

$$
\begin{align*}
{\left[\mathrm{HIn}^{-}\right] } & =\frac{\mathrm{F}_{\mathrm{In}}}{R_{\mathrm{In}}+1}  \tag{B}\\
{\left[\mathrm{In}^{2-}\right] } & =\frac{K_{\mathrm{In}} \mathrm{~F}_{\text {In }}}{\left[\mathrm{H}^{+}\right]\left(R_{\mathrm{In}}+1\right)} \tag{C}
\end{align*}
$$

(c) Show that $\left[\mathrm{H}^{+}\right]=K_{\mathrm{In}} / R_{\mathrm{In}}$.
(d) From the carbonic acid dissociation equilibria, show that

$$
\begin{align*}
{\left[\mathrm{HCO}_{3}^{-}\right] } & =\frac{K_{1}\left[\mathrm{CO}_{2}(a q)\right]}{\left[\mathrm{H}^{+}\right]}  \tag{E}\\
{\left[\mathrm{CO}_{3}^{2-}\right] } & =\frac{K_{1} K_{2}\left[\mathrm{CO}_{2}(a q)\right]}{\left[\mathrm{H}^{+}\right]^{2}} \tag{F}
\end{align*}
$$

(e) Write the charge balance for the solution in the sensor compartment. Substitute in expressions B, C, E, and F for $\left[\mathrm{HIn}^{-}\right],\left[\mathrm{In}^{2-}\right]$, $\left[\mathrm{HCO}_{3}^{-}\right]$, and $\left[\mathrm{CO}_{3}^{2-}\right]$.
(f) Suppose that the various constants have the following values:

$$
\begin{array}{ll}
\varepsilon_{434}^{\mathrm{Hin}}=8.00 \times 10^{3} \mathrm{M}^{-1} \mathrm{~cm}^{-1} & K_{1}=3.0 \times 10^{-7} \\
\varepsilon_{620}^{\mathrm{Hn}}=0 & K_{2}=3.3 \times 10^{-11} \\
\varepsilon_{434}^{\mathrm{Hn}^{2-}}=1.90 \times 10^{3} \mathrm{M}^{-1} \mathrm{~cm}^{-1} & K_{\mathrm{In}}=2.0 \times 10^{-7} \\
\varepsilon_{620}^{\mathrm{In}^{2-}}=1.70 \times 10^{4} \mathrm{M}^{-1} \mathrm{~cm}^{-1} & K_{\mathrm{w}}=6.7 \times 10^{-15}
\end{array}
$$

From the measured absorbance ratio $R_{\mathrm{A}}=A_{620} / A_{434}=2.84$, find $\left[\mathrm{CO}_{2}(a q)\right]$ in the seawater.
(g) Approximately what is the ionic strength inside the sensor compartment? Were we justified in neglecting activity coefficients in working this problem?

## Measuring an Equilibrium Constant

18-10. Figure 18-7 is a Scatchard plot for the addition of $0-20 \mathrm{nM}$ antigen X to a fixed concentration of antibody $\mathrm{P}\left(\mathrm{P}_{0}=10 \mathrm{nM}\right)$. Prepare a Scatchard plot from the data in the table and find $K$ for the reaction $\mathrm{P}+\mathrm{X} \rightleftharpoons \mathrm{PX}$. The table gives measured concentrations of unbound X and the complex PX. It is recommended that the fraction of saturation should span the range $\sim 0.2-0.8$. What is the range of the fraction of saturation for the data?

| $[\mathrm{X}](\mathrm{nM})$ | $[\mathrm{PX}](\mathrm{nM})$ | $[\mathrm{X}](\mathrm{nM})$ | $[\mathrm{PX}](\mathrm{nM})$ |
| :--- | :--- | :--- | :--- |
| $0.12_{0}$ | $2.8_{7}$ | $0.73_{1}$ | $6.2_{9}$ |
| $0.19_{2}$ | $3.8_{0}$ | $1.2_{2}$ | $6.7_{7}$ |
| $0.29_{6}$ | $4.6_{6}$ | $1.5_{0}$ | $7.5_{2}$ |
| $0.45_{0}$ | $5.5_{4}$ | $3.6_{1}$ | $8.4_{5}$ |

18-11. Scatchard plot for binding of estradiol to albumin. Data in the table come from a student experiment to measure the binding constant of the radioactively labeled hormone estradiol (X) to the protein, bovine serum albumin (P). Estradiol ( 7.5 nM ) was equilibrated with various concentrations of albumin for 30 min at $37^{\circ} \mathrm{C}$. A small fraction of unbound estradiol was removed by solid-phase microextraction (Section 23-4) and measured by liquid scintillation counting. Albumin is present in large excess, so its concentration in any given solution is essentially equal to its initial concentration in that solution. Call the initial concentration of estradiol $[\mathrm{X}]_{0}$ and the final concentration of unbound estradiol [X]. Then bound estradiol is $[\mathrm{X}]_{0}-[\mathrm{X}]$ and the equilibrium constant is

$$
\mathrm{X}+\mathrm{P} \rightleftharpoons \mathrm{PX} \quad K=\frac{[\mathrm{PX}]}{[\mathrm{X}][\mathrm{P}]}=\frac{[\mathrm{X}]_{0}-[\mathrm{X}]}{[\mathrm{X}][\mathrm{P}]}
$$

which you can rearrange to

$$
\frac{[\mathrm{X}]_{0}}{[\mathrm{X}]}=K[\mathrm{P}]+1
$$

A graph of $[\mathrm{X}]_{0} /[\mathrm{X}]$ versus $[\mathrm{P}]$ should be a straight line with a slope of $K$. The quotient $[\mathrm{X}]_{0} /[\mathrm{X}]$ is equal to the counts of radioactive
estradiol extracted from a solution without albumin divided by the counts of estradiol extracted from a solution with estradiol.
(a) Prepare a graph of $[\mathrm{X}]_{0} /[\mathrm{X}]$ versus $[\mathrm{P}]$ and find $K$. From the standard deviation of the slope, find the $95 \%$ confidence interval for $K$.
(b) What fraction of estradiol is bound to albumin at the first and last points?

| $[\mathrm{X}]_{0} /[\mathrm{X}]$ | $[\mathrm{P}](\mu \mathrm{M})$ | $[\mathrm{X}]_{0} /[\mathrm{X}]$ | $[\mathrm{P}](\mu \mathrm{M})$ |
| :--- | :---: | :--- | :--- |
| 1.26 | 6.3 | 3.33 | 50.0 |
| 1.62 | 10.0 | 4.19 | 60.0 |
| 2.16 | 20.0 | 4.13 | 70.0 |
| 2.51 | 30.0 | 4.36 | 80.0 |
| 3.34 | 40.0 |  |  |

source: P. Liang, B. Adhyaru, W. L. Pearson, and K. R. Williams, "The Binding Constant of Estradiol to Bovine Serum Albumin," J. Chem. Ed. 2006, 83, 294.
18-12. Iodine reacts with mesitylene to form a complex with an absorption maximum at 332 nm in $\mathrm{CCl}_{4}$ solution:

(a) Given that the product absorbs at 332 nm , but neither reactant has significant absorbance at this wavelength, use the equilibrium constant, $K$, and Beer's law to show that

$$
\frac{A}{[\text { mesitylene }]\left[\mathrm{I}_{2}\right]_{\mathrm{tot}}}=K \varepsilon-\frac{K A}{\left[\mathrm{I}_{2}\right]_{\mathrm{tot}}}
$$

where $A$ is the absorbance at $332 \mathrm{~nm}, \varepsilon$ is the molar absorptivity of the complex at 332 nm , [mesitylene] is the concentration of free mesitylene, and $\left[\mathrm{I}_{2}\right]_{\mathrm{tot}}$ is the total concentration of iodine in the solution $\left(=\left[\mathrm{I}_{2}\right]+\right.$ complex] $)$. The cell pathlength is 1.000 cm .
(b) Spectrophotometric data for this reaction are shown in the table. Because [mesitylene $]_{\text {tot }} \gg\left[\mathrm{I}_{2}\right]$, we can say that [mesitylene] $\approx$ [mesitylene $]_{\text {tot }}$. Prepare a graph of $A /\left([\right.$ mesitylene $\left.]\left[I_{2}\right]_{\text {tot }}\right)$ versus $A /\left[\mathrm{I}_{2}\right]_{\text {tot }}$ and find the equilibrium constant and molar absorptivity of the complex.

| $[\text { Mesitylene }]_{\text {tot }}(\mathrm{M})$ | $\left[\mathrm{I}_{2}\right]_{\text {tot }}(\mathrm{M})$ | Absorbance <br> at 332 nm |
| :--- | :--- | :--- |
| 1.690 | $7.817 \times 10^{-5}$ | 0.369 |
| 0.9218 | $2.558 \times 10^{-4}$ | 0.822 |
| 0.6338 | $3.224 \times 10^{-4}$ | 0.787 |
| 0.4829 | $3.573 \times 10^{-4}$ | 0.703 |
| 0.3900 | $3.788 \times 10^{-4}$ | 0.624 |
| 0.3271 | $3.934 \times 10^{-4}$ | 0.556 |

Source: P. J. Ogren and J. R. Norton, "Applying a Simple Linear Least-Squares Algorithm to Data with Uncertainties in Both Variables," J. Chem. Ed. 1992, 69, A130.
18-13. Now we use Solver to find $K$ for the previous problem. The only absorbing species at 332 nm is the complex, so, from Beer's law, $[$ complex $]=A / \varepsilon$ (because pathlength $=1.000 \mathrm{~cm}$ ). $\mathrm{I}_{2}$ is either free or bound in the complex, so $\left[\mathrm{I}_{2}\right]=\left[\mathrm{I}_{2}\right]_{\text {tot }}-$ [complex]. There is a huge excess of mesitylene, so $[$ mesitylene $] \approx[\text { mesitylene }]_{\text {tot }}$.

$$
K=\frac{[\text { complex }]}{\left[\mathrm{I}_{2}\right][\text { mesitylene }]}=\frac{A / \varepsilon}{\left(\left[\mathrm{I}_{2}\right]_{\mathrm{tot}}-A / \varepsilon\right)[\text { mesitylene }]_{\mathrm{tot}}}
$$

The spreadsheet shows some of the data. You will need to use all the data. Column A contains [mesitylene] and column B contains $\left[I_{2}\right]_{\text {tot }}$.

Column C lists the measured absorbance. Guess a value of the molar absorptivity of the complex, $\varepsilon$, in cell A7. Then compute the concentration of the complex ( $=A / \varepsilon$ ) in column D. The equilibrium constant in column E is given by $\mathrm{E} 2=[$ complex $] /\left(\left[\mathrm{I}_{2}\right][\right.$ mesitylene $\left.]\right)=$ (D2)/((B2-D2)*A2).

|  | $\mathbf{A}$ | $\mathbf{B}$ | $\mathbf{C}$ | $\mathbf{D}$ | $\mathbf{E}$ |
| :---: | ---: | :---: | :---: | :---: | :---: |
| $\mathbf{1}$ | [Mesitylene] | $[12]$ tot | A | $[$ Complex $]=\mathrm{A} / \varepsilon$ | Keq |
| $\mathbf{2}$ | 1.6900 | $7.817 \mathrm{E}-05$ | 0.369 | $7.380 \mathrm{E}-05$ | 9.99282 |
| $\mathbf{3}$ | 0.9218 | $2.558 \mathrm{E}-04$ | 0.822 | $1.644 \mathrm{E}-04$ | 1.95128 |
| $\mathbf{4}$ | 0.6338 | $3.224 \mathrm{E}-04$ | 0.787 | $1.574 \mathrm{E}-04$ | 1.50511 |
| $\mathbf{5}$ |  |  |  | Average $=$ | 4.48307 |
| $\mathbf{6}$ | Guess for $\varepsilon:$ |  |  | Standard Dev $=$ | 4.77680 |
| $\mathbf{7}$ | $5.000 \mathrm{E}+03$ |  |  | Stdev/Average $=$ | 1.06552 |

What should we minimize with Solver? We want to vary $\varepsilon$ in cell A7 until the values of $K$ in column E are as constant as possible. We would like to minimize a function like $\Sigma\left(K_{i}-K_{\text {average }}\right)^{2}$, where $K_{i}$ is the value in each line of the table and $K_{\text {average }}$ is the average of all computed values. The problem with $\Sigma\left(K_{i}-K_{\text {average }}\right)^{2}$ is that we can minimize this function simply by making $K_{i}$ very small, but not necessarily constant. What we really want is for all the $K_{i}$ to be clustered around the mean value. A good way to do this is to minimize the relative standard deviation of the $K_{i}$, which is (standard deviation)/average. In cell E5, we compute the average value of $K$ and in cell E6 the standard deviation. Cell E7 contains the relative standard deviation. Use Solver to minimize cell E7 by varying cell A7. Compare your answer with that of Problem 18-12.

## Method of Continuous Variation

18-14. Method of continuous variation. Make a graph of absorbance versus mole fraction of thiocyanate from the data in the table.

| mL Fe |  |  |
| :--- | :--- | :--- |
| s+ <br> solution $^{a}$ | $\mathrm{mL} \mathrm{SCN}^{-}$ <br> solution $^{b}$ | Absorbance <br> at 455 nm |

| 0.500 | 0.348 |  |  |

source: L. Perring and B. Bourqui, "An Alternative Method for Fluoride Determination by Ion Chromatography Using Post-Column Reaction," Am. Lab. News Ed., March 2002, p. 28.
18-16. 島閏 Simulating a Job's plot. Consider the reaction $\mathrm{A}+2 \mathrm{~B} \rightleftharpoons \mathrm{AB}_{2}$, for which $K=\left[\mathrm{AB}_{2}\right] /[\mathrm{A}][\mathrm{B}]^{2}$. Suppose that the following mixtures of A and B at a fixed total concentration of $10^{-4}$ M are prepared:

| $[\mathrm{A}]_{\text {total }}(\mathrm{M})$ | $[\mathrm{B}]_{\text {total }}(\mathrm{M})$ | $[\mathrm{A}]_{\text {total }}(\mathrm{M})$ | $[\mathrm{B}]_{\text {total }}(\mathrm{M})$ |
| :--- | :--- | :--- | :--- |
| $1.00 \times 10^{-5}$ | $9.00 \times 10^{-5}$ | $5.00 \times 10^{-5}$ | $5.00 \times 10^{-5}$ |
| $2.00 \times 10^{-5}$ | $8.00 \times 10^{-5}$ | $6.00 \times 10^{-5}$ | $4.00 \times 10^{-5}$ |
| $2.50 \times 10^{-5}$ | $7.50 \times 10^{-5}$ | $7.00 \times 10^{-5}$ | $3.00 \times 10^{-5}$ |
| $3.00 \times 10^{-5}$ | $7.00 \times 10^{-5}$ | $8.00 \times 10^{-5}$ | $2.00 \times 10^{-5}$ |
| $3.33 \times 10^{-5}$ | $6.67 \times 10^{-5}$ | $9.00 \times 10^{-5}$ | $1.00 \times 10^{-5}$ |
| $4.00 \times 10^{-5}$ | $6.00 \times 10^{-5}$ |  |  |

(a) Prepare a spreadsheet to find the concentration of $\mathrm{AB}_{2}$ for each mixture, for equilibrium constants of $K=10^{6}, 10^{7}$, and $10^{8}$. One way to do this is to enter the values of $[\mathrm{A}]_{\text {total }}$ and $[\mathrm{B}]_{\text {total }}$ in columns A and B, respectively. Then put a trial (guessed) value of $\left[\mathrm{AB}_{2}\right]$ in column C. From the mass balances $[\mathrm{A}]_{\text {total }}=[\mathrm{A}]+$ $\left[\mathrm{AB}_{2}\right]$ and $[\mathrm{B}]_{\text {total }}=[\mathrm{B}]+2\left[\mathrm{AB}_{2}\right]$, we can write $K=$ $\left[\mathrm{AB}_{2}\right] /[\mathrm{A}][\mathrm{B}]^{2}=\left[\mathrm{AB}_{2}\right] /\left\{\left([\mathrm{A}]_{\text {total }}-\left[\mathrm{AB}_{2}\right]\right)\left([\mathrm{B}]_{\text {total }}-2\left[\mathrm{AB}_{2}\right]\right)^{2}\right\}$. In column $D$, enter the reaction quotient $\left[\mathrm{AB}_{2}\right] /[\mathrm{A}][\mathrm{B}]^{2}$. For example, cell D2 has the formula " $=\mathrm{C} 2 /\left((\mathrm{A} 2-\mathrm{C} 2)(\mathrm{B} 2-2 * \mathrm{C} 2)^{\wedge} 2\right)$ ". Then vary the value of $\left[\mathrm{AB}_{2}\right]$ in cell C 2 with Solver until the reaction quotient in cell D 2 is equal to the desired equilibrium constant (such as $10^{8}$ ).
(b) Prepare a graph by the method of continuous variation in which you plot $\left[\mathrm{AB}_{2}\right]$ versus mole fraction of A for each equilibrium constant. Explain the shapes of the curves.
18-17. A study was conducted with derivatives of the DNA nucleotide bases adenine and thymine bound inside micelles (Box 25-1) in aqueous solution.

Sodium dodecyl sulfate forms micelles with the hydrocarbon tails pointed inward and ionic headgroups exposed to water. It was
hypothesized that the bases would form a 1:1 hydrogen-bonded complex inside the micelle as they do in DNA:

Hydrogen-bonded base pair inside micelle, with hydrocarbon tails anchoring the bases to the micelle.

To test the hypothesis, aliquots of 5.0 mM adenine derivative were mixed with aliquots of 5.0 mM thymine derivative in proportions shown in the table. Each solution also contained 20 mM sodium dodecyl sulfate. The concentration of product measured by nuclear magnetic resonance also is shown in the table. Are the results consistent with formation of a $1: 1$ complex? Explain your answer.

| Adenine volume <br> $(\mathrm{mL})$ | Thymine volume <br> $(\mathrm{mL})$ | Concentration of <br> product $(\mathrm{mM})$ |
| :--- | :--- | :--- |
| 0.450 | 0.050 | $0.118 \pm 0.009$ |
| 0.400 | 0.100 | $0.202 \pm 0.038$ |
| 0.350 | 0.150 | $0.265 \pm 0.021$ |
| 0.300 | 0.200 | $0.307 \pm 0.032$ |
| 0.250 | 0.250 | $0.312 \pm 0.060$ |
| 0.200 | 0.300 | $0.296 \pm 0.073$ |
| 0.150 | 0.350 | $0.260 \pm 0.122$ |
| 0.100 | 0.400 | $0.187 \pm 0.110$ |
| 0.050 | 0.450 | $0.103 \pm 0.104$ |

Flow Injection, Luminescence, and Immunoassay
18-18. Explain what is done in flow injection analysis and sequential injection. What is the principal difference between the two techniques? Which one is called "lab-on-a-valve"?

18-19. Explain how signal amplification is achieved in enzymelinked immunosorbent assays.

18-20. What is the advantage of a time-resolved emission measurement with $\mathrm{Eu}^{3+}$ versus measurement of fluorescence from organic chromophores?

18-21. Here is an immunoassay to measure explosives such as trinitrotoluene (TNT) in organic solvent extracts of soil. The assay employs a flow cytometer, which counts small particles (such as living cells) flowing through a narrow tube past a detector. The cytometer in this experiment irradiates the particles with a green laser and measures fluorescence from each particle as it flows past the detector.

1. Antibodies that bind TNT are chemically attached to $5-\mu \mathrm{m}-$ diameter latex beads.
2. The beads are incubated with a fluorescent derivative of TNT to saturate the antibodies, and excess TNT derivative is removed. The beads are resuspended in aqueous detergent.

3. $5 \mu \mathrm{~L}$ of the suspension are added to $100 \mu \mathrm{~L}$ of sample or standard. TNT in the sample or standard displaces some derivatized TNT from bound antibodies. The higher the concentration of TNT, the more derivatized TNT is displaced.
4. An aliquot is injected into the flow cytometer, which measures fluorescence of individual beads as they pass the detector. The figure shows median fluorescence intensity $\pm$ standard deviation. TNT can be quantified in the ppb to ppm range.

Fluorescence of TNT-antibody-beads versus TNT concentration. [From G. P. Anderson, S. C. Moreira, P. T. Charles, I. L. Medintz, E. R. Goldman, M. Zeinali, and C. R. Taitt, "TNT Detection Using Multiplexed Liquid Array Displacement Immunoassays," Anal. Chem. 2006, 78, 2279.]

Draw pictures showing the state of the beads in steps 1,2 , and 3 and explain how this method works.

18-22. The graph shows the effect of pH on quenching of luminescence of tris( $2,2^{\prime}$-bipyridine) Ru(II) by 2,6-dimethylphenol. The ordinate, $K_{\mathrm{SV}}$, is the collection of constants, $k_{\mathrm{q}} /\left(k_{\mathrm{e}}+k_{\mathrm{d}}\right)$, in the Stern-Volmer equation 18-25. The greater $K_{\mathrm{SV}}$, the greater the quenching. Suggest an explanation for the shape of the graph and estimate $\mathrm{p} K_{\mathrm{a}}$ for 2,6-dimethylphenol.

2,6-Dimethylphenol

Tris(2,2'-bipyridine)ruthenium(II)

Quenching of tris(2,2'-bipyridine)Ru(II) by 2,6-dimethylphenol as a function of pH. [Data from H. Gsponer, G. A. Argüello, and G. A. Argüello, "Determinations of $\mathrm{p} K_{\mathrm{a}}$ from Luminescence Quenching Data," J. Chem. Ed. 1997, 74, 968.]

18-23. Fluorescence quenching in micelles. Consider an aqueous solution with a high concentration of micelles (Box 25-1) and relatively low concentrations of the fluorescent molecule pyrene and a quencher (cetylpyridinium chloride, designated Q ), both of which dissolve in the micelles.

Pyrene
(fluorescent species)

Cetylpyridinium chloride (quencher, Q)

Quenching occurs if pyrene and Q are in the same micelle. Let the total concentration of quencher be $[\mathrm{Q}]$ and the concentration of micelles be $[\mathrm{M}]$. The average number of quenchers per micelle is $\overline{\mathrm{Q}}=[\mathrm{Q}] /[\mathrm{M}]$. If Q is randomly distributed among the micelles, then the probability that a particular micelle has $n$ molecules of Q is given by the Poisson distribution: ${ }^{32}$

$$
\begin{equation*}
\text { Probability of } n \text { molecules of } \mathrm{Q} \text { in micelle } \equiv P_{n}=\frac{\overline{\mathrm{Q}}^{n}}{n!} \mathrm{e}^{-\overline{\mathrm{Q}}} \tag{1}
\end{equation*}
$$

where $n$ ! is $n$ factorial $(=n[n-1][n-2] \ldots[1])$. The probability that there are no molecules of Q in a micelle is

Probability of 0 molecules of Q in micelle $=\frac{\overline{\mathrm{Q}}^{0}}{0!} \mathrm{e}^{-\overline{\mathrm{Q}}}=\mathrm{e}^{-\overline{\mathrm{Q}}}$
because $0!\equiv 1$.
Let $I_{0}$ be the fluorescence intensity of pyrene in the absence of Q and let $I_{\mathrm{Q}}$ be the intensity in the presence of Q (both measured at
the same concentration of micelles). The quotient $I_{\mathrm{Q}} / I_{0}$ must be $\mathrm{e}^{-\overline{\mathrm{Q}}}$, which is the probability that a micelle does not possess a quencher molecule. Substituting $\overline{\mathrm{Q}}=[\mathrm{Q}] /[\mathrm{M}]$ gives

$$
\begin{equation*}
I_{\mathrm{Q}} / I_{0}=\mathrm{e}^{-\overline{\mathrm{Q}}}=\mathrm{e}^{-[\mathrm{Q}] /[\mathrm{M}]} \tag{3}
\end{equation*}
$$

Micelles are made of the surfactant molecule, sodium dodecyl sulfate (shown in Problem 18-17). When surfactant is added to a solution, no micelles form until a minimum concentration called the critical micelle concentration (CMC) is attained. When the total concentration of surfactant, $[\mathrm{S}]$, exceeds the critical concentration, then the surfactant found in micelles is [S] - [CMC]. The molar concentration of micelles is

$$
\begin{equation*}
[\mathrm{M}]=\frac{[\mathrm{S}]-[\mathrm{CMC}]}{N_{\mathrm{av}}} \tag{4}
\end{equation*}
$$

where $N_{\mathrm{av}}$ is the average number of molecules of surfactant in each micelle.

Combining Equations 3 and 4 gives an expression for fluorescence as a function of total quencher concentration, $[\mathrm{Q}]$ :

$$
\begin{equation*}
\ln \frac{I_{0}}{I_{\mathrm{Q}}}=\frac{[\mathrm{Q}] N_{\mathrm{av}}}{[\mathrm{~S}]-[\mathrm{CMC}]} \tag{5}
\end{equation*}
$$

By measuring fluorescence intensity as a function of $[\mathrm{Q}]$ at fixed $[\mathrm{S}]$, we can find the average number of molecules of $S$ per micelle if we know the critical micelle concentration (which is independently measured in solutions of S). The table gives data for $3.8 \mu \mathrm{M}$ pyrene in a micellar solution with a total concentration of sodium dodecyl sulfate $[\mathrm{S}]=20.8 \mathrm{mM}$.

| $\mathrm{Q}(\mu \mathrm{M})$ | $I_{0} / I_{\mathrm{Q}}$ | $\mathrm{Q}(\mu \mathrm{M})$ | $I_{0} / I_{\mathrm{Q}}$ | $\mathrm{Q}(\mu \mathrm{M})$ | $I_{0} / I_{\mathrm{Q}}$ |
| ---: | :--- | :--- | :--- | :--- | :--- |
| 0 | 1 | 158 | 2.03 | 316 | 4.04 |
| 53 | 1.28 | 210 | 2.60 | 366 | 5.02 |
| 105 | 1.61 | 262 | 3.30 | 418 | 6.32 |

(a) If micelles were not present, quenching would be expected to follow the Stern-Volmer equation 18-25. Show that the graph of $I_{0} / I_{\mathrm{Q}}$ versus $[\mathrm{Q}]$ is not linear.
(b) The critical micelle concentration is 8.1 mM . Prepare a graph of $\ln \left(I_{0} / I_{\mathrm{Q}}\right)$ versus [Q]. Use Equation 5 to find $N_{\mathrm{av}}$, the average number of sodium dodecyl sulfate molecules per micelle.
(c) Find the concentration of micelles, $[\mathrm{M}]$, and the average number of molecules of Q per micelle, $\overline{\mathrm{Q}}$, when $[\mathrm{Q}]=0.200 \mathrm{mM}$.
(d) Compute the fractions of micelles containing 0,1 , and 2 molecules of Q when $[\mathrm{Q}]=0.200 \mathrm{mM}$.

## CAVITY RING-DOWN SPECTROSCOPY: DO YOU HAVE AN ULCER?

Cavity ring-down spectrum of $\sim 3$ mbar of $\mathrm{CO}_{2}$, which is similar to the concentration in human breath. [From E. R. Crosson, K. N. Ricci, B. A. Richman, F. C. Chilese, T. G. Owano, R. A. Provencal, M. W. Todd, J. Glasser, A. A. Kachanov, B. A. Paldus, T. G. Spence, and R. N. Zare, "Stable Isotope Ratios Using Cavity Ring-Down Spectroscopy: Determination of ${ }^{13} \mathrm{C} /{ }^{12} \mathrm{C}$ for Carbon Dioxide in Human Breath," Anal. Chem. 2002, 74, 2003.]

Cavity ring-down can measure absorbance as low as $\sim 10^{-6}$ and has the potential to provide sensitive detectors for chromatography. ${ }^{1}$ In panel $a$, a laser pulse is directed into a cavity with mirrors on both ends. If the mirror reflectivity is $99.98 \%$, then $0.02 \%$ of the power penetrates mirror $\mathrm{M}_{1}$ and enters the cavity. The laser is shut off and light inside the cavity bounces back and forth, losing $0.02 \%$ of its intensity each time it strikes a mirror. A detector outside mirror $\mathrm{M}_{2}$ measures light leaking through $\mathrm{M}_{2}$. Graph $b$ shows decay of the detector signal from a cavity containing a nonabsorbing liquid. If an absorbing species is present, decay is faster because signal is lost by absorption during each pass between the mirrors. The difference in signal decay time with and without absorber provides a measure of absorbance. The effective pathlength is $\sim 10^{3}$ times the length of the cavity because light makes $\sim 10^{3}$ passes between mirrors during the measurement. A commercial cavity ring-down spectrometer for measurement of isotopes of gases such as $\mathrm{CO}_{2}, \mathrm{CH}_{4}, \mathrm{NH}_{3}, \mathrm{H}_{2} \mathrm{~S}, \mathrm{HF}, \mathrm{H}_{2} \mathrm{CO}$, and $\mathrm{C}_{2} \mathrm{H}_{4}$ has an effective pathlength of nearly $20 \mathrm{~km} .^{2}$

Spectrum $c$ shows absorbance measured for $\mathrm{CO}_{2}(g)$ with the natural mixture of $98.9 \%{ }^{12} \mathrm{C}$ and $1.1 \%{ }^{13} \mathrm{C}$. Peaks arise from transitions between rotational levels of two vibrational states. The spectral region was chosen to include a strong absorption of ${ }^{13} \mathrm{CO}_{2}$ and a weak absorption of ${ }^{12} \mathrm{CO}_{2}$, so the intensities of the isotopic peaks are similar. Each point in the spectrum was obtained by varying the laser frequency.

The areas of the ${ }^{13} \mathrm{CO}_{2}$ and ${ }^{12} \mathrm{CO}_{2}$ peaks from human breath were used to determine whether a patient was infected with Helicobacter pylori, a bacterium that causes ulcers. After a patient ingests ${ }^{13} \mathrm{C}$-urea, H . pylori converts ${ }^{13} \mathrm{C}$-urea into ${ }^{13} \mathrm{CO}_{2}$, which appears in the patient's breath. The ratio ${ }^{13} \mathrm{C} /{ }^{12} \mathrm{C}$ in the breath of an infected person increases by $1-5 \%$, whereas the ratio ${ }^{13} \mathrm{C} /{ }^{12} \mathrm{C}$ from an uninfected person is constant to within $0.1 \%$.

Transmittance: $T=P / P_{\mathbf{0}}$
Absorbance: $A=-\log T=\varepsilon b c$
$\varepsilon=$ molar absorptivity
$b=$ pathlength
$c=$ concentration

Figure 17-4 showed the essential features of a single-beam spectrophotometer. Light from a source is separated into narrow bands of wavelength by a monochromator, passed through a sample, and measured by a detector. We measure the irradiance ( $P_{0}$, watts $/ \mathrm{m}^{2}$ ) striking the detector with a reference cell (a solvent blank or reagent blank) in the sample compartment. When the reference is replaced by the sample of interest, some radiation is usually absorbed and the irradiance striking the detector, $P$, is smaller than $P_{0}$. The quotient $P / P_{0}$, which is a number between 0 and 1 , is the transmittance, T. Absorbance, which is proportional to concentration, is $A=\log P_{0} / P=-\log T$.

A single-beam spectrophotometer is inconvenient because the sample and reference must be placed alternately in the beam. For measurements at multiple wavelengths, the reference
 incident beam is passed alternately through the sample and reference cuvets by the rotating beam chopper.

headlight), and the ultraviolet source is a deuterium arc lamp that emits in the range 200 to 400 nm . Only one lamp is used at a time. Grating 1 selects a narrow band of wavelengths to enter the monochromator, which in turn selects an even narrower band to pass through the sample. After being chopped and transmitted through the sample and reference cells, the signal is detected by a photomultiplier tube, which creates an electric current proportional to irradiance. Figure 19-3 shows a research-quality double-beam spectrophotometer. Now we describe the components of the spectrophotometer in more detail.

## 19-1 Lamps and Lasers: Sources of Light

A tungsten lamp is an excellent source of continuous visible and near-infrared radiation. A typical tungsten filament operates at a temperature near 3000 K and produces useful radiation in the range 320 to 2500 nm (Figure 19-4). This range covers the entire visible region and parts of the infrared and ultraviolet regions as well. Ultraviolet spectroscopy normally employs a deuterium arc lamp in which a controlled electric discharge causes $\mathrm{D}_{2}$ to dissociate and emit ultraviolet radiation from 110 to 400 nm (Figure 19-4). In a typical ultravioletvisible spectrophotometer, a switch is made between deuterium and tungsten lamps when passing through 360 nm , so that the source with the highest intensity is always employed. For selected visible and ultraviolet frequencies, electric discharge arc lamps filled with mercury vapor (Box 17-2) or xenon gas are widely used. Light-emitting diodes provide narrow bands of visible and near-infrared (close to visible) radiation. ${ }^{3}$

Infrared radiation in the range 4000 to $200 \mathrm{~cm}^{-1}$ is commonly obtained from a silicon carbide globar, heated to near 1500 K by an electric current. The globar emits radiation with approximately the same spectrum as a blackbody at 1000 K (Box 19-1).

Lasers provide isolated lines of a single wavelength for many applications. A laser with a wavelength of $3 \mu \mathrm{~m}$ might have a bandwidth (range of wavelengths) of $3 \times 10^{-14}$ to $3 \times 10^{-8} \mu \mathrm{~m}$. The bandwidth is measured where the radiant power falls to half of its maximum value. The brightness of a low-power laser at its output wavelength is $10^{13}$ times greater than that of the sun at its brightest (yellow) wavelength. (Of course, the sun emits all wavelengths, whereas the laser emits only a narrow band. The total brightness of the sun is much greater than that of the laser.) The angular divergence of the laser beam from its direction of travel is typically less than $0.05^{\circ}$, a property that allows us to illuminate a small target. Laser light is typically plane polarized, with the electric field

FIGURE 19-4 Intensities of a tungsten filament at 3200 K and a deuterium lamp.

Caution Ultraviolet radiation is harmful to the naked eye. Do not view an ultraviolet source without protection.

Properties of laser light:

| polarized: | all waves in phase |

When an object is heated, it emits radiation-it glows. Even at room temperature, objects emit infrared radiation. Imagine a hollow sphere whose inside surface is perfectly black. That is, the surface absorbs all radiation striking it. If the sphere is at constant temperature, it must emit as much radiation as it absorbs, or else its temperature would rise. If a small hole were made in the wall, we would observe that the escaping radiation has a continuous spectral distribution. The object is called a blackbody, and the radiation is called blackbody radiation. Emission from real objects such as the tungsten filament of a light bulb resembles that from an ideal blackbody.

The power per unit area radiating from the surface of an object is called the exitance (or emittance), M. For a blackbody, exitance is given by

## Exitance from blackbody: $\quad M=\sigma T^{4}$

where $\sigma$ is the Stefan-Boltzmann constant (5.669 $8 \times 10^{-8} \mathrm{~W} /$ $\left(\mathrm{m}^{2} \cdot \mathrm{~K}^{4}\right)$ ). A blackbody whose temperature is 1000 K radiates $5.67 \times 10^{4}$ watts per square meter of surface area. If the temperature is doubled, the exitance increases by a factor of $2^{4}=16$.

Balance between energy reaching Earth from the sun and energy reradiated to space. Exchange of infrared radiation between Earth and its atmosphere keeps Earth's surface 33 K warmer than the upper atmosphere.
oscillating in one plane perpendicular to the direction of travel (Figure 17-1). Laser light is coherent, which means that all waves emerging from the laser oscillate in phase with one another.

A necessary condition for lasing is population inversion, in which a higher energy state has a greater population, $n$, than a lower energy state in the lasing medium. In Figure 19-5a, this condition occurs when the population of state $E_{2}$ exceeds that of $E_{1}$. Molecules in ground state $E_{0}$ of the lasing medium are pumped to excited state $E_{3}$ by broadband radiation from a powerful lamp or by an electric discharge. Molecules in state $E_{3}$ rapidly relax to $E_{2}$, which has a relatively long lifetime. After a molecule in $E_{2}$ decays to $E_{1}$, it rapidly relaxes to the ground state, $E_{0}$ (thereby keeping the population of $E_{2}$ greater than the population of $E_{1}$ ).

A photon with an energy that exactly spans two states can be absorbed to raise a molecule to an excited state. Alternatively, that same photon can stimulate the excited molecule to emit a photon and return to the lower state. This is called stimulated emission. When a photon emitted by a molecule falling from $E_{2}$ to $E_{1}$ strikes another molecule in $E_{2}$, a second photon can be emitted with the same phase and polarization as the incident photon. If there is a

Spectral distribution of blackbody radiation. Both axes are logarithmic. The family of curves is called the Planck distribution after the German physicist, Max Planck (1858-1947). His derivation of the law governing blackbody radiation in 1900 relied on the hypothesis that electromagnetic energy could only be emitted in discrete quanta. Planck received the Nobel Prize in 1918.

The graph shows that maximum blackbody emission for an object near 300 K occurs at infrared wavelengths ( $\sim 10 \mu \mathrm{~m}$ ). The surface of the sun behaves like a blackbody with a temperature near 5800 K , emitting mainly visible light ( $\sim 0.5 \mu \mathrm{~m}=500 \mathrm{~nm}$ ).

Of the solar flux of $1368 \mathrm{~W} / \mathrm{m}^{2}$ reaching Earth's upper atmosphere, $23 \%$ is absorbed by the atmosphere and $25 \%$ is reflected back into space. Earth absorbs $48 \%$ of the solar flux and reflects $4 \%$. Radiation reaching Earth should be just enough to keep the surface temperature at 254 K , which would not support life as we know it. Why does the average temperature of Earth's surface stay at a comfortable 287 K ?

The blackbody curves tell us that Earth radiates mainly infrared radiation, rather than visible light. Although the atmosphere is transparent to incoming visible light, it absorbs outgoing infrared radiation. The main absorbers, called greenhouse gases, are water ${ }^{4}$ and $\mathrm{CO}_{2}$ and, to lesser extents, $\mathrm{O}_{3}, \mathrm{CH}_{4}$, chlorofluorocarbons, and $\mathrm{N}_{2} \mathrm{O}$. Radiation emitted from Earth is absorbed by the atmosphere and part of it is reradiated back to Earth. The atmosphere behaves like an insulating blanket, maintaining Earth's surface temperature 33 K warmer than the temperature of the upper atmosphere. ${ }^{5}$

Man's activities since the dawn of the Industrial Revolution have increased atmospheric $\mathrm{CO}_{2}$ through the burning of fossil fuel. Relative to preindustrial conditions, $\mathrm{CO}_{2}$ in 2005 was estimated to contribute an additional $1.7 \mathrm{~W} / \mathrm{m}^{2}$ of radiative heating of Earth's surface. ${ }^{6} \mathrm{CO}_{2}$ is the largest anthropogenic source of radiative heating. The chart shows that Earth's surface was $\sim 0.8^{\circ} \mathrm{C}$ warmer in 2000-2005 than it was in 1850-1899. ${ }^{6}$ Will there be disastrous climatic changes? Will there be compensating responses that lead to little temperature change? We cannot accurately answer these questions, but prudence suggests that we should avoid making such large relative changes in our atmosphere.

Estimate of global temperature based on proxy data such as tree rings and isotope ratios in sediments and ice cores. The 1990s was the warmest decade in 2000 years. [From Report of the Intergovernmental Panel on Climate Change, 2007. ${ }^{6}$ See also M. E. Mann and P. D. Jones, "Global Surface Temperatures over the Past Two Millennia," Geophys. Res. Lett. 2003, 30, 1820.]
population inversion ( $n_{2}>n_{1}$ ), one photon stimulates the emission of many photons as it travels through the laser.

Figure 19-5b shows essential components of a laser. Pump energy directed through the side of the lasing medium creates the population inversion. One end of the laser cavity is a mirror that reflects all light ( $0 \%$ transmittance). The other end is a partially transparent mirror that reflects most light ( $1 \%$ transmittance). Photons with energy $E_{2}-E_{1}$ bouncing back and forth between the mirrors stimulate an avalanche of new photons. The small fraction of light passing through the partially transparent mirror at the right is the useful output of the laser.

A helium-neon laser is a common source of red light with a wavelength of 632.8 nm and an output power of $0.1-25 \mathrm{~mW}$. An electric discharge pumps helium atoms to state $E_{3}$ in Figure 19-5. The excited helium transfers energy by colliding with a neon atom, raising the neon to state $E_{2}$. The high concentration of helium and intense electric pumping create a population inversion among neon atoms.

In a laser diode, population inversion of charge carriers in a semiconductor is achieved by a high electric field across a pn junction in $\mathrm{GaAs},{ }^{7} \mathrm{GaN},{ }^{8}$ or compositions such as $\mathrm{Al}_{x} \mathrm{Ga}_{1}-{ }_{x} \mathrm{~N}$. Commonly available laser diodes cover the range 360-1 550 nm .

Grating: optical element with closely spaced lines

Diffraction: bending of light by a grating Refraction: bending of light by a lens or prism

Polychromatic: many wavelengths
Monochromatic: one wavelength

FIGURE 19-6 Czerny-Turner grating monochromator.

FIGURE 19-5 (a) Energy-level diagram illustrating the principle of operation of a laser. (b) Basic components of a laser. The population inversion is created in the lasing medium. Pump energy might be derived from either intense lamps or an electric discharge.

## 19-2 Monochromators

A monochromator disperses light into its component wavelengths and selects a narrow band of wavelengths to pass on to the sample or detector. The monochromator in Figure 19-2 consists of entrance and exit slits, mirrors, and a grating to disperse the light. Prisms were used instead of gratings in older instruments.

## Gratings ${ }^{9}$

A grating is a reflective or transmissive optical component with a series of closely ruled lines. When light is reflected from or transmitted through the grating, each line behaves as a separate source of radiation. Different wavelengths of light are reflected or transmitted at different angles from the grating (Color Plate 12). The bending of light rays by a grating is called diffraction. (The bending of light rays by a prism or lens, which is called refraction, is discussed in Section 19-4.)

In the grating monochromator in Figure 19-6, polychromatic radiation from the entrance slit is collimated (made into a beam of parallel rays) by a concave mirror. These rays fall on a reflection grating, whereupon different wavelengths are diffracted at different angles. The light strikes a second concave mirror, which focuses each wavelength at a different point on the focal plane. The orientation of the reflection grating directs only one narrow band of wavelengths to the exit slit of the monochromator. Rotation of the grating allows different wavelengths to pass through the exit slit.

The reflection grating in Figure 19-7 is ruled with a series of closely spaced, parallel grooves with a repeat distance $d$. The grating is coated with aluminum to make it reflective. A thin layer of silica $\left(\mathrm{SiO}_{2}\right)$ on top of the aluminum protects the metal from oxidation, which would reduce its reflectivity. When light is reflected from the grating, each groove behaves as a source of radiation. When adjacent light rays are in phase, they reinforce one another. When they are not in phase, they partially or completely cancel one another (Figure 19-8).

Consider the incident and emerging light rays shown in Figure 19-7. Fully constructive interference occurs when the difference in length of the two paths is an integral multiple of the wavelength of light. The difference in pathlength is $a-b$ in Figure 19-7. Constructive interference occurs if

$$
\begin{equation*}
n \lambda=a-b \tag{19-1}
\end{equation*}
$$

where the diffraction order $n= \pm 1, \pm 2, \pm 3, \pm 4, \ldots$ The interference maximum for which $n= \pm 1$ is called first-order diffraction. When $n= \pm 2$, we have second-order diffraction, and so on.

In Figure 19-7, the incident angle $\theta$ is defined to be positive. The diffraction angle $\phi$ goes in the opposite direction, so, by convention, $\phi$ is negative. It is possible for $\phi$ to be on the same side of the facet normal as $\theta$, in which case $\phi$ would be positive. In Figure 19-7, $a=d \sin \theta$ and $b=-d \sin \phi$ (because $\phi$ is negative and $\sin \phi$ is negative). Substituting into Equation 19-1 gives the condition for constructive interference:

$$
\begin{equation*}
\text { Grating equation: } \quad n \lambda=d(\sin \theta+\sin \phi) \tag{19-2}
\end{equation*}
$$

where $d$ is the distance between adjacent grooves. For each incident angle, $\theta$, there is a series of reflection angles, $\phi$, at which a given wavelength will produce maximum constructive interference (Color Plate 20).

FIGURE 19-7 Principle of a reflection grating.

FIGURE 19-8 Interference of adjacent waves that are (a) $0^{\circ},(b) 90^{\circ}$, and (c) $180^{\circ}$ out of phase.

Resolution: ability to distinguish two closely spaced peaks
Dispersion: ability to produce angular separation of adjacent wavelengths

Trade-off between resolution and signal: The narrower the exit slit, the greater the resolution and the noisier the signal.

Specular reflection: For a flat reflective surface, such as a mirror, the angle of incidence ( $\alpha$ in Figure 19-7) is equal to the angle of reflection ( $\beta$ ).

FIGURE 19-9 Efficiencies of diffraction gratings with 3000 grooves/cm and blaze angles optimized for different wavelengths. [Courtesy Princeton Instruments, Trenton, NJ.]

## Resolution, Dispersion, and Efficiency of a Grating

Resolution measures the ability to separate two closely spaced peaks. The greater the resolution, the smaller is the difference $(\Delta \lambda)$ between two wavelengths that can be distinguished from each other. The precise definition (which is beyond the scope of this discussion) means that the valley between the two peaks is about three-fourths of the height of the peaks when they are just barely resolved. The resolution of a grating is given by

## Resolution of grating:

$$
\begin{equation*}
\frac{\lambda}{\Delta \lambda}=n N \tag{19-3}
\end{equation*}
$$

where $\lambda$ is wavelength, $n$ is the diffraction order in Equation 19-1, and $N$ is the number of grooves of the grating that are illuminated. The more grooves in a grating, the better the resolution between closely spaced wavelengths. If we need to resolve lines that are 0.05 nm apart at a wavelength of 500 nm , the required resolution is $\lambda / \Delta \lambda=500 \mathrm{~nm} / 0.05 \mathrm{~nm}=10^{4}$. Equation 19-3 tells us that, if we desire a first-order resolution of $10^{4}$, there must be $10^{4}$ grooves in the grating. If the grating has a ruled length of 10 cm , we require $10^{3}$ grooves $/ \mathrm{cm}$.

Dispersion measures the ability to separate wavelengths differing by $\Delta \lambda$ through the difference in angle, $\Delta \phi$ (radians). For the grating in Figure 19-7, the dispersion is

Dispersion of grating:

$$
\begin{equation*}
\frac{\Delta \phi}{\Delta \lambda}=\frac{n}{d \cos \phi} \tag{19-4}
\end{equation*}
$$

where $n$ is the diffraction order. Dispersion and resolution both increase with decreasing groove spacing. Equation 19-4 tells us that a grating with $10^{3}$ grooves/cm provides a resolution of 0.102 radians $\left(5.8^{\circ}\right)$ per micrometer of wavelength if $n=1$ and $\phi=10^{\circ}$. Wavelengths differing by $1 \mu \mathrm{~m}$ would be separated by an angle of $5.8^{\circ}$.

To select a narrower band of wavelengths from the monochromator, we decrease the exit slit width in Figure 19-6. Decreasing the exit slit width decreases the energy reaching the detector. Thus, resolution of closely spaced absorption bands is achieved at the expense of decreased signal-to-noise ratio. For quantitative analysis, a monochromator bandwidth that is $\lesssim 1 / 5$ of the width of the absorption band (measured at half the peak height) is reasonable.

The relative efficiency of a grating (which is typically 45-80\%) is defined as

$$
\begin{equation*}
\text { Relative efficiency }=\frac{E_{\lambda}^{n}(\text { grating })}{E_{\lambda}(\text { mirror })} \tag{19-5}
\end{equation*}
$$

where $E_{\lambda}^{n}$ (grating) is the irradiance at a particular wavelength diffracted in the order of interest, $n$, and $E_{\lambda}$ (mirror) is the irradiance at the same wavelength that would be reflected by a mirror with the same coating as the grating. Efficiency is partially controlled by the blaze angle at which the grooves are cut in Figure 19-7. Reflection from a flat surface is maximum when the angle of incidence $(\alpha)$ is equal to the angle of reflection ( $\beta$ ). These angles are measured with respect to the facet normal in Figure 19-7. To optimize diffraction for a certain wavelength, the blaze angle is chosen to satisfy the two conditions $n \lambda=d(\sin \theta+\sin \phi)$ and $\alpha=\beta$. Each grating is optimized for a limited range of wavelengths (Figure 19-9), so a spectrophotometer may require several different gratings to scan through its entire spectral range.

## Choosing the Monochromator Bandwidth

The wider the exit slit in Figure 19-6, the wider the band of wavelengths selected by the monochromator. We usually measure slit width in terms of the bandwidth of radiation selected by the slit. Instead of saying that a slit is 0.3 mm wide, we might say that the bandwidth getting through the slit is 1.0 nm .

FIGURE 19-10 Increasing monochromator bandwidth broadens the bands and decreases the apparent absorbance of $\mathrm{Pr}^{3+}$ in a crystal of yttrium aluminum garnet (a laser material). [Courtesy M. D. Seltzer, Michelson Laboratory, China Lake, CA.]

A wide slit increases the energy reaching the detector and gives a high signal-to-noise ratio, leading to good precision in measuring absorbance. However, Figure 19-10 shows that, if the bandwidth is large relative to the width of the peak being measured, peak shape is distorted. We choose a bandwidth as wide as the spectrum permits to allow the most possible light to reach the detector. A monochromator bandwidth that is $1 / 5$ as wide as the absorption peak generally gives acceptably small distortion of the peak shape. ${ }^{10}$

## Stray Light

In every instrument, some stray light (wavelengths outside the bandwidth expected from the monochromator) reaches the detector. Stray light coming through the monochromator from the light source arises from diffraction into unwanted orders and angles and unintended scatter from optical components and walls. Stray light can also come from outside the instrument if the sample compartment is not perfectly sealed. Entry holes for tubing or electrical wires required at the sample for some experiments should be sealed to reduce stray light. Error from stray light is most serious when the sample absorbance is high (Figure 19-11) because the stray light constitutes a large fraction of the light reaching the detector. Stray light is expressed as a percentage of $P_{0}$, which is the irradiance reaching the detector in the absence of the sample.

## EXAMPLE Stray Light

If the true absorbance of a sample is 2.00 and there is $1.0 \%$ stray light, find the apparent absorbance.

Solution A true absorbance of 2.00 means that the true transmittance is $T=10^{-A}=$ $10^{-2.00}=0.010=1.0 \%$. Transmittance is the irradiance passing through the sample, $P$, divided by the irradiance passing through the reference, $P_{0}: T=P / P_{0}$. If stray light with irradiance $S$ passes through both the sample and the reference, the apparent transmittance is

$$
\begin{equation*}
\text { Apparent transmittance }=\frac{P+S}{P_{0}+S} \tag{19-6}
\end{equation*}
$$

Monochromator bandwidth should be as large as possible, but small compared with the width of the peak being measured.

High-quality spectrometers could have two monochromators in series (called a double monochromator) to reduce stray light. Unwanted radiation that passes through the first monochromator is rejected by the second monochromator.

FIGURE 19-11 Absorbance error introduced by different levels of stray light. Stray light is expressed as a percentage of the irradiance incident on the sample. [From M. R. Sharp, "Stray Light in UV-VIS Spectrophotometers," Anal. Chem. 1984, 53, 339A.]

If $P / P_{0}=0.010$ and there is $1.0 \%$ stray light, then $S=0.010$ and the apparent transmittance is

$$
\text { Apparent transmittance }=\frac{P+S}{P_{0}+S}=\frac{0.010+0.010}{1+0.010}=0.019_{8}
$$

The apparent absorbance is $-\log T=-\log \left(0.019_{8}\right)=1.70$, instead of 2.00.
Test Yourself What level of stray light gives an absorbance error of 0.01 at an absorbance of 2 ? That is, what value of $S$ gives an apparent absorbance of 1.99 ? (Answer: $S=0.00023_{54}=0.024 \%$ )

Stray light in research-quality instruments can be $0.01 \%$ to $0.0001 \%$, or even less.
Table 19-1 gives the absorbance of a solution that you can prepare to test the accuracy of absorbance measurements on your spectrophotometer. Absorbance accuracy is affected by all components of the spectrophotometer, as well as stray light. Two wavelength accuracy standards are a solution of holmium oxide ${ }^{11}$ for absorption and a mercury-argon discharge lamp for emission. ${ }^{12}$

## TABLE 19-1 Calibration standard for ultraviolet absorbance

| Wavelength (nm) | Absorbance of $\mathbf{K}_{2} \mathrm{Cr}_{2} \mathrm{O}_{7}(60.06 \mathrm{mg} / \mathrm{L})$ <br> in $5.0 \mathrm{mM} \mathbf{H}_{2} \mathbf{S O}_{4}$ in 1 - -cm cell |
| :--- | :--- |
| 235 | $0.748 \pm 0.010$ |
| 257 | $0.865 \pm 0.010$ |
| 313 | $0.292 \pm 0.010$ |
| 350 | $0.640 \pm 0.010$ |

## Filters

It is frequently necessary to filter (remove) bands of radiation from a signal. For example, the grating monochromator in Figure 19-6 directs first-order diffraction of a small wavelength band to the exit slit. (By "first order," we mean $n=1$ in Equation 19-2.) Let $\lambda_{1}$ be the wavelength whose first-order diffraction reaches the exit slit. Equation 19-2 shows that, if $n=2$, the wavelength $\frac{1}{2} \lambda_{1}$ also reaches the same exit slit because $\frac{1}{2} \lambda_{1}$ gives constructive interference at the same angle as $\lambda_{1}$. For $n=3$, the wavelength $\frac{1}{3} \lambda_{1}$ also reaches the slit. One solution for selecting just $\lambda_{1}$ is to place a filter in the beam, so that wavelengths $\frac{1}{2} \lambda_{1}$ and $\frac{1}{3} \lambda_{1}$ will be blocked. To scan a wide range of wavelengths, it may be necessary to use several filters and to change them as the wavelength changes.

The simplest filter is colored glass, which absorbs a broad portion of the spectrum and transmits other portions. For finer control, interference filters and holographic filters are constructed to pass radiation in the region of interest and reflect other wavelengths (Figure 19-12). These devices derive their performance from constructive or destructive interference of light waves within the filter. Some holographic notch filters have such a sharp cutoff that it is possible to attenuate the Rayleigh line in Raman spectroscopy (Box 17-3) by a factor of $10^{6}$ while allowing signals to be observed $100 \mathrm{~cm}^{-1}$ away from the Rayleigh line.

## 19-3 Detectors

A detector produces an electric signal when it is struck by photons. For example, a phototube emits electrons from a photosensitive, negatively charged surface (the cathode) when struck by visible light or ultraviolet radiation. Electrons flow through a vacuum to a positively charged collector whose current is proportional to the radiation intensity.

Figure 19-13 shows that detector response depends on the wavelength of the incident photons. For example, for a given radiant power (W/m²) of 420-nm light, the S-20 photomultiplier produces a current about four times greater than the current produced for the same radiant power of $300-\mathrm{nm}$ radiation. The response below 280 nm and above 800 nm is essentially 0 . In a single-beam spectrophotometer, the $100 \%$ transmittance control must be readjusted

each time the wavelength is changed. This calibration adjusts the spectrophotometer to the maximum detector output that can be obtained at each wavelength. Subsequent readings are scaled to the $100 \%$ reading.

## Photomultiplier Tube

A photomultiplier tube (Figure 19-14) is a very sensitive device in which electrons emitted from the photosensitive surface strike a second surface, called a dynode, which is positive with respect to the photosensitive emitter. Electrons are accelerated and strike the dynode with more than their original kinetic energy. Each energetic electron knocks more than one electron from the dynode. These new electrons are accelerated toward a second dynode, which is more positive than the first dynode. Upon striking the second dynode, even more electrons are knocked off and accelerated toward a third dynode. This process is repeated several times, so more than $10^{6}$ electrons are finally collected for each photon striking the first surface. Extremely low light intensities are translated into measurable electric signals. As sensitive as a photomultiplier is, your eye is even more sensitive (Box 19-2).

FIGURE 19-12 Transmission of filters.
(a) Wide band-pass dielectric interference filter has $\sim 90 \%$ transmission in the 3 - to $5-\mu \mathrm{m}$ wavelength range but $<0.01 \%$ transmittance outside this range. (b) Narrow band-pass filter dielectric interference has a transmission width of $0.1 \mu \mathrm{~m}$ centered at $4 \mu \mathrm{~m}$. [Courtesy Barr Associates, Westford, MA.] (c) Holographic interference filter provides greater attenuation and narrower band-pass than dielectric filter. [From H. Owen, "The Impact of Volume Phase Holographic Filters and Gratings on the Development of Raman Instrumentation," J. Chem. Ed. 2007, 84, 61.]

FIGURE 19-13 Detector response. The greater the sensitivity, the greater the current or voltage produced by the detector for a given incident irradiance ( $\mathrm{W} / \mathrm{m}^{2}$ ) of photons. Each curve is normalized to a maximum value of 1 . $\mathrm{In}_{x} \mathrm{Ga}_{1-\chi} \mathrm{As}$ response can be shifted to longer or shorter wavelength by varying the composition. [Courtesy Barr Associates, Westford, MA. GaN data from APA Optics, Blaine, MN.]

FIGURE 19-14 Photomultiplier tube with nine dynodes. Amplification of the signal occurs at each dynode, which is approximately 90 volts more positive than the previous dynode. [Photo by David J. Green/Alamy.]

All photodetectors produce a small response in the absence of light. This dark current could arise from spontaneous emission of electrons from the cathode of a photomultiplier tube or spontaneous generation of electrons and holes in a semiconductor device. For example, atomic vibrations can provide enough energy to an electron for it to escape from the cathode. The higher the temperature of the cathode, the greater the dark current.

## BOX 19-2 The Most Important Photoreceptor

The retina at the back of your eye contains photosensitive cells, called rods and cones, that are sensitive to levels of light varying over seven orders of magnitude. Light impinging on these cells is translated into nerve impulses that are transmitted by the optic nerve to the brain. Rod cells detect the dimmest light but cannot distinguish colors. Cone cells operate in bright light and give us color vision.

A stack of about 1000 disks in each rod cell contains the light-sensing protein rhodopsin, ${ }^{13}$ in which the chromophore 11-cis-retinal (from vitamin A) is attached to the protein opsin. When light is absorbed by rhodopsin, a series of rapid transformations releases all-trans-retinal. At this stage, the pigment is bleached (loses all color) and cannot respond to more light until retinal isomerizes back to the 11-cis form and recombines with the protein.

In the dark, there is a continuous flow of $10^{9} \mathrm{Na}^{+}$ions per second out of the rod cell's inner segment, through the adjoining medium, and into the cell's outer segment. An energy-dependent process using adenosine triphosphate (ATP) and oxygen pumps $\mathrm{Na}^{+}$out of the cell. Another process involving a molecule called cyclic GMP keeps the gates of the outer segment open for ions to flow back into the cell. When light is absorbed and rhodopsin is bleached, a series of reactions leads to destruction of cyclic GMP and shutdown of the channels through which $\mathrm{Na}^{+}$flows into the cell. A single photon reduces the ion current by $3 \%$-corresponding to a decreased current of $3 \times 10^{7}$ ions per second. This amplification is greater than that of a photomultiplier tube, which is one of the most sensitive man-made photodetectors. The ion current returns to its dark value as the protein and retinal recombine and cyclic GMP is restored to its initial concentration.

## Photodiode Array

Spectrophotometers with a photomultiplier tube detector scan slowly through a spectrum one wavelength at a time. A photodiode array spectrophotometer records the entire spectrum at once in a fraction of a second. One application of rapid scanning is chromatography, in which the full spectrum of a compound is recorded as it emerges from the column.

At the heart of rapid spectroscopy is the photodiode array shown in Figure 19-15 (or the charge coupled device described later). Rows of $p$-type silicon on a substrate (the underlying body) of $n$-type silicon create a series of $p n$ junction diodes. A reverse bias is applied to each diode, drawing electrons and holes away from the junction. In the depletion region at each junction, there are few electrons and holes. The junction acts as a capacitor, with charge stored on either side of the depletion region. At the beginning of the measurement cycle, each diode is fully charged.

When radiation strikes the semiconductor, free electrons and holes are created and migrate to regions of opposite charge, partially discharging the capacitor. The more radiation that strikes each diode, the less charge remains at the end of the measurement. The longer the array is irradiated between readings, the more each capacitor is discharged. The state of each capacitor is determined at the end of the cycle by measuring the current needed to recharge the capacitor.

In a dispersive spectrometer (Figure 19-1), only one narrow band of wavelengths reaches the detector at any time. In a photodiode array spectrophotometer (Figure 19-16), all wavelengths are recorded simultaneously, allowing more rapid acquisition of the spectrum or higher signal-to-noise ratio, or some combination of both. In the photodiode array spectrophotometer, white light (with all wavelengths) passes through the sample. The light then enters a polychromator, which disperses the light into its component wavelengths and directs the light at the diode array. Each diode receives a different wavelength, and all wavelengths are measured simultaneously. Resolution depends on how closely spaced the diodes are and how much dispersion is produced by the polychromator.

Photodiode arrays allow faster spectral acquisition ( $<1 \mathrm{~s}$ ) than dispersive instruments (which require several minutes). Photodiode array instruments have almost no moving parts, so they are more rugged than dispersive instruments that must rotate the grating and change filters to scan through the spectrum. The resolution of $\sim 0.1 \mathrm{~nm}$ attainable with a dispersive instrument and the wavelength accuracy are better than those of a photodiode array ( $\sim 0.5-1.5 \mathrm{~nm}$ resolution). Stray light is less in a dispersive instrument than in a photodiode instrument, thus giving the dispersive instrument a greater dynamic range for measuring high absorbance. Stray light in a photodiode array instrument is not substantially increased when the sample compartment is open. In a dispersive instrument, the compartment must be tightly closed.

FIGURE 19-15 (a) Schematic cross-sectional view of photodiode array. (b) Photograph of array with 1024 elements, each $25 \mu \mathrm{~m}$ wide and 2.5 mm high. The central black rectangle is the photosensitive area. The entire chip is 5 cm in length. [Courtesy Oriel Corporation, Stratford, CT.]

For a refresher on semiconductors, see Section 14-8.

A photodiode array spectrophotometer measures all wavelengths at once, giving faster acquisition and higher signal-to-noise ratio.

FIGURE 19-16 Design of photodiode array spectrophotometer.

Digital cameras use charge coupled devices to record the image.

Electrons from adjacent pixels can be combined to create a single, larger picture element. This process, called binning, increases the sensitivity of the charge coupled device at the expense of resolution.
W. S. Boyle and G. E. Smith of Bell Laboratories shared a Nobel Prize in 2009 for inventing the charge coupled device in 1969.

FIGURE 19-17 Schematic representation of a charge coupled device. (a) Cross-sectional view, indicating charge generation and storage in each pixel. (b) Top view, showing twodimensional nature of an array. An actual array is about the size of a postage stamp. (c) Effect of multiplier stage on signal-to-noise ratio of a signal that is too weak to be seen without multiplication. [From C. G. Coates, "A Sensitive Detector of Ultralow-Light Imaging," Am. Lab., August 2004, p. 13. Courtesy C. G. Coates, Andor Technology, Belfast, Ireland.]

## Charge Coupled Device ${ }^{14}$

A charge coupled device is an extremely sensitive detector that stores photo-generated charge in a two-dimensional array. A charge coupled device can produce a higher signal-tonoise ratio than can be obtained with a photomultiplier tube. The device in Figure 19-17a is constructed of $p$-doped Si on an $n$-doped substrate. The structure is capped with an insulating layer of $\mathrm{SiO}_{2}$, on top of which is placed a pattern of conducting Si electrodes. When light is absorbed in the $p$-doped region, an electron is introduced into the conduction band and a hole is left in the valence band. The electron is attracted to the region beneath the positive electrode, where it is stored. The hole migrates to the $n$-doped substrate, where it combines with an electron. Each electrode can store $\sim 10^{5}$ electrons before electrons spill out into adjacent elements.

The charge coupled device is a two-dimensional array, as shown in Figure 19-17b. After the desired observation time, electrons stored in each pixel (picture element) of the top row are moved into the serial register at the top and then moved, one pixel at a time, to the top right position, where the charge is read out. Then the next row is moved up and read out, and the sequence is repeated until the entire array has been read. The transfer of stored charges is carried out by an array of electrodes considerably more complex than we have indicated in

Figure 19-17a. Charge transfer from one pixel to the next is extremely efficient, with a loss of approximately five of every million electrons.

The minimum detectable signal for visible light in Table 19-2 is 17 photons/s. The sensitivity of the charge coupled device is derived from its high quantum efficiency (electrons generated per incident photon), low background electrical noise (thermally generated free electrons), and low noise associated with readout.

The most sensitive charge coupled devices have a "multiplication stage," which multiplies the signal by $\sim 10^{2}$ to $10^{3}$ between the serial register and the output amplifier. Noise that occurs during signal collection is also multiplied, but noise associated with readout is not. For the weakest signals in which readout is the dominant source of noise, multiplication increases the signal-to-noise ratio (Figure 19-17c). For cases in which the dominant noise occurs during signal collection, multiplication cannot improve the signal-to-noise ratio, but multiplication does decrease the time needed to collect the signal.

## Infrared Detectors

Detectors for visible and ultraviolet radiation rely on incoming photons to eject electrons from a photosensitive surface or to promote electrons from the valence band of silicon to the conduction band. Infrared photons do not have sufficient energy to generate a signal in either kind of detector. Therefore, other kinds of devices are used for infrared detection.

A thermocouple is a junction between two different electrical conductors. Electrons have lower free energy in one conductor than in the other, so they flow from one to the other until the resulting voltage difference prevents further flow. The junction potential is temperature dependent because electrons flow back to the high-energy conductor at higher temperature. If a thermocouple is blackened to absorb radiation, its temperature (and hence voltage) becomes sensitive to radiation. A typical sensitivity is 6 V per watt of radiation absorbed.

A ferroelectric material, such as deuterated triglycine sulfate, has a permanent electric polarization because of alignment of the molecules in the crystal. One face of the crystal is positively charged and the opposite face is negative. The polarization is temperature dependent, and its variation with temperature is called the pyroelectric effect. When the crystal absorbs infrared radiation, its temperature and polarization change. The voltage change is the signal in a pyroelectric detector. Deuterated triglycine sulfate is a common detector in Fourier transform spectrometers described later in this chapter.

A photoconductive detector is a semiconductor whose conductivity increases when infrared radiation excites electrons from the valence band to the conduction band. Photovoltaic detectors contain $p n$ junctions, across which an electric field exists. Absorption of infrared radiation creates electrons and holes, which are attracted to opposite sides of the junction and which change the voltage across the junction. Mercury cadmium telluride $\left(\operatorname{Hg}_{1-x} \mathrm{Cd}_{x} \mathrm{Te}\right.$, $0<x<1$ ) is a detector material whose sensitivity to different wavelengths is affected by the stoichiometry coefficient, $x$. Photoconductive and photovoltaic devices can be cooled to 77 K (liquid nitrogen temperature) to reduce thermal electrical noise by more than an order of magnitude.

The infrared spectrophotometer set up by Charles David Keeling (Section 0-1) to measure atmospheric $\mathrm{CO}_{2}$ on Mauna Loa in Hawaii in 1958 used a simple detector that is very different from any we have described. This instrument, described in Box 19-3, operated for 48 years before it was retired.

## Calibrating Detector Response for Luminescence Measurements

Figure 19-13 showed that each kind of detector has a different spectral response. For the same number of input photons at different wavelengths, a particular detector will generate different

In a ferroelectric material, dipole moments of molecules remain aligned in the absence of an external field. This alignment gives the material a permanent electric polarization.

Infrared radiation promotes electrons from the valence band of silicon to the conduction band. Semiconductors that are used as infrared detectors have smaller band gaps than silicon.

## BOX 19-3 Nondispersive Infrared Measurement of $\mathrm{CO}_{2}$ on Mauna Loa

When Charles David Keeling proposed continuous monitoring of atmospheric $\mathrm{CO}_{2}$ at Mauna Loa in Hawaii in 1956, he chose a nondispersive infrared analyzer that is very different from today's instruments. ${ }^{15}$ "Nondispersive" means that there was no prism or grating to spread the radiation into its component wavelengths.

The infrared source is a resistively heated wire at $\sim 525^{\circ} \mathrm{C}$. Radiation is split into two beams and "chopped" (interrupted) at 20 Hz by a rotating wheel. The sample cell contains dry air pumped in from outside the observatory. The reference cell contains dry, $\mathrm{CO}_{2}$-free air. $\mathrm{CO}_{2}$ in the sample cell absorbs some infrared radiation, but gas in the reference cell does not. Detector cells contain $\mathrm{CO}_{2}$ in Ar. $\mathrm{CO}_{2}$ in the detector absorbs infrared radiation, so the detector gas alternately warms (expands) and cools (contracts) at a frequency of 20 Hz . Warming and cooling create a pressure oscillation at 20 Hz that is detected by a microphone in each detector. The recorder displays the difference in the responses of the two detectors. The more $\mathrm{CO}_{2}$ in the sample, the less radiation reaches the detector, and the larger the difference between the responses of the two cells.

The observatory on Mauna Loa in Hawaii at an altitude of 3.4 km is intended to measure pristine air over the Pacific Ocean. Four air
intakes located $90^{\circ}$ apart are each 7 m above the ground and 175 m from the observatory. The two upwind intakes are selected for monitoring. The spectrometer monitors air from one intake for 10 min , then monitors the other for 10 min , and then measures a reference gas for 10 min .

A strip chart recorder shows the average difference between air and reference gas from four air measurements each hour. Sometimes readings are steady and other times they vary when $\mathrm{CO}_{2}$ is emitted from volcanic vents on Mauna Loa. Data representing pristine air was obtained by rejecting readings for any hour when the variation in $\mathrm{CO}_{2}$ was more than 0.5 ppm . A reading for a given day required that there be at least 6 consecutive hours of steady data from which to compose an average. If readings varied too much, no value was reported for that day.

The key to accuracy was the reference gas measured by manometry (Box 3-2) in Keeling's lab in California. Experimental uncertainty for $\mathrm{CO}_{2}$ in air was estimated as $\pm 0.2 \mathrm{ppm}$ for levels of $300-400 \mathrm{ppm}$. Annually increasing $\mathrm{CO}_{2}$ since 1957 in Figure 0-4 has awakened us to our influence on Earth's atmosphere.

output signals. This variation in response is not a problem when measuring transmittance, which is the quotient of transmitted irradiance $(P)$ divided by incident irradiance $\left(P_{0}\right)$. The ratio at a given wavelength does not depend on how sensitive the detector is at that wavelength. Spectral response of the detector is also not a problem for quantitative analysis using luminescence at a single wavelength, as in Figure 17-23.

However, if you want to measure the true shape of a luminescence band, you must know how your detector responds at different wavelengths. Figure 19-18 shows fluorescence from one solution measured by two fluorometers. The band measured by instrument A lies at shorter wavelength than the same fluorescence measured by instrument B. The detector in instrument B is more sensitive at long wavelength than is the detector in instrument A .

To obtain the true shape of a luminescence spectrum, we must measure the relative response of the detector at each wavelength. Calibration can be done with certified luminescence standards whose fluorescence has been measured with calibrated detectors. ${ }^{16}$ Apparent fluorescence measured by your instrument is compared with the known fluorescence to obtain a calibration factor at each wavelength. When a measured spectrum is multiplied by the calibration factor at each wavelength, a true spectral shape is obtained. The corrected spectra in Figure 19-18 coincide-as they must-because they come from the same solution.

## 19-4 Optical Sensors

An optode is a chemical sensor based on an optical fiber. ${ }^{17}$ To understand how optodes work, we first need to know a little about refraction of light.

## Refraction

The speed of light in a medium of refractive index $n$ is $c / n$, where $c$ is the speed of light in vacuum. That is, for vacuum, $n=1$. The refractive index of a liquid is commonly reported for $20^{\circ} \mathrm{C}$ at the wavelength of the sodium D line $(\lambda=589.3 \mathrm{~nm})$. The frequency of light, $\nu$, inside a medium does not change from the frequency in vacuum. The wavelength of light in matter decreases from that in vacuum because $\lambda v=c / n$.

When light is reflected, the angle of reflection is equal to the angle of incidence (Figure 19-19). When light passes from one medium into another, its path is bent (Color Plate 21). This bending, called refraction, is described by Snell's law:

Snell's law:

$$
\begin{equation*}
n_{1} \sin \theta_{1}=n_{2} \sin \theta_{2} \tag{19-7}
\end{equation*}
$$

where $n_{1}$ and $n_{2}$ are the refractive indexes of the two media and $\theta_{1}$ and $\theta_{2}$ are angles defined in Figure 19-19.

## EXAMPLE Refraction of Light by Water

Visible light travels from air (medium 1) into water (medium 2) at a $45^{\circ}$ angle ( $\theta_{1}$ in Figure 19-19). At what angle, $\theta_{2}$, does the light ray pass through the water?

Solution The refractive index is close to 1 for air and 1.33 for water. From Snell's law,

$$
(1.00)\left(\sin 45^{\circ}\right)=(1.33)\left(\sin \theta_{2}\right) \Rightarrow \theta_{2}=32^{\circ}
$$

If your radians and inverse trigonometric functions are rusty, here is how to solve for $\theta_{2}$ : $\sin \theta_{2}=\left(\sin 45^{\circ}\right) / 1.33=0.5317$, so $\theta_{2}=\sin ^{-1}(0.5317) \equiv \arcsin (0.5137)$. In Excel, the inverse sine function is ASIN and angles are expressed in radians. The Excel function ASIN (0.5317) returns a value of 0.5606 radians. Degrees $=180 \times \frac{\text { radians }}{\pi}=$ $180 \times \frac{0.5606}{\pi}=32^{\circ}$.

What is $\theta_{2}$ if the incident ray is perpendicular to the surface (that is, $\theta_{1}=0^{\circ}$ )?

$$
(1.00)\left(\sin 0^{\circ}\right)=(1.33)\left(\sin \theta_{2}\right) \Rightarrow \theta_{2}=0^{\circ}
$$

A perpendicular ray is not refracted.
Test Yourself Visible light strikes the surface of benzene at a $45^{\circ}$ angle. At what angle does the light ray pass through the benzene? (Answer: $2^{\circ}$ )

FIGURE 19-18 Uncorrected fluorescence spectra of the same solution recorded with two different spectrophotometers are different from each other. After correcting for response of each detector, the spectra are superimposed. [From U. Resch-Genger and P. Nording, Sigma-Aldrich Certified Luminescence Standards application note. Courtesy Sigma-Aldrich, St. Louis, MO.]

Refractive index at sodium D line:

| vacuum | 1 |
| :--- | :--- |
| air $\left(0^{\circ}, 1\right.$ bar $)$ | 1.00029 |
| water | 1.33 |
| fused silica | 1.46 |
| benzene | 1.50 |
| bromine | 1.66 |
| iodine | 3.34 |

FIGURE 19-19 Snell's law: $n_{1} \sin \theta_{1}=n_{2} \sin \theta_{2}$. When light passes from air into any medium, the greater the refractive index of the medium, the smaller is $\theta_{2}$.

FIGURE 19-20 (a) Optical fiber construction and (b) principle of operation. Any light ray entering within the cone of acceptance will be totally reflected at the wall of the fiber.

Light traveling from a region of high refractive index $\left(n_{1}\right)$ to a region of low refractive index $\left(n_{2}\right)$ is totally reflected if the angle of incidence exceeds the critical angle given by $\sin \theta_{\text {critical }}=n_{2} / n_{1}$.

Question How many molecules are in 10 amol? (Answer: 6 million)

(a)

(b)

## Optical Fibers

Optical fibers carry light by total internal reflection. Optical fibers are replacing electrical wires for communication because fibers are immune to electrical noise, transmit data at a higher rate, and can handle more signals. Optical fibers can bring an optical signal from inside a chemical reactor out to a spectrophotometer for process monitoring.

A flexible optical fiber has a high-refractive-index, transparent core enclosed in a lower-refractive-index, transparent cladding (Figure 19-20a). The cladding is enclosed in a protective plastic jacket. The core and coating can be made from glass or polymer.

Consider the light ray striking the wall of the core in Figure 19-20b at the angle of incidence, $\theta_{\mathrm{i}}$. Part of the ray is reflected inside the core, and part might be transmitted into the cladding at the angle of refraction, $\theta_{\mathrm{r}}$ (Color Plate 22). If the index of refraction of the core is $n_{1}$ and the index of the cladding is $n_{2}$, Snell's law (Equation 19-7) tells us that

$$
\begin{equation*}
n_{1} \sin \theta_{\mathrm{i}}=n_{2} \sin \theta_{\mathrm{r}} \Rightarrow \sin \theta_{\mathrm{r}}=\frac{n_{1}}{n_{2}} \sin \theta_{\mathrm{i}} \tag{19-8}
\end{equation*}
$$

If $\left(n_{1} / n_{2}\right) \sin \theta_{\mathrm{i}}$ is greater than 1 , no light is transmitted into the cladding because $\sin \theta_{\mathrm{r}}$ cannot be greater than 1 . In such case, $\theta_{\mathrm{i}}$ exceeds the critical angle for total internal reflection. If $n_{1} / n_{2}>1$, there is a range of angles $\theta_{i}$ in which essentially all light is reflected at the walls of the core, and a negligible amount enters the cladding. All rays entering one end of the fiber within a certain cone of acceptance emerge from the other end of the fiber with little loss.

## Optodes

We can create optical sensors for specific analytes by placing a chemically sensitive layer at the end of the fiber. An optical fiber sensor is called an optode (or optrode), derived from the words "optical" and "electrode." Optodes have been designed to respond to analytes such as dissolved $\mathrm{O}_{2}$ and $\mathrm{pH}, \mathrm{Li}^{+}$in blood, NO in cells, and sulfites in food. ${ }^{18}$

The end of the $\mathrm{O}_{2}$ optode in Color Plate 23 is coated with a $\mathrm{Ru}(\mathrm{II})$ complex in a layer of polymer. Luminescence from $\mathrm{Ru}(\mathrm{II})$ is quenched (decreased) by $\mathrm{O}_{2}$, as discussed in Section 18-6. The optode is inserted into a liquid sample as small as $100 \mathrm{fL}\left(100 \times 10^{-15} \mathrm{~L}\right)$ on the stage of a microscope. The degree of quenching tells us the concentration of $\mathrm{O}_{2}$. The detection limit is 10 amol of $\mathrm{O}_{2}$. By incorporating the enzyme glucose oxidase (Reaction 16-13), the optode becomes a glucose sensor with a detection limit of 1 fmol of glucose. ${ }^{19}$ An optode for measuring biochemical oxygen demand (Box 15-2) uses yeast cells immobilized in a membrane to consume $\mathrm{O}_{2}$ and $\mathrm{Ru}(\mathrm{II})$ luminescence for measuring $\mathrm{O}_{2} .{ }^{20}$

## Fiber-Optic Spectrophotometer

You are now ready to appreciate the fiber-optic spectrophotometer used in flow injection and sequential injection analysis. Figure 18-10 showed the main features of flow injection, including a flow cell to measure absorbance. Sample flows through a cylindrical cell that is irradiated at one end with visible light delivered by a fiber optic from a tungsten-halogen lamp. On the other end of the flow cell, a fiber optic delivers transmitted light to a spectrophotometer. Figure 18-16 shows a sequential analyzer with a flow cell. Figure 18-12 employs a fiber optic spectrophotometer to measure fluorescence.

Figure 19-21 shows the optical train of the spectrophotometer. An optical fiber from the flow cell delivers light through connector 1 and entrance slit 2 . The entrance slit width determines how many lines of the diffraction grating will be illuminated and, therefore, the resolution of the monochromator (Equation 19-3). Filter 3 allows only a limited band of wavelengths to enter the spectrophotometer. Mirror 4 collimates the beam so that all rays are

parallel. Grating 5 disperses light into its component wavelengths. Mirror 6 focuses diffracted light onto the cylindrical collection lens 7, which directs the light onto the 3648 -pixel linear charge coupled device detector 8 . Each pixel, whose physical size is $8 \mu \mathrm{~m}$ wide and $200 \mu \mathrm{~m}$ tall, receives a range of wavelengths. Filter 9, located between lens 7 and detector 8, blocks second- and third-order ( $n=2$ and $n=3$ ) diffracted radiation.

When a customer orders the spectrophotometer, she specifies the wavelength range of interest for her application. The manufacturer installs the grating and filters at the factory for the desired wavelength range. The spectrometer is capable of operating in parts of the 200 to 1100 nm range with different gratings and filters. Visible stray light is $\sim 0.05$ to $0.1 \%$. The instrument requires just 4 ms to measure a spectrum. Signal can be integrated for as long as 10 s to improve the signal-to-noise ratio (Section 19-6). There are no moving parts in this rugged and relatively inexpensive instrument.

## Attenuated Total Reflectance

Figure 19-20 showed total internal reflection of a light ray traveling through an optical fiber. The same behavior is observed in a flat layer of material whose refractive index, $n_{1}$, is greater than the refractive index of the surroundings, $n_{2}$. A planar layer in which light is totally reflected is called a waveguide. A chemical sensor can be fabricated by placing a chemically sensitive layer on a waveguide. ${ }^{21}$

When light in Figure 19-20 strikes the wall, the ray is totally reflected if $\theta_{i}$ exceeds the critical angle given by $\sin \theta_{\text {critical }}=n_{2} / n_{1}$. Even though light is totally reflected, the electric field of the light penetrates the cladding to some extent. Figure 19-22 shows that the field dies out exponentially inside the cladding. The part of the light that penetrates the wall of an optical fiber or waveguide is called an evanescent wave.

FIGURE 19-21 Optical train of Ocean Optics USB 4000 fiber-optic spectrophotometer used in flow injection and sequential injection analysis. This miniature spectrophotometer fits in your hand and weighs 190 grams. [Courtesy Ocean Optics, Dunedin, FL.]

Evanescent means "vanishing" or "fleeting." Light "escapes" from the waveguide, but it vanishes over a short distance.

FIGURE 19-22 Behavior of electromagnetic wave when it strikes a surface from which it is totally reflected. The field penetrates the reflective barrier and dies out exponentially.

The electric field, $E$, of the evanescent wave in Figure 19-22 decays as

$$
\begin{equation*}
\frac{E}{E_{0}}=\mathrm{e}^{-x / d_{\mathrm{p}}} \quad\left(d_{\mathrm{p}}=\frac{\lambda / n_{1}}{2 \pi \sqrt{\sin ^{2} \theta_{i}-\left(n_{2} / n_{1}\right)^{2}}}\right) \tag{19-9}
\end{equation*}
$$

where $E_{0}$ is the magnitude of the field at the reflective interface, $x$ is the distance into the cladding, and $\lambda$ is the wavelength of light in a vacuum. The penetration depth, $d_{\mathrm{p}}$, is the distance at which the evanescent field dies down to $1 / \mathrm{e}$ of its value at the interface. Consider a waveguide with $n_{1}=1.70$ and $n_{2}=1.45$, giving a critical angle of $58.5^{\circ}$. If light with a wavelength of 590 nm has a $70^{\circ}$ angle of incidence, then the penetration depth is 140 nm . This depth is great enough to allow the light to interact with many layers of large molecules, such as proteins, whose dimensions are on the order of 10 nm .

Figure 19-23a shows an attenuated total reflectance infrared sensor for measuring caffeine in soft drinks. "Attenuated" means "decreased." The diamond crystal at the right side of the diagram acts as a waveguide; it has a circular upper surface whose diameter is 3 mm . When light passes through the crystal, it is totally reflected three times. The upper surface is in contact with a liquid channel carved into a block of poly(tetrafluoroethylene) (Teflon ${ }^{\circledR}$ ). At the center of the channel are 5 mg of hydrophobic sorbent beads made from polystyrene-divinylbenzene (Figure 25-1) held in place by cotton wool. When soft drink flows through the channel, caffeine is adsorbed by the beads and becomes concentrated in the beads. Sugar and caramel colorant present in the soft drink are not retained by the beads.

FIGURE 19-23 (a) Sequential injection apparatus for measuring caffeine in soft drinks by attenuated total reflectance from analyte retained by sorbent beads. (b) Attenuated total reflectance spectrum of caffeine adsorbed from 3 mL of standard containing $50 \mu \mathrm{~g}$ caffeine $/ \mathrm{mL}$. [Adapted from M. C. Alcudia-León, R. Lucena, $S$. Cárdenas, and $M$. Valcárcel, "Characterization of an Attenuated Total Reflection-Based Sensor for Integrated Solid-Phase Extraction and Infrared Detection," Anal. Chem. 2008, 80, 1146.]

The evanescent wave from infrared radiation traveling through the diamond waveguide extends into the sorbent beads. When caffeine is present, wavelengths absorbed by caffeine are attenuated. The resulting spectrum is shown in Figure 19-23b. Each peak in the spectrum arises from a vibrational mode of caffeine. The integrated area beneath the entire spectrum is taken as the signal in this experiment.

Sequential injection apparatus (Section 18-4) in Figure 19-23a carries out the following operations. First, 2 mL of water are pumped through the detector cell and a background spectrum is recorded. Then 3 mL of soft drink or standard are pumped through the cell. Caffeine is retained by the beads while sugar and caramel colorant in the soft drink are not retained. After washing the beads with 2 mL of water to remove sugar and colorant, a second spectrum is recorded. The background spectrum is subtracted from the second spectrum to obtain a spectrum whose integrated intensity is proportional to the concentration of caffeine in the soft drink. Finally, the beads are washed with 0.25 mL of acetonitrile, which quantitatively removes caffeine. The procedure can be repeated indefinitely to measure more unknowns and standards.

## Surface Plasmon Resonance ${ }^{22}$

Conduction electrons in a metal are nearly free to move within the metal in response to an applied electric field. A surface plasma wave, also called a surface plasmon, is an electromagnetic wave that propagates along the boundary between a metal and a dielectric (an electrical insulator). The electromagnetic field decreases exponentially into both layers but is concentrated in the dielectric layer.

Figure 19-24a shows essentials of one common surface plasmon resonance measurement. Monochromatic light whose electric field oscillates in the plane of the page is directed into a prism whose bottom face is coated with $\sim 50 \mathrm{~nm}$ of gold. The bottom surface of the gold is coated with a chemical layer ( $\sim 2-20 \mathrm{~nm}$ ) that selectively binds an analyte of interest. At low angles of incidence, $\theta$, much, but not all of the light is reflected by the gold. When $\theta$ increases to the critical angle for total internal reflection, the reflectivity is ideally $100 \%$. As $\theta$ increases further, a surface plasmon (oscillating electron cloud) is set up, absorbing energy from the incident light. Because some of the energy is absorbed in the gold layer, the reflectivity decreases from $100 \%$. There is a small range of angles at which the plasmon is in resonance with the incident light, a condition creating the sharp dip in the curve in Figure 19-24b. As $\theta$ increases beyond the resonance condition, less energy is absorbed and reflectivity increases.

The angle at which reflectivity is minimum depends on the refractive indexes of all the layers in Figure 19-24a. The angle for minimum reflectivity in Figure 19-24b changes by $\sim 0.1^{\circ}$ when a thin layer of polymer is coated onto the gold. When analyte binds to a chemically sensitive layer on the gold, the refractive index of that layer changes slightly and the angle for minimum reflectivity changes slightly. Commercial instruments can measure changes in the surface plasmon resonance angle with a precision of $\sim 10^{-4}$ to $10^{-5}$ degrees. For biosensors, the chemically sensitive layer might contain an antibody or antigen, DNA or RNA, a protein, or a carbohydrate that has a selective interaction with some analyte.

Figures 19-25 shows a scheme by which surface plasmon resonance can detect a specific sequence of DNA. A gold coating on a prism is treated with a synthetic peptide nucleic acid and mercaptohexanol. Peptide nucleic acid (abbreviated PNA) has the same bases as DNA (abbreviated A, T, C, and G), but the deoxyribose sugar-phosphate backbone of DNA is

FIGURE 19-24 (a) Essentials of a surface plasmon resonance measurement. (b) Reflectivity versus
angle, $\theta$. [Adapted from J. M. Brockman, B. P. Nelson, and R. M. Corn, "Surface Plasmon Resonance Imaging Measurements of Ultrathin Organic Films," Annu. Rev. Phys. Chem. 2000, 51, 41.]

FIGURE 19-25 Scheme for detection of specific DNA sequence by surface plasmon resonance.

FIGURE 19-26 A small shift in surface plasmon resonance angle occurs when a small strand of DNA binds to complementary PNA on a gold surface. A large shift occurs when the protein streptavidin binds to biotin at the end of the DNA strand. [From J. Liu, S. Tian, L. Tiefenauer, P. E. Nielsen, and W. Knoll, "Simultaneously Amplified Electrochemical and Surface Plasmon Detection of DNA Hybridization Based on Ferrocene-Streptavidin Conjugates," Anal. Chem. 2005, 77, 2756.$]$

$\xrightarrow[\text { DNA }]{\text { 1. Add DNA-biotin }}$
2. Wash away
noncomplementary DNA

replaced by a peptide backbone. A sulfur atom at one end of the PNA chain binds to the gold surface. Mercaptohexanol occupies binding sites on gold not occupied by PNA. The complex (called a hybrid) between PNA and a complementary strand of DNA is stronger than the complex between two strands of complementary DNA. The sensor is designed to detect a specific, short sequence of DNA that is complementary to the synthetic PNA. When a mixture of DNA strands is incubated with PNA, only complementary DNA binds tightly. Noncomplementary DNA can be washed away. Hybrids of DNA to PNA are more stable to variations in temperature and ionic strength than are hybrids of DNA to DNA.

Prior to exposing unknown DNA to the Au-PNA surface, biotin is attached to one end of each DNA strand. Biotin is an essential B vitamin. The protein streptavidin is a $53000-$ dalton tetrameric protein isolated from the bacterium Streptomyces avidinii. It has a strong, specific affinity for biotin, with a formation constant of $10^{15}$. When biotin-DNA is exposed to streptavidin, the protein binds tightly to biotin (Figure 19-25).

The solid line in Figure 19-26 is the surface plasmon resonance of the gold film with bound PNA and mercaptohexanol. When complementary DNA labeled with biotin binds to the PNA, the resonance shown by the dotted line is almost imperceptibly shifted because the

amount of DNA that is bound is very small and the refractive index of the thin surface layer is barely changed. When streptavidin is added, the large protein binds to the biotin on the end of every DNA. The massive protein changes the refractive index of the organic film enough to shift the resonance position by $0.3^{\circ}$ (dashed line in Figure 19-26). The signal in Figure 19-26 arises from $\sim 1 \times 10^{12}$ PNA molecules per square centimeter of gold surface. DNA with 12 nucleotide bases and one mismatch with the PNA does not bind to the PNA.

## 19-5 Fourier Transform Infrared Spectroscopy ${ }^{23}$

A photodiode array or charge coupled device can measure an entire spectrum at once. The spectrum is spread into its component wavelengths, and each wavelength is directed onto one detector element. For the infrared region, the most important method for observing the entire spectrum at once is Fourier transform spectroscopy.

## Fourier Analysis

Fourier analysis is a procedure in which a curve is decomposed into a sum of sine and cosine terms, called a Fourier series. To analyze the curve in Figure 19-27, which spans the interval $x_{1}=0$ to $x_{2}=10$, the Fourier series has the form
Fourier series: $\quad y=a_{0} \sin (0 \omega x)+b_{0} \cos (0 \omega x)+a_{1} \sin (1 \omega x)+b_{1} \cos (1 \omega x)$

$$
+a_{2} \sin (2 \omega x)+b_{2} \cos (2 \omega x)+\ldots
$$

$$
\begin{equation*}
=\sum_{n=0}^{\infty}\left[a_{n} \sin (n \omega x)+b_{n} \cos (n \omega x)\right. \tag{19-10}
\end{equation*}
$$

where

$$
\begin{equation*}
\omega=\frac{2 \pi}{x_{2}-x_{1}}=\frac{2 \pi}{10-0}=\frac{\pi}{5} \tag{19-11}
\end{equation*}
$$

Equation 19-10 says that the value of $y$ for any value of $x$ can be expressed by an infinite sum of sine and cosine waves. Successive terms correspond to waves with increasing frequency.

Figure 19-28 shows how sequences of three, five, or nine sine and cosine waves give better and better approximations to the curve in Figure 19-27. The coefficients $a_{n}$ and $b_{n}$ required to construct the curves in Figure 19-28 are given in Table 19-3.

FIGURE 19-28 Fourier series reconstruction of the curve in Figure 19-27. Solid line is the original curve and dashed lines are made from a series of $n=0$ to $n=2,4$, or 8 in Equation 19-10. Coefficients $a_{n}$ and $b_{n}$ are given in Table 19-3.

## Interferometry

The heart of a Fourier transform infrared spectrophotometer is the interferometer in Figure 19-29. Radiation from the source at the left strikes a beamsplitter, which transmits some light and reflects some light. For ease of explanation, consider a beam of monochromatic radiation. (In fact, the Fourier transform spectrophotometer uses a continuum source of infrared radiation, not a monochromatic source.) Suppose that the beamsplitter reflects half of the light and transmits half. When light strikes the beamsplitter at point O , some is reflected to a stationary

FIGURE 19-29 Schematic diagram of Michelson interferometer. Detector response as a function of retardation $(=2[O M-O S])$ is shown for monochromatic incident radiation of wavelength $\lambda$.

Albert Michelson developed the interferometer around 1880 and conducted the Michelson-Morley experiment in 1887, in which it was found that the speed of light is independent of the motion of the source and the observer. This crucial experiment led Einstein to the theory of relativity. Michelson also used the interferometer to create the predecessor of today's length standard based on the wavelength of light. He received the Nobel Prize in 1907 "for precision optical instruments and the spectroscopic and metrological investigations carried out with their aid."
mirror at a distance OS and some is transmitted to a movable mirror at a distance OM. Rays reflected by the mirrors travel back to the beamsplitter, where half of each ray is transmitted and half is reflected. One recombined ray travels in the direction of the detector, and another heads back to the source.

In general, the paths OM and OS are not equal, so the two waves reaching the detector are not in phase. If the two waves are in phase, they interfere constructively to give a wave with twice the amplitude, as shown in Figure 19-8. If the waves are one-half wavelength $\left(180^{\circ}\right)$ out of phase, they interfere destructively and cancel. For any intermediate phase difference, there is partial cancellation.

The difference in pathlength followed by the two waves in Figure 19-29 is 2(OM - OS). This difference is called the retardation, $\delta$. Constructive interference occurs whenever $\delta$ is an integer multiple of the wavelength, $\lambda$. A minimum appears when $\delta$ is a half-integer multiple of $\lambda$. If mirror M moves away from the beamsplitter at a constant speed, light reaching the detector goes through a sequence of maxima and minima as the interference alternates between constructive and destructive phases.

A graph of output light intensity versus retardation, $\delta$, is called an interferogram. If the light from the source is monochromatic, the interferogram is a simple cosine wave:

$$
\begin{equation*}
I(\delta)=\mathrm{B}(\widetilde{v}) \cos \left(\frac{2 \pi \delta}{\lambda}\right)=\mathrm{B}(\widetilde{v}) \cos (2 \pi \widetilde{v} \delta) \tag{19-12}
\end{equation*}
$$

where $I(\delta)$ is the intensity of light reaching the detector and $\tilde{v}$ is the wavenumber $(=1 / \lambda)$ of the light. Clearly, $I$ is a function of the retardation, $\delta . B(\widetilde{v})$ is a constant that accounts for the intensity of the light source, efficiency of the beamsplitter (which never gives exactly $50 \%$ reflection and $50 \%$ transmission), and response of the detector. All these factors depend on $\tilde{v}$. For monochromatic light, there is only one value of $\tilde{v}$.

Figure 19-30a shows the interferogram produced by monochromatic radiation of wavenumber $\tilde{v}_{0}=2 \mathrm{~cm}^{-1}$. The wavelength (repeat distance) of the interferogram can be seen in the figure to be $\lambda=0.5 \mathrm{~cm}$, which is equal to $1 / \tilde{v}_{0}=1 /\left(2 \mathrm{~cm}^{-1}\right)$. Figure 19-30b shows the interferogram that results from a source with two monochromatic waves ( $\widetilde{v}_{0}=2$ and $\left.\tilde{v}_{0}=8 \mathrm{~cm}^{-1}\right)$ with relative intensities $1: 1$. A short wave oscillation $\left(\lambda=\frac{1}{8} \mathrm{~cm}\right)$ is superimposed on a long wave oscillation $\left(\lambda=\frac{1}{2} \mathrm{~cm}\right)$. The interferogram is a sum of two terms:

$$
\begin{equation*}
I(\delta)=B_{1} \cos \left(2 \pi \tilde{\nu}_{1} \delta\right)+B_{2} \cos \left(2 \pi \tilde{\nu}_{2} \delta\right) \tag{19-13}
\end{equation*}
$$

where $B_{1}=1, \widetilde{v}_{1}=2 \mathrm{~cm}^{-1}, B_{2}=1$, and $\tilde{v}_{2}=8 \mathrm{~cm}^{-1}$.

## (a)

FIGURE 19-30 Interferograms produced by different spectra.

Fourier analysis of the interferogram gives back the spectrum from which the interferogram is made. The spectrum is the Fourier transform of the interferogram.

The interferogram loses intensity at those wavelengths absorbed by the sample.
resolution $\approx(1 / \Delta) \mathrm{cm}^{-1}$
$\Delta=$ maximum retardation (cm)

For a spectral range of $\Delta \widetilde{\nu} \mathrm{cm}^{-1}$, points must be taken at retardation intervals of $1 /(2 \Delta \widetilde{v})$.
Capital delta has two different purposes in this section:
$\Delta \tilde{v}=$ spectral range $\left(\mathrm{cm}^{-1}\right)$
$\Delta=$ maximum retardation (cm)

Fourier analysis decomposes a curve into its component wavelengths. Fourier analysis of the interferogram in Figure 19-30a gives the (trivial) result that the interferogram is made from a single wavelength function, with $\lambda=\frac{1}{2} \mathrm{~cm}$. Fourier analysis of the interferogram in Figure $19-30 \mathrm{~b}$ gives the slightly more interesting result that the interferogram is composed of two wavelengths ( $\lambda=\frac{1}{2}$ and $\lambda=\frac{1}{8} \mathrm{~cm}$ ) with relative contributions $1: 1$. We say that the spectrum is the Fourier transform of the interferogram.

The interferogram in Figure $19-30 \mathrm{c}$ is derived from a spectrum with an absorption band centered at $\tilde{v}_{0}=4 \mathrm{~cm}^{-1}$. The interferogram is the sum of contributions from all source wavelengths. The Fourier transform of the interferogram in Figure 19-30c is indeed the third spectrum in Figure 19-30c. That is, decomposition of the interferogram into its component wavelengths gives back the band centered at $\tilde{v}_{0}=4 \mathrm{~cm}^{-1}$. Fourier analysis of the interferogram gives back the intensities of its component wavelengths.

The interferogram in Figure 19-30d comes from two absorption bands in the spectrum at the left. The Fourier transform of this interferogram gives back the spectrum to its left.

## Fourier Transform Spectroscopy

In a Fourier transform spectrometer, the sample is usually placed between the interferometer and the detector, as in Figures 19-29 and 19-31. Because the sample absorbs certain wavelengths, the interferogram contains the spectrum of the source minus the spectrum of the sample. An interferogram of a reference sample containing the cell and solvent is first recorded and transformed into a spectrum. Then the interferogram of a sample in the same solvent is recorded and transformed into a spectrum. The quotient of the sample spectrum divided by the reference spectrum is the transmission spectrum of the sample (Figure 19-32). The quotient is the same as computing $P / P_{0}$ to find transmittance. $P_{0}$ is the irradiance received at the detector through the reference, and $P$ is the irradiance received after passage through the sample.

The interferogram is recorded at discrete intervals. The resolution of the spectrum (ability to discern closely spaced peaks) is approximately equal to $(1 / \Delta) \mathrm{cm}^{-1}$, where $\Delta$ is the maximum retardation. If the mirror travel is $\pm 2 \mathrm{~cm}$, the retardation is $\pm 4 \mathrm{~cm}$ and the resolution is $1 /(4 \mathrm{~cm})=0.25 \mathrm{~cm}^{-1}$.

The wavenumber range of the spectrum is determined by how the interferogram is sampled. The closer the spacing between data points, the greater the range. Covering a range of $\Delta \tilde{v}$ wavenumbers requires sampling the interferogram at retardation intervals of $\delta=1 /(2 \Delta \tilde{v})$. If $\Delta \tilde{\nu}$ is $4000 \mathrm{~cm}^{-1}$, sampling must occur at intervals of $\delta=1 /\left(2 \cdot 4000 \mathrm{~cm}^{-1}\right)=1.25 \times 10^{-4} \mathrm{~cm}=$ $1.25 \mu \mathrm{~m}$. This sampling interval corresponds to a mirror motion of $0.625 \mu \mathrm{~m}$. For every centimeter of mirror travel, $1.6 \times 10^{4}$ data points must be collected. If the mirror moves at a rate of 2 mm per second, the data collection rate would be 3200 points per second.

FIGURE 19-31 Layout of Fourier transform infrared spectrometer. [Courtesy Nicolet, Madison, WI.]

FIGURE 19-32 Fourier transform infrared spectrum of polystyrene film. The Fourier transform of the background interferogram gives a spectrum determined by the source intensity, beamsplitter efficiency, detector response, and absorption by traces of $\mathrm{H}_{2} \mathrm{O}$ and $\mathrm{CO}_{2}$ in the atmosphere. The sample compartment is purged with dry $\mathrm{N}_{2}$ to reduce the levels of $\mathrm{H}_{2} \mathrm{O}$ and $\mathrm{CO}_{2}$. The transform of the sample interferogram is a measure of all the instrumental factors, plus absorption by the sample. The transmission spectrum is obtained by dividing the sample transform by the background transform. Each interferogram is an average of 32 scans and contains 4096 data points, giving a resolution of $4 \mathrm{~cm}^{-1}$. The mirror velocity was $0.693 \mathrm{~cm} / \mathrm{s}$. [Courtesy M. P. Nadler, Michelson Laboratory, China Lake, CA.]

The source, beamsplitter, and detector each limit the usable wavelength range. Clearly, the instrument cannot respond to a wavelength that is absorbed by the beamsplitter or a wavelength to which the detector does not respond. The beamsplitter for the mid-infrared region ( $\sim 4000$ to $400 \mathrm{~cm}^{-1}$ ) is typically a layer of germanium evaporated onto a KBr plate. For longer wavelengths ( $\tilde{v}<400 \mathrm{~cm}^{-1}$ ), a film of the organic polymer Mylar is a suitable beamsplitter.

To control the sampling interval for the interferogram, a monochromatic visible laser beam is passed through the interferometer along with the polychromatic infrared light (Figure 19-31). The laser gives destructive interference whenever the retardation is a half-integer multiple of the laser wavelength. These zeros in the laser signal, observed with a visible detector,

FIGURE 19-33 Effect of signal averaging on a simulated noisy spectrum. Labels refer to number of scans averaged. [From R. Q. Thompson, "Experiments in Software Data Handling," J. Chem. Ed. 1985, 62, 866.]

To improve the signal-to-noise ratio by a factor of $n$ requires averaging $n^{2}$ spectra.

Question By what factor should the signal-to-noise ratio be improved when 16 spectra are averaged? Measure the noise level in Figure 19-33 to test your prediction.
are used to control sampling of the infrared interferogram. For example, an infrared data point might be taken at every second zero point of the visible-light interferogram. The precision with which the laser frequency is known gives an accuracy of $0.01 \mathrm{~cm}^{-1}$ in the infrared spectrum, which is a 100 -fold improvement over the accuracy of dispersive (grating) instruments.

## Advantages of Fourier Transform Spectroscopy

Compared with dispersive instruments, the Fourier transform spectrometer offers improved signal-to-noise ratio at a given resolution, better frequency accuracy, speed, and built-in datahandling capabilities. Signal-to-noise improvement comes mainly because the Fourier transform spectrometer uses energy from the entire spectrum, instead of analyzing a sequence of small wavebands available from a monochromator. Precise reproduction of wavenumber position from one spectrum to the next allows Fourier transform instruments to average signals from multiple scans to further improve the signal-to-noise ratio. Wavenumber precision and low noise levels allow spectra with slight differences to be subtracted from each other to expose those differences. Fourier transform instruments are not as accurate as dispersive spectrometers for measuring transmittance.

Advantages of Fourier transform infrared spectrometers are so great that it is nearly impossible to purchase a dispersive infrared spectrometer. Fourier transform visible and ultraviolet spectrometers are not commercially available, because of the requirement to sample the interferometer at intervals of $\delta=1 /(2 \Delta \tilde{v})$. For visible spectroscopy, $\Delta \tilde{v}$ could be $25000 \mathrm{~cm}^{-1}$ (corresponding to 400 nm ), giving $\delta=0.2 \mu \mathrm{~m}$ and a mirror movement of $0.1 \mu \mathrm{~m}$ between data points. Such fine control over significant ranges of mirror motion is not feasible.

## 19-6 Dealing with Noise ${ }^{24}$

An advantage of Fourier transform spectroscopy is that the entire interferogram is recorded in a few seconds and stored in a computer. The signal-to-noise ratio can be improved by collecting tens or hundreds of interferograms and averaging them.

## Signal Averaging

Signal averaging can improve the quality of data, as illustrated in Figure 19-33. ${ }^{25}$ The lowest trace contains a great deal of noise. A simple way to estimate the noise level is to measure the maximum amplitude of the noise in a region free of signal. The signal is measured from the middle of the baseline noise to the middle of the noisy peak. By this criterion, the lowest trace of Figure 19-33 has a signal-to-noise ratio of $14 / 9=1.6$.

A more common measurement of noise, which requires a digitized signal, is the root-mean-square (rms) noise, defined as
Root-mean-square noise: $\quad$ rms noise $=\sqrt{\frac{\sum_{i}\left(A_{i}-\bar{A}\right)^{2}}{n}}$
where $A_{i}$ is the measured signal for the $i$ th data point, $\bar{A}$ is the mean signal, and $n$ is the number of data points. For a large number of data points, the rms noise is the standard deviation of the noise. It is best to apply Equation 19-14 where the signal is flat, as it is at the left and right sides of Figure 19-33. If you must use data at the center of Figure 19-33, the average $\bar{A}$ must be fitted to the continuously rising or falling signal. The rms noise is $\sim 5$ times less than the peak-to-peak noise. If we used rms noise instead of peak-to-peak noise, we would say that the noise in the bottom spectrum of Figure $19-33$ is $9 / 5=1.8$ and the signal-to-noise ratio is $14 / 1.8=7.8$. Clearly, the signal-to-noise ratio depends on how you define noise.

Consider what happens if you record the spectrum twice and add the results. The signal is the same in both spectra and adds to give twice the value of each spectrum. If $n$ spectra are added, the signal will be $n$ times as large as in the first spectrum. Noise is random, so it may be positive or negative at any point. It turns out that, if $n$ spectra are added, the noise increases in proportion to $\sqrt{n}$. Because the signal increases in proportion to $n$, the signal-to-noise ratio increases in proportion to $n / \sqrt{n}=\sqrt{n}$.

When we average $n$ spectra, the signal-to-noise ratio is improved by $\sqrt{n}$. To improve the signal-to-noise ratio by a factor of 2 requires averaging four spectra. To improve the signal-to-noise ratio by a factor of 10 requires averaging 100 spectra. Spectroscopists record as many as $10^{4}$ to $10^{5}$ scans to observe weak signals. It is rarely possible to do better than this because instrumental instabilities cause drift in addition to random noise.

## Types of Noise

Figure 19-34 shows three common types of noise in electrical instruments. ${ }^{26}$ The upper trace is white noise, also called Gaussian noise. One source of white noise, called Johnson noise, is random fluctuations of electrons in an electronic device. Lowering the operating temperature is one way to reduce Johnson noise. Shot noise is another form of white noise attributable to the quantized nature of charge carriers and photons. At low signal levels, noise arises from random variation in the small number of photons reaching a detector or the small number of electrons and holes generated in a semiconductor.

The second trace in Figure 19-34 shows 1/f noise, also called drift, which is greatest at zero frequency and decreases in proportion to $1 /$ frequency. An example of low-frequency noise in laboratory instruments is flickering or drifting of a light source in a spectrophotometer or a flame in atomic spectroscopy. Drift arises from causes such as slow changes in instrument components with temperature and age or variation of power-line voltage to an instrument. The classical way to detect and account for drift is to periodically measure standards and correct the instrument reading for any observed change. ${ }^{27}$

The bottom trace of Figure 19-34 shows line noise (also called interference or whistle noise) at discrete frequencies such as the $60-\mathrm{Hz}$ transmission-line frequency or the $0.2-\mathrm{Hz}$ vibrational frequency when elephants walk through the basement of your building. Electrical shielding and grounding the shielding and instrument to the same ground point help reduce line noise.

## Beam Chopping

Spectrophotometers in Figures 19-1 through 19-3 have a rotating mirror called a chopper that alternately sends light through sample and reference cells. Chopping allows both cells to be sampled almost continuously, and it provides a means of noise reduction. Beam chopping moves the analytical signal from zero frequency to the frequency of the chopper. The chopping frequency can be selected so that $1 / f$ noise and line noise are minimal. High-frequency detector circuits are required to take advantage of beam chopping.

## A Low-Noise Spectrophotometer

Spectrophotometer noise is broadly attributable to (i) sources that are independent of the light level, (ii) sources that are proportional to photo-generated current, and (iii) variation of the intensity of the light source. ${ }^{28}$ For several decades, precision has been governed by variation of intensity of the light source, which produces a root-mean-square noise equivalent to an apparent absorbance of $\sim 0.00003$ at visible wavelengths. That is, absorbance below $\sim 0.00003$ cannot be measured because it is hidden in the noise.

Figure 19-35 shows a system designed to cancel the noise generated by variation of the light source. Visible light from a tungsten-halogen lamp goes through a monochromator and is then split into two beams that pass through sample and reference cells. Light from the sample cell goes to a photodetector that generates current $I_{\text {sam }}$. Light from the reference cell goes to a photodetector that generates current $I_{\mathrm{ref}}$. Electronics then convert the currents to voltages $V_{\text {sam }}$ and $V_{\text {ref }}$ and the difference voltage $V_{\text {dif }}=V_{\text {sam }}-V_{\text {ref }}$. Noise from variation of the light source intensity affects $V_{\text {sam }}$ and $V_{\text {ref }}$ equally. That is, if the light momentarily increases by $0.1 \%$, the voltages recorded by each detector increase by $0.1 \%$. The difference $V_{\text {dif }}$ should be zero in the absence of sample absorption. The traces at the right of Figure 19-35 are simulations showing a weak absorption superimposed on strong noise. The signal is too weak to see in the sample spectrum $\left(V_{\text {sam }}\right)$, but is loud and clear in the difference spectrum $\left(V_{\text {dif }}\right)$.

FIGURE 19-35 Principle of low-noise spectrophotometer. [Adapted from Z. Xu and D. W. Larsen, "Development of Ultra-Low-Noise Spectrophotometry for Analytical Applications," Anal. Chem. 2005, 77, 6463.]

FIGURE 19-34 Three types of noise in electrical instruments. White noise is always present. A beam chopping frequency can be selected to reduce $1 / f$ noise and line noise to insignificant values.

FIGURE 19-36 Spectrum of 2 nM Nile Blue in methanol recorded with (a) commercial spectrophotometer and (b) same instrument modified to cancel light source variation. [From Z. Xu and D. W. Larsen, "Development of Ultra-LowNoise Spectrophotometry for Analytical Applications," Anal. Chem. 2005, 77, 6463.]

Figure 19-36 is an experimental implementation of the scheme to cancel source intensity noise. The upper trace is the absorption spectrum of a $9-\mathrm{nM}$ dye solution with a peak absorbance of 0.0002 . The lower spectrum was obtained from the same instrument modified to display absorbance computed from the difference voltage $V_{\text {dif }}{ }^{29}$ The signal-to-noise ratio is improved by a factor of 10 . Hardware modifications are expected to enable an additional factor-of-10 improvement for a total signal-to-noise ratio reduction of 100 .

## Summary

Spectrophotometer components include the source, sample cell, monochromator, and detector. Tungsten and deuterium lamps provide visible and ultraviolet radiation; a silicon carbide globar is a good infrared source. Tungsten and silicon carbide lamps behave approximately as blackbodies, which are objects that absorb all light striking them. Emission of radiant energy from the surface of the blackbody is proportional to the fourth power of temperature and shifts to shorter wavelengths as temperature increases. Lasers provide high-intensity, coherent, monochromatic radiation by stimulated emission from a medium in which an excited state has been pumped to a higher population than that of a lower state. Sample cells must be transparent to the radiation of interest. A reference sample compensates for reflection and scattering by the cell and solvent. A grating monochromator disperses light into its component wavelengths. The finer a grating is ruled, the higher the resolution and the greater the dispersion of wavelengths over angles. Narrow slits improve resolution but increase noise, because less light reaches the detector. A bandwidth that is $1 / 5$ of the width of the spectral peak is a good compromise between maximizing signal-to-noise ratio and minimizing peak distortion. Stray light introduces absorbance errors that are most serious when the transmittance of a sample is very low. Filters pass wide bands of wavelength and reject other bands.

A photomultiplier tube is a sensitive detector of visible and ultraviolet radiation; photons cause electrons to be ejected from a
metallic cathode. The signal is amplified at each successive dynode on which the photoelectrons impinge. Photodiode arrays and charge coupled devices are solid-state detectors in which photons create electrons and holes in semiconductor materials. Coupled to a polychromator, these devices can record all wavelengths of a spectrum simultaneously, with resolution limited by the number and spacing of detector elements. Common infrared detectors include thermocouples, ferroelectric materials, and photoconductive and photovoltaic devices.

When light passes from a region of refractive index $n_{1}$ to a region of refractive index $n_{2}$, the angle of refraction $\left(\theta_{2}\right)$ is related to the angle of incidence $\left(\theta_{1}\right)$ by Snell's law: $n_{1} \sin \theta_{1}=n_{2} \sin \theta_{2}$. Optical fibers and flat waveguides transmit light by a series of total internal reflections. Optodes are sensors based on optical fibers. Some optodes have a layer of material whose absorbance or fluorescence changes in the presence of analyte. Light can be carried to and from the tip by the optical fiber. When light is transmitted through a fiber optic or a waveguide by total internal reflectance, some light, called the evanescent wave, penetrates through the reflective interface during each reflection. In attenuated total reflectance devices, the waveguide is coated with a substance that absorbs light in the presence of analyte. In a surface plasmon resonance sensor, we measure the change in the angle of minimum reflectance from a gold film coated with a chemically sensitive layer on the back face of a prism.

Fourier analysis decomposes a signal into its component wavelengths. An interferometer contains a beamsplitter, a stationary mirror, and a movable mirror. Reflection of light from the two mirrors creates an interferogram. Fourier analysis of the interferogram tells us what frequencies went into the interferogram. In a Fourier transform spectrophotometer, the interferogram of the source is first measured without sample. Then sample is placed in the beam and a second interferogram is recorded. The transforms of the interferograms tell what amount of light at each frequency reaches the detector with and without the sample. The quotient of the two transforms is the transmission spectrum. The resolution of a Fourier transform spectrum is approximately $1 / \Delta$, where $\Delta$ is the maximum retardation. To cover a wavenumber range $\Delta \widetilde{v}$ requires sampling the interferogram at intervals of $\delta=1 /(2 \Delta \widetilde{v})$.

If you average $n$ scans, the signal-to-noise ratio should increase by $\sqrt{n}$. White noise, which is independent of frequency, arises from sources such as random fluctuations of electrons in components (Johnson noise) and the discrete nature of charge carriers and photons (shot noise). $1 / f$ noise decreases with increasing frequency. Drift and flicker of the intensity of a light source or brightness of a flame in atomic spectroscopy are sources of $1 / f$ noise. Line noise occurs at discrete frequencies such as the $60-\mathrm{Hz}$ line frequency of a power supply. Beam chopping in a dual-beam spectrophotometer reduces $1 / f$ and line noise. A spectrometer modified to record the difference between the sample and reference signals can reduce noise from lamp flicker by at least an additional factor of 10 .

## Exercises

19-A. (a) If a diffraction grating has a resolution of $10^{4}$, is it possible to distinguish two spectral lines with wavelengths of 10.00 and $10.01 \mu \mathrm{~m}$ ?
(b) With a resolution of $10^{4}$, how close in wavenumbers $\left(\mathrm{cm}^{-1}\right)$ is the closest line to $1000 \mathrm{~cm}^{-1}$ that can barely be resolved?
(c) Calculate the resolution of a $5.0-\mathrm{cm}$-long grating ruled at 250 lines $/ \mathrm{mm}$ for first-order $(n=1)$ diffraction and tenth-order $(n=10)$ diffraction.
(d) Find the angular dispersion ( $\Delta \phi$, in radians and degrees) between light rays with wavenumbers of 1000 and $1001 \mathrm{~cm}^{-1}$ for second-order diffraction ( $n=2$ ) from a grating with 250 lines $/ \mathrm{mm}$ and $\phi=30^{\circ}$.
$19-\mathrm{B}$. The true absorbance of a sample is 1.000 , but the monochromator passes $1.0 \%$ stray light. Add the light coming through the sample to the stray light to find the apparent transmittance of the sample. Convert this answer back into absorbance and find the relative error in the calculated concentration of the sample.
19-C. Refer to the Fourier transform infrared spectrum in Figure 19-32.
(a) The interferogram was sampled at retardation intervals of $1.2660 \times 10^{-4} \mathrm{~cm}$. What is the theoretical wavenumber range ( 0 to ?) of the spectrum?
(b) A total of 4096 data points were collected from $\delta=-\Delta$ to $\delta=+\Delta$. Compute the value of $\Delta$, the maximum retardation.
(c) Calculate the approximate resolution of the spectrum.
(d) The interferometer mirror velocity is given in the figure caption.

How many microseconds elapse between each datum?
(e) How many seconds were required to record each interferogram once?
(f) What kind of beamsplitter is typically used for the region 400 to $4000 \mathrm{~cm}^{-1}$ ? Why is the region below $400 \mathrm{~cm}^{-1}$ not observed?

19-ID. The table shows signal-to-noise ratios recorded in a nuclear magnetic resonance experiment. Construct graphs of (a) signal-tonoise ratio versus $n$ and (b) signal-to-noise ratio versus $\sqrt{n}$, where $n$ is the number of scans. Draw error bars corresponding to the standard deviation at each point. Is the signal-to-noise ratio proportional to $\sqrt{n}$ ? Find the $95 \%$ confidence interval for each row of the table.

> Signal-to-noise ratio at the aromatic protons of $1 \%$ ethylbenzene in $\mathrm{CCl}_{4}$

| Number of <br> experiments | Number of <br> accumulations | Signal-to-noise <br> ratio | Standard <br> deviation |
| :--- | :---: | :---: | :---: |
| 8 | 1 | 18.9 | 1.9 |
| 6 | 4 | 36.4 | 3.7 |
| 6 | 9 | 47.3 | 4.9 |

## Problems

## The Spectrophotometer

19-1. Describe the role of each component of the spectrophotometer in Figure 19-1.

19-2. Explain how a laser generates light. List important properties of laser light.

19-3. Would you use a tungsten or a deuterium lamp as a source of $300-\mathrm{nm}$ radiation? What kind of lamp provides radiation at $4-\mu \mathrm{m}$ wavelength?

19-4. Which variables increase the resolution of a grating? Which variables increase the dispersion of the grating? How is
the blaze angle chosen to optimize a grating for a particular wavelength?
19-5. What is the role of a filter in a grating monochromator?
19-6. What are the advantages and disadvantages of decreasing monochromator slit width?

19-7. Explain how the following detectors of visible radiation work: (a) photomultiplier tube, (b) photodiode array, and (c) charge coupled device.
19-8. Deuterated triglycine sulfate (abbreviated DTGS) is a common ferroelectric infrared detector material. Explain how it works.

19-9. Consider a reflection grating operating with an incident angle of $40^{\circ}$ in Figure 19-7.
(a) How many lines per centimeter should be etched in the grating if the first-order diffraction angle for $600-\mathrm{nm}$ (visible) light is to be $-30^{\circ}$ ?
(b) Answer the same question for $1000 \mathrm{~cm}^{-1}$ (infrared) light.

19-10. Show that a grating with $10^{3}$ grooves $/ \mathrm{cm}$ provides a dispersion of $5.8^{\circ}$ per $\mu \mathrm{m}$ of wavelength if $n=1$ and $\phi=10^{\circ}$ in Equation 19-4.

19-11. (a) What resolution is required for a diffraction grating to resolve wavelengths of 512.23 and 512.26 nm ?
(b) With a resolution of $10^{4}$, how close in nm is the closest line to 512.23 nm that can barely be resolved?
(c) Calculate the fourth-order resolution of a grating that is 8.00 cm long and is ruled at 185 lines $/ \mathrm{mm}$.
(d) Find the angular dispersion $(\Delta \phi)$ between light rays with wavelengths of 512.23 and 512.26 nm for first-order diffraction ( $n=1$ ) and thirtieth-order diffraction from a grating with 250 lines $/ \mathrm{mm}$ and $\phi=3.0^{\circ}$.
19-12. (a) The true absorbance of a sample is 1.500 , but $0.50 \%$ stray light reaches the detector. Find the apparent transmittance and apparent absorbance of the sample.
(b) How much stray light can be tolerated if the absorbance error is not to exceed 0.001 at a true absorbance of 2 ?
(c) A research-quality spectrophotometer has a stray light level of $<0.00005 \%$ at 340 nm . What will be the maximum absorbance error for a sample with a true absorbance of 2 ? Of 3 ?

19-13. The pathlength of a cell for infrared spectroscopy can be measured by counting interference fringes (ripples in the transmission spectrum). The following spectrum shows 30 interference maxima between 1906 and $698 \mathrm{~cm}^{-1}$ obtained by placing an empty KBr cell in a spectrophotometer.

The fringes arise because light reflected from the cell compartment interferes constructively or destructively with the unreflected beam.

If the reflected beam travels an extra distance $\lambda$, it will interfere constructively with the unreflected beam. If the reflection pathlength is $\lambda / 2$, destructive interference occurs. Peaks therefore arise when $m \lambda=2 b$ and troughs occur when $m \lambda / 2=2 b$, where $m$ is an integer. If the medium between the KBr plates has refractive index $n$, the wavelength in the medium is $\lambda / n$, so the equations become $m \lambda / n=2 b$ and $m \lambda / 2 n=2 b$. The cell pathlength can be shown to be given by

$$
b=\frac{N}{2 n} \cdot \frac{\lambda_{1} \lambda_{2}}{\lambda_{2}-\lambda_{1}}=\frac{N}{2 n} \cdot \frac{1}{\tilde{v}_{1}-\tilde{v}_{2}}
$$

where $N$ maxima occur between wavelengths $\lambda_{1}$ and $\lambda_{2}$. Calculate the pathlength of the cell that gave the interference fringes shown earlier.

19-14. Calculate the power per unit area (the exitance, $\mathrm{W} / \mathrm{m}^{2}$ ) radiating from a blackbody at 77 K (liquid nitrogen temperature) and at 298 K (room temperature).
19-15. The exitance (power per unit area per unit wavelength) from a blackbody (Box 19-1) is given by the Planck distribution:

$$
M_{\lambda}=\frac{2 \pi h c^{2}}{\lambda^{5}}\left(\frac{1}{e^{h c / \lambda k T}-1}\right)
$$

where $\lambda$ is wavelength, $T$ is temperature ( K ), $h$ is Planck's constant, $c$ is the speed of light, and $k$ is Boltzmann's constant. The area under each curve between two wavelengths in the blackbody graph in Box $19-1$ is equal to the power per unit area ( $\mathrm{W} / \mathrm{m}^{2}$ ) emitted between those two wavelengths. We find the area by integrating the Planck function between wavelengths $\lambda_{1}$ and $\lambda_{2}$ :

$$
\text { Power emitted }=\int_{\lambda_{1}}^{\lambda_{2}} M_{\lambda} d \lambda
$$

For a narrow wavelength range, $\Delta \lambda$, the value of $M_{\lambda}$ is nearly constant and the power emitted is simply the product $M_{\lambda} \Delta \lambda$.
(a) Evaluate $M_{\lambda}$ at $\lambda=2.00 \mu \mathrm{~m}$ and at $\lambda=10.00 \mu \mathrm{~m}$ at $T=1000 \mathrm{~K}$.
(b) Calculate the power emitted per square meter at 1000 K in the interval $\lambda=1.99 \mu \mathrm{~m}$ to $\lambda=2.01 \mu \mathrm{~m}$ by evaluating the product $M_{\lambda} \Delta \lambda$, where $\Delta \lambda=0.02 \mu \mathrm{~m}$.
(c) Repeat part (b) for the interval 9.99 to $10.01 \mu \mathrm{~m}$.
(d) The quantity $\left[M_{\lambda}(\lambda=2 \mu \mathrm{~m})\right] /\left[M_{\lambda}(\lambda=10 \mu \mathrm{~m})\right]$ is the relative exitance at the two wavelengths. Compare the relative exitance at these two wavelengths at 1000 K with the relative exitance at 100 K . What does your answer mean?
19-16. In the cavity ring-down measurement at the opening of this chapter, absorbance is given by

$$
A=\frac{L}{c \ln 10}\left(\frac{1}{\tau}-\frac{1}{\tau_{0}}\right)
$$

where $L$ is the length of the cavity between mirrors, $c$ is the speed of light, $\tau$ is the ring-down lifetime with sample in the cavity, and $\tau_{0}$ is the ring-down lifetime with no sample in the cavity. Ring-down lifetime is obtained by fitting the observed ring-down signal intensity $I$ to an exponential decay of the form $I=I_{0} \mathrm{e}^{-t / \tau}$, where $I_{0}$ is the initial intensity and $t$ is time. A measurement of $\mathrm{CO}_{2}$ is made at a wavelength absorbed by the molecule. The ring-down lifetime for a $21.0-\mathrm{cm}$-long empty cavity is $18.52 \mu \mathrm{~s}$ and $16.06 \mu \mathrm{~s}$ for a cavity containing $\mathrm{CO}_{2}$. Find the absorbance of $\mathrm{CO}_{2}$ at this wavelength.

## Optical Sensors

19-17. Light passes from benzene (medium 1) to water (medium 2) in Figure 19-19 at (a) $\theta_{1}=30^{\circ}$ or (b) $\theta_{1}=0^{\circ}$. Find the angle $\theta_{2}$ in each case.

19-18. Explain how an optical fiber works. Why does the fiber still work when it is bent?

19-19. The photograph of upconversion in Color Plate 19 shows total internal reflection of the blue ray inside the cuvet. The angle of incidence of the blue ray on the wall of the cuvet is $\sim 55^{\circ}$. We estimate that the refractive index of the organic solvent is 1.50 and the refractive index of the fused-silica cuvet is 1.46 . Calculate the critical angle for total internal reflection at the solvent/silica interface and at the silica/air interface. From your calculation, which interface is responsible for total internal reflection in the photo?

19-20. Explain how the attenuated total reflection sensor in Figure 19-23 works.

19-21. Consider a planar waveguide used for attenuated total reflection measurement of a film coated on one surface of the waveguide. For a given angle of incidence, the sensitivity of attenuated total reflectance increases as the thickness of the waveguide decreases. Explain why. (The waveguide can be less than $1 \mu \mathrm{~m}$ thick.)

19-22. (a) Find the critical value of $\theta_{i}$ in Figure 19-20 beyond which there is total internal reflection in a $\mathrm{ZrF}_{4}$-based infrared optical fiber whose core refractive index is 1.52 and whose cladding refractive index is 1.50 .
(b) The loss of radiant power (due to absorption and scatter) in an optical fiber of length $\ell$ is expressed in decibels per meter ( $\mathrm{dB} / \mathrm{m}$ ), defined as

$$
\frac{\text { Power out }}{\text { Power in }}=10^{-\ell(\mathrm{dB} / \mathrm{m}) / 10}
$$

Calculate the quotient power out/power in for a 20.0 -m-long fiber with a loss of $0.0100 \mathrm{~dB} / \mathrm{m}$.

19-23. Find the minimum angle $\theta_{\mathrm{i}}$ for total reflection in the optical fiber in Figure 19-20 if the index of refraction of the cladding is 1.400 and the index of refraction of the core is (a) 1.600 or (b) 1.800 .

19-24. The prism shown here is used to totally reflect light at a $90^{\circ}$ angle. No surface of this prism is silvered. Use Snell's law to explain why total reflection occurs. What is the minimum refractive index of the prism for total reflection?

19-25. Here is an extremely sensitive method for measuring nitrite $\left(\mathrm{NO}_{2}^{-}\right)$down to 1 nM in natural waters. The water sample is treated
with sulfanilamide and $N$-(1-naphthylethylenediamine) in acid solution to produce a colored product with a molar absorptivity of $4.5 \times 10^{4} \mathrm{M}^{-1} \mathrm{~cm}^{-1}$ at 540 nm . The colored solution is pumped into a 4.5 -meter-long, coiled Teflon tube whose fluorocarbon wall has a refractive index of 1.29. The aqueous solution inside the tube has a refractive index near 1.33. The colored solution is pumped through the coiled tube. An optical fiber delivers white light into one end of the tube, and an optical fiber at the other end leads to a polychromator and detector.

Long-pathlength spectrometer. [Adapted from W. Yao, R. H. Byrne, and R. D. Waterbury, "Determination of Nanomolar Concentrations of Nitrite and Nitrate Using Long Path Length Absorbance Spectroscopy," Environ. Sci. Technol. 1998, 32, 2646.]
(a) Explain the purpose of the coiled Teflon tube and explain how it functions.
(b) What is the critical angle of incidence for total internal reflection at the Teflon/water interface?
(c) What is the predicted absorbance of a $1.0-\mathrm{nM}$ solution of colored reagent?
19-26. (a) A particular silica glass waveguide is reported to have a loss coefficient of $0.050 \mathrm{~dB} / \mathrm{cm}$ (power out/power in, defined in Problem 19-22) for 514-nm-wavelength light. The thickness of the waveguide is $0.60 \mu \mathrm{~m}$ and the length is 3.0 cm . The angle of incidence ( $\theta_{\mathrm{i}}$ in the figure) is $70^{\circ}$. What fraction of the incident radiant intensity is transmitted through the waveguide?

(b) If the index of refraction of the waveguide material is 1.5 , what is the wavelength of light inside the waveguide? What is the frequency?
19-27. fused silica is given by

$$
\begin{aligned}
n^{2}-1= & \frac{(0.6961663) \lambda^{2}}{\lambda^{2}-(0.0684043)^{2}}+\frac{(0.4079426) \lambda^{2}}{\lambda^{2}-(0.1162414)^{2}} \\
& +\frac{(0.8974794) \lambda^{2}}{\lambda^{2}-(9.896161)^{2}}
\end{aligned}
$$

where $\lambda$ is expressed in $\mu \mathrm{m}$.
(a) Make a graph of $n$ versus $\lambda$ with points at the following wavelengths: $0.2,0.4,0.6,0.8,1,2,3,4,5$, and $6 \mu \mathrm{~m}$.
(b) The ability of a prism to spread apart (disperse) neighboring wavelengths increases as the slope $d n / d \lambda$ increases. Is the dispersion of fused silica greater for blue light or red light?

## Fourier Transform Spectroscopy

19-28. The interferometer mirror of a Fourier transform infrared spectrophotometer travels $\pm 1 \mathrm{~cm}$.
(a) How many centimeters is the maximum retardation, $\Delta$ ?
(b) State what is meant by resolution.
(c) What is the approximate resolution $\left(\mathrm{cm}^{-1}\right)$ of the instrument?
(d) At what retardation interval, $\delta$, must the interferogram be sampled (converted into digital form) to cover a spectral range of 0 to $2000 \mathrm{~cm}^{-1}$ ?

19-29. Explain why the transmission spectrum in Figure 19-32 is calculated from the quotient (sample transform)/(background transform) instead of the difference (sample transform) - (background transform).

## Dealing with Noise

19-30. Describe three general types of noise that have a different dependence on frequency. Give an example of the source of each kind of noise.

19-31. Explain how beam chopping reduces line noise and noise from source drift.

19-32. Explain how the difference voltage in Figure 19-35 reduces noise from source flicker.
19-33. A spectrum has a signal-to-noise ratio of $8 / 1$. How many spectra must be averaged to increase the signal-to-noise ratio to 20/1?
19-34. A measurement with a signal-to-noise ratio of $100 / 1$ can be thought of as a signal, $S$, with $1 \%$ uncertainty, $e$. That is, the measurement is $S \pm e=100 \pm 1$.
(a) Use the rules for propagation of uncertainty to show that, if you add two such signals, the result is total signal $=200 \pm \sqrt{2}$, giving a signal-to-noise ratio of $200 / \sqrt{2}=141 / 1$.
(b) Show that if you add four such measurements, the signal-to-noise ratio increases to 200/1.
(c) Show that averaging $n$ measurements increases the signal-to-noise ratio by a factor of $\sqrt{n}$ compared with the value for one measurement.

19-35. Results of an electrochemical experiment are shown in the figure. In each case, a voltage is applied between two electrodes at time $=20 \mathrm{~s}$ and the absorbance of a solution decreases until the voltage is stepped back to its initial value at time $=60 \mathrm{~s}$. The upper traces show the average results for 100,300 , and 1000 repetitions of the experiment. The measured signal-to-rms noise ratio in the upper trace is 60.0 . Predict the signal-to-noise ratios expected for 300,100 , and 1 cycle and compare your answers with the observed values in the figure.

Signal averaging in an experiment in which absorbance is measured after the electric potential is changed at 20 s. [From A. F. Slaterbeck, T. H. Ridgeway, C. J. Seliskar, and W. R. Heineman, "Spectroelectrochemical Sensing Based on Multimode Selectivity Simultaneously Achievable in a Single Device," Anal. Chem. 1999, 71, 1196.]

In atomic spectroscopy, a substance is decomposed into atoms in a flame, furnace, or plasma. (A plasma is a gas that is hot enough to contain ions and free electrons.) Each element is measured by absorption or emission of ultraviolet or visible radiation by the gaseous atoms. To measure trace elements in a tooth, tiny portions of the tooth are vaporized (ablated) by a laser pulse ${ }^{1}$ and swept into a plasma. The plasma ionizes some of the atoms, which pass into a mass spectrometer that separates ions by their mass and measures their quantity.

Elements are incorporated into teeth from the diet or by inhalation. The figure shows trace element profiles measured by laser ablation-plasma ionization-mass spectrometry of the dentine of teeth from a modern person and one who lived in Scandinavia about A.D. 1800. The contrast is striking. The old tooth contains significant amounts of tin and bismuth, which are nearly absent in the modern tooth. The old tooth contains more lead and antimony than the modern tooth. Tin and lead are constituents of pewter, which was used for cooking vessels and utensils. Bismuth and antimony also might come from pewter.

Even more striking in the old tooth is the abundance of rare earths (dysprosium, holmium, erbium, thulium, ytterbium, and lutetium) and the elements tantalum, tungsten, gold, thorium, and uranium. Rare earth minerals are found in Scandinavia (in fact, many rare earth elements were discovered there), but what were they used for? Did people prepare food with them? Did they somehow get into the food chain?

Trace element profile of a tooth from a modern man and from a person who lived in Scandinavia 200 years ago. [From A. Cox, F. Keenan, M. Cooke, and J. Appleton, "Trace Element Profiling of Dental Tissues Using Laser Ablation Inductively Coupled Plasma-Mass Spectrometry," Fresenius J. Anal. Chem. 1996, 354, 254.]

Inductively coupled argon plasma atomizes substances at 6000 K .
|n atomic spectroscopy, samples vaporized at $2000-8000 \mathrm{~K}$ decompose into atoms. Concentrations of atoms in the vapor are measured by emission or absorption of characteristic wavelengths of radiation. Because of its high sensitivity, its ability to distinguish one element from another in a complex sample, its ability to perform simultaneous multielement

Preconcentration: concentrating a dilute analyte to a level high enough to be analyzed

## Types of atomic spectroscopy:

- emission from a thermally populated excited state
- absorption of sharp lines from hollowcathode lamp
- fluorescence following absorption of laser radiation
analyses, and the ease with which many samples can be automatically analyzed, atomic spectroscopy is a principal tool of analytical chemistry. ${ }^{2,3}$ Ions in the vapor can also be measured in a mass spectrometer, which we describe in this chapter. Equipment for atomic spectroscopy is expensive, but widely available.

Analyte is measured at parts per million ( $\mu \mathrm{g} / \mathrm{g}$ ) to parts per trillion ( $\mathrm{pg} / \mathrm{g}$ ) levels. To analyze major constituents, the sample must be diluted. Trace constituents can be measured directly without preconcentration. The precision of atomic spectroscopy is typically a few percent (depending on the type of sample and matrix), which is not as good as that of some wet chemical methods. Done in the most careful manner with suitable samples, inductively coupled plasma-atomic emission spectroscopy has an accuracy and precision on the order of $0.1 \%$ and can be used to certify DNA reference materials on the basis of phosphorus content. ${ }^{4}$

## 20-1 An Overview

Three forms of atomic spectroscopy are based on absorption, emission, and fluorescence (Figure 20-1). ${ }^{5}$ In atomic absorption in Figure 20-2, a liquid sample is aspirated (sucked) into a flame whose temperature is $2000-3000 \mathrm{~K}$. Liquid evaporates and the remaining solid is atomized (broken into atoms) in the flame, which replaces the cuvet of conventional spectrophotometry. The pathlength of the flame is typically 10 cm . The hollow-cathode lamp at the left in Figure 20-2 has an iron cathode. When the cathode is bombarded with energetic $\mathrm{Ne}^{+}$or $\mathrm{Ar}^{+}$ions, excited Fe atoms vaporize and emit light with the same frequencies absorbed by analyte Fe in the flame. At the right side of Figure 20-2, a detector measures the amount of light that passes through the flame.

An important difference between atomic and molecular spectroscopy is the width of absorption or emission bands. Absorption and emission spectra of liquids and solids typi-

FIGURE 20-1 Emission, absorption, and fluorescence by atoms in a flame. In atomic absorption, atoms absorb part of the light from the source and the remainder of the light reaches the detector. Atomic emission comes from atoms that are in an excited state because of the high thermal energy of the flame. To observe atomic fluorescence, atoms are excited by an external lamp or laser. An excited atom can fall to a lower state and emit radiation.

FIGURE 20-2 Atomic absorption experiment. As in Figure 17-4, transmittance $=T=P / P_{0}$ and absorbance $=A=-\log T$. In practice, $P_{0}$ is the irradiance reaching the detector when no sample is going into the flame, and $P$ is measured while sample is present.
cally have bandwidths of $\sim 10$ to 100 nm , as in Figures 17-8 and 17-18. In contrast, spectra of gaseous atoms consist of sharp lines with widths of $\sim 0.001 \mathrm{~nm}$ (Figure 20-3). Lines are so sharp that there is usually little overlap between the spectra of different elements in the same sample. Therefore, some instruments can measure more than 70 elements simultaneously. We will see later that sharp analyte absorption lines require that the light source also has sharp lines.

Figure 20-1 also illustrates an atomic fluorescence experiment. Atoms in the flame are irradiated by a laser to promote them to an excited electronic state from which they can fluoresce to return to the ground state. Figure 20-4 shows atomic fluorescence from 2 ppb of lead in tap water. Atomic fluorescence is potentially a thousand times more sensitive than atomic absorption, but equipment for atomic fluorescence is not common. An important example of atomic fluorescence is in the analysis of mercury (Box 20-1).

Fluorescence is more sensitive than absorption because we can observe a weak fluorescence signal above a dark background. In absorption, we are looking for small differences between large amounts of light reaching the detector.

FIGURE 20-3 A portion of the emission spectrum of a steel hollow-cathode lamp, showing lines from gaseous $\mathrm{Fe}, \mathrm{Ni}$, and Cr atoms and weak lines from $\mathrm{Cr}^{+}$and $\mathrm{Fe}^{+}$ions. The monochromator resolution is 0.001 nm , which is comparable to the true linewidths.

FIGURE 20-4 Atomic fluorescence from Pb at 405.8 nm . Water containing parts per billion of colloidal $\mathrm{PbCO}_{3}$ was ejected from a capillary tube and exposed to a 6 -ns pulse of $1064-\mathrm{nm}$ laser radiation focused on the drop. This pulse created a plume of vapor moving toward the laser. After $2.5 \mu \mathrm{~s}$, the plume was exposed to a $193-\mathrm{nm}$ laser pulse, creating excited Pb atoms whose fluorescence was measured for $0.1 \mu \mathrm{~s}$ with an optical system whose resolution was 0.2 nm . The figure shows a calibration curve constructed from colloidal $\mathrm{PbCO}_{3}$ standards and the signal from tap water containing 2 ppb Pb . [From S. K. Ho and N. H. Cheung, "Sub-Part-per-Billion Analysis of Aqueous Lead Colloids by ArF Laser Induced Atomic Fluorescence," Anal. Chem. 2005, 77, 193.]

Mercury is a volatile toxic pollutant. The map shows $\mathrm{Hg}(0)$ concentrations in the air near Earth's surface. Mercury is also found as $\mathrm{Hg}(\mathrm{II})(a q)$ in clouds and on particles in the atmosphere. Approximately two-thirds of atmospheric mercury comes from human activities, including coal burning, waste incineration, and $\mathrm{Cl}_{2}$ production by the chlor-alkali process (Problem 16-7).

Global annual average surface concentration of $\mathrm{Hg}(0)$. [From C. Seigneur, K. Vijayaraghavan, P. Karamchandani, and C. Scott, "Global Source Attribution of Mercury Deposition in the United States," Environ. Sci. Technol. 2004, 38, 555.]

A sensitive method to measure mercury in matrices such as water, soil, and fish generates $\operatorname{Hg}(g)$, which is measured by atomic absorption or fluorescence. For most environmental samples, automated digestion/analysis equipment is available. ${ }^{6,7}$ For water analysis by one standard method, all mercury is first oxidized to Hg (II) with BrCl in the purge flask in the drawing at the right. Halogens are reduced with hydroxylamine $\left(\mathrm{NH}_{2} \mathrm{OH}\right)$, and Hg (II) is reduced to $\mathrm{Hg}(0)$ with $\mathrm{SnCl}_{2} . \mathrm{Hg}(0)$ is then purged from solution by bubbling
purified Ar or $\mathrm{N}_{2} . \mathrm{Hg}(0)$ is collected at room temperature in the sample trap, which contains gold-coated silica sand. Hg binds to Au while other gases in the purge stream pass through. The sample trap is then heated to $450^{\circ} \mathrm{C}$ to release $\mathrm{Hg}(g)$, which is caught in the analytical trap at room temperature. Two traps are used so that all other gaseous impurities are removed prior to analysis. $\mathrm{Hg}(g)$ is then released from the analytical trap by heating and flows into the fluorescence cell. Fluorescence intensity strongly depends on gaseous impurities that can quench the emission from Hg .

The lower limit of quantitation is $\sim 0.5 \mathrm{ng} / \mathrm{L}$ (parts per trillion). To measure such small quantities requires extraordinary care at every stage of analysis to prevent contamination. Mercury amalgam fillings in a worker's teeth can contaminate samples exposed to exhaled breath.

Mercury analysis by U.S. Environmental Protection Agency Method 1631.

Organic solvents with surface tensions lower than that of water are excellent for atomic spectroscopy because they form smaller droplets, thus leading to more efficient atomization.

By contrast, atomic emission (Figure 20-1) is widely used. ${ }^{8}$ Collisions in the hot plasma promote some atoms to excited electronic states from which they can emit photons to return to lower energy states. No lamp is required. Emission intensity is proportional to the concentration of the element in the sample. Emission from atoms in a plasma is now the dominant form of atomic spectroscopy.

## 20-2 Atomization: Flames, Furnaces, and Plasmas

In atomic spectroscopy, analyte is atomized in a flame, an electrically heated furnace, or a plasma. Flames were used for decades, but they have been replaced by the inductively coupled plasma and the graphite furnace. We begin our discussion with flames because they are still common in teaching labs.

## Flames

Most flame spectrometers use a premix burner, such as that in Figure 20-5, in which fuel, oxidant, and sample are mixed before introduction into the flame. Sample solution is drawn into the pneumatic nebulizer by the rapid flow of oxidant (usually air) past the tip of the sample capillary. Liquid breaks into a fine mist as it leaves the capillary. The spray is directed against a glass bead, upon which the droplets break into smaller particles. The formation of small droplets is termed nebulization. A fine suspension of liquid (or solid) particles in a gas is called an aerosol. The nebulizer creates an aerosol from the liquid sample. The mist, oxidant, and fuel flow past baffles that promote further mixing and block large droplets of liquid.

Excess liquid collects at the bottom of the spray chamber and flows out to a drain. Aerosol reaching the flame contains only about $5 \%$ of the initial sample.

The most common fuel-oxidizer combination is acetylene and air, which produces a flame temperature of $2400-2700 \mathrm{~K}$ (Table 20-1). If a hotter flame is required to atomize highboiling elements (called refractory elements), acetylene and nitrous oxide are usually used. In the flame profile in Figure 20-5b, gas entering the preheating region is heated by conduction and radiation from the primary reaction zone (the blue cone in the flame). Combustion is completed in the outer cone, where surrounding air is drawn into the flame. Flames emit light that must be subtracted from the total signal to obtain the analyte signal.

Droplets entering the flame evaporate; then the remaining solid vaporizes and decomposes into atoms. Many elements form oxides and hydroxides in the outer cone. Molecules do not have the same spectra as atoms, so the atomic signal is lowered. Molecules also emit broad radiation that must be subtracted from the sharp atomic signals. If the flame is relatively rich in fuel (a "rich" flame), excess carbon tends to reduce metal oxides and hydroxides and thereby increases sensitivity. A "lean" flame, with excess oxidant, is hotter. Different elements require either rich or lean flames for best analysis. The height in the flame at which maximum atomic absorption or emission is observed depends on the element being measured and the flow rates of sample, fuel, and oxidizer. ${ }^{9}$

TABLE 20-1 Maximum flame temperatures

| Fuel | Oxidant | Temperature (K) |
| :--- | :--- | :--- |
| Acetylene, $\mathrm{HC} \equiv \mathrm{CH}$ | Air | $2400-2700$ |
| Acetylene | Nitrous oxide, $\mathrm{N}_{2} \mathrm{O}$ | $2900-3100$ |
| Acetylene | Oxygen | $3300-3400$ |
| Hydrogen | Air | $2300-2400$ |
| Hydrogen | Oxygen | $2800-3000$ |
| Cyanogen, $\mathrm{N} \equiv \mathrm{C}-\mathrm{C} \equiv \mathrm{N}$ | Oxygen | 4800 |

## Furnaces ${ }^{10}$

An electrically heated graphite furnace is more sensitive than a flame and requires less sample. From 1 to $100 \mu \mathrm{~L}$ of sample are injected into the furnace through the hole at the center of Figure 20-6. Light from a hollow-cathode lamp travels through windows at each end of the graphite tube. To prevent oxidation of the graphite, Ar gas is passed over the furnace and the maximum recommended temperature is $2550^{\circ} \mathrm{C}$ for not more than 7 s .

In flame spectroscopy, the residence time of analyte in the optical path is $<1 \mathrm{~s}$ as it rises through the flame. A graphite furnace confines the atomized sample in the optical path for several seconds, thereby affording higher sensitivity. Whereas $1-2 \mathrm{~mL}$ is the minimum volume of solution necessary for flame analysis, as little as $1 \mu \mathrm{~L}$ is adequate for a furnace. Precision is rarely better than $5-10 \%$ with manual sample injection, but automated injection improves reproducibility to $\sim 1 \%$.

FIGURE 20-5 (a) Premix burner. (b) End view of flame. The slot in the burner head is about 0.5 mm wide. (c) Distribution of droplet sizes produced by a particular nebulizer. [From R. H. Clifford, I. Ishii, A. Montaser, and G. A. Meyer, "Droplet-Size and Velocity Distributions of Aerosols from Commonly Used Nebulizers," Anal. Chem. 1990, 62, 390.]

You must determine reasonable time and temperature for each stage of the analysis. Once a program is established, it can be applied to a large number of similar samples.

FIGURE 20-7 (a) Correct position for injecting sample into a graphite furnace deposits the droplet in a small volume on the floor of the furnace. (b) If injection is too high, sample splatters and precision is poor. [From P. K. Booth, "Improvements in Method Development for Graphite Furnace Atomic Absorption Spectrometry," Am. Lab., February 1995, p. 48X.]

When you inject sample, the droplet should contact the floor of the furnace and remain in a small area (Figure 20-7a). If you inject the droplet too high (Figure 20-7b), it splashes and spreads, leading to poor precision. In the worst case, the drop adheres to the tip of the pipet and is finally deposited around the injector hole when the pipet is withdrawn.

Compared with flames, furnaces require more operator skill to find proper conditions for each type of sample. The furnace is heated in three or more steps to properly atomize the sample. To measure Fe in the iron-storage protein ferritin, $10 \mu \mathrm{~L}$ of sample containing $\sim 0.1 \mathrm{ppm} \mathrm{Fe}$ are injected into the furnace at $\sim 90^{\circ} \mathrm{C}$. The furnace is programmed to $d r y$ the sample at $125^{\circ} \mathrm{C}$ for 20 s to remove solvent. Drying is followed by 60 s of charring at $1400^{\circ} \mathrm{C}$ to destroy organic matter. Charring is also called pyrolysis, which means decomposing with heat. Charring creates smoke that would interfere with the Fe determination. After charring, the sample is atomized at $2100^{\circ} \mathrm{C}$ for 10 s . Absorbance reaches a maximum and then decreases as Fe evaporates from the oven. The analytical signal is the time-integrated absorbance (the peak area) during atomization. After atomization, the furnace is heated to $2500^{\circ} \mathrm{C}$ for 3 s to clean out remaining residue.

The furnace is purged with Ar or $\mathrm{N}_{2}$ during each step except atomization to remove volatile material. Gas flow is halted during atomization to avoid blowing analyte out of the furnace. When developing a method for a new kind of sample, it is important to record the signal as a function of time, because signals are also observed from smoke during charring and from the glow of the red-hot furnace in the last part of atomization. A skilled operator interprets which signal is due to analyte so that the right peak is integrated.

The furnace in Figure 20-8a performs better than a simple graphite tube. Sample is injected onto a platform that is heated by radiation from the furnace wall, so its temperature lags behind that of the wall. Analyte does not vaporize until the wall reaches constant temperature (Figure 20-8b). At constant furnace temperature, the area under the absorbance peak in Figure $20-8 \mathrm{~b}$ is a reliable measure of the analyte. A heating rate of $2000 \mathrm{~K} / \mathrm{s}$ rapidly dissociates molecules and increases the concentration of free atoms in the furnace.

The furnace in Figure 20-8a is heated transversely (from side to side) to provide nearly uniform temperature over the whole furnace. In furnaces with longitudinal (end-to-end) heating, the center of the furnace is hotter than the ends. Atoms from the central region condense at the ends, where they can vaporize during the next sample run. Interference from previous runs, called a memory effect, is reduced in a transversely heated furnace. To further reduce memory effects, ordinary graphite is coated with a dense layer of pyrolytic graphite formed by thermal decomposition of an organic vapor. The coating seals the relatively porous graphite, so it cannot absorb foreign atoms.

A sample can be preconcentrated by injecting and evaporating multiple aliquots in the graphite furnace prior to analysis. ${ }^{11}$ To measure traces of As in drinking water, a $30-\mu \mathrm{L}$ aliquot of water plus matrix modifier was injected and evaporated. The procedure was

FIGURE 20-8 (a) Transversely heated graphite furnace maintains nearly constant temperature over its whole length, thereby reducing memory effect from previous runs. The L'vov platform is uniformly heated by radiation from the outer wall, not by conduction. The platform is attached to the wall by one small connection that is hidden from view. [Courtesy PerkinElmer Corp., Norwalk, CT.] (b) Heating profiles comparing analyte evaporation from wall and from platform. [From W. Slavin, "Atomic Absorption Spectroscopy," Anal. Chem. 1982, 54, 685A.]
repeated five more times so that the total sample volume was $180 \mu \mathrm{~L}$. The detection limit for As was $0.3 \mu \mathrm{~g} / \mathrm{L}$ (parts per billion). Without preconcentration, the detection limit would have been $1.8 \mu \mathrm{~g} / \mathrm{L}$. This increased capability is critical because As is considered to be a health hazard at concentrations of just a few parts per billion.

Liquid samples are ordinarily used in furnaces. However, in direct solid sampling, a solid is analyzed without sample preparation (Figure 20-9). For example, trace impurities in tungsten powder used to make components for industry can be analyzed by weighing 0.1 to 100 mg of powder onto a graphite platform. ${ }^{12}$ The platform is transferred into the furnace and heated to $2600^{\circ} \mathrm{C}$ to atomize impurities in the tungsten, but not the tungsten itself, which melts at $3410^{\circ} \mathrm{C}$. After several runs, residual tungsten is scraped off the platform, which could be reused 400 times. Because so much more sample is analyzed when solid is injected than when liquid is injected, detection limits can be 100 times lower than those obtained for liquid injection. For example, Zn could be detected at a level of $10 \mathrm{pg} / \mathrm{g}$ ( 10 parts per trillion) in 100 mg of tungsten. Calibration curves are obtained by injecting standard solutions of the trace elements and analyzing them as conventional liquids. Results obtained from direct solid sampling are in good agreement with results obtained by laboriously dissolving the solid. Other solids that have been analyzed by direct solid sampling include graphite, silicon carbide, cement, river sediments, hair, and vegetable matter. ${ }^{13}$

## Matrix Modifiers for Furnaces

Everything in a sample other than analyte is called the matrix. Ideally, the matrix decomposes and vaporizes during the charring step. A matrix modifier is a substance added to the sample to reduce the loss of analyte during charring by making the matrix more volatile or the analyte less volatile.

The matrix modifier ammonium nitrate can be added to seawater to increase the volatility of the matrix NaCl . Figure 20-10a shows a graphite furnace heating profile used to analyze Mn in seawater. When 0.5 M NaCl solution is subjected to this profile, signals are observed at the analytical wavelength of Mn (Figure 20-10b). Much of the apparent absorbance is probably due to optical scatter by smoke created by heating NaCl . Absorption at the start of the atomization step interferes with the measurement of Mn . Adding $\mathrm{NH}_{4} \mathrm{NO}_{3}$ to the sample in Figure 20-10c reduces matrix absorption peaks. $\mathrm{NH}_{4} \mathrm{NO}_{3}$ plus NaCl give $\mathrm{NH}_{4} \mathrm{Cl}$ and $\mathrm{NaNO}_{3}$, which cleanly evaporate instead of making smoke.

The matrix modifier $\mathrm{Pd}\left(\mathrm{NO}_{3}\right)_{2}$ is added to seawater to decrease the volatility of the analyte Sb . In the absence of modifier, $90 \%$ of Sb is lost during charring at $1250^{\circ} \mathrm{C}$. With the modifier, seawater matrix can be largely evaporated at $1400^{\circ} \mathrm{C}$ without loss of $\mathrm{Sb} .^{14}$

FIGURE 20-10 Reduction of interference by using a matrix modifier. (a) Graphite furnace temperature profile for analysis of Mn in seawater. (b) Absorbance profile from $10 \mu \mathrm{~L}$ of 0.5 M reagent-grade NaCl subjected to temperature profile in panel $a$. Absorbance is monitored at the Mn wavelength of 279.5 nm with a bandwidth of 0.5 nm . (c) Reduced absorbance from $10 \mu \mathrm{~L}$ of 0.5 M NaCl plus $10 \mu \mathrm{~L}$ of $50 \mathrm{wt} \% \mathrm{NH}_{4} \mathrm{NO}_{3}$ matrix modifier. [From M. N. Quigley and F. Vernon, "Matrix Modification Experiment for Electrothermal Atomic Absorption Spectrophotometry," J. Chem. Ed. 1996, 73, 980.]

FIGURE 20-9 Direct solid sampling showing end view of furnace.

Matrix modifier: increases volatility of matrix or decreases volatility of analyte to obtain a cleaner separation between matrix and analyte.

FIGURE 20-11 Temperature profile of inductively coupled plasma. [From V. A. Fassel, "Simultaneous or Sequential Determination of the Elements at All Concentration Levels," Anal. Chem. 1979, 51, 1290A.]

FIGURE 20-12 Inductively coupled plasma burner. [From R. N. Savage and G. M. Hieftje, "Miniature Inductively Coupled Plasma Source for Atomic Emission Spectrometry," Anal. Chem. 1979, 51, 408.]

The matrix modifier $\mathrm{Mg}\left(\mathrm{NO}_{3}\right)_{2}$ raises the temperature for atomization of Al analyte. ${ }^{15} \mathrm{At}$ high temperature, $\mathrm{Mg}\left(\mathrm{NO}_{3}\right)_{2}$ decomposes to $\mathrm{MgO}(\mathrm{g})$ and Al is converted into $\mathrm{Al}_{2} \mathrm{O}_{3}$. At sufficiently high temperature, $\mathrm{Al}_{2} \mathrm{O}_{3}$ decomposes to Al and O , and Al evaporates. Evaporation of Al is retarded by $\mathrm{MgO}(\mathrm{g})$ by virtue of the reaction

$$
\begin{equation*}
3 \mathrm{MgO}(g)+2 \mathrm{Al}(s) \rightleftharpoons 3 \mathrm{Mg}(g)+\mathrm{Al}_{2} \mathrm{O}_{3}(s) \tag{20-1}
\end{equation*}
$$

When MgO has evaporated, Reaction 20-1 no longer occurs and $\mathrm{Al}_{2} \mathrm{O}_{3}$ decomposes and evaporates. A matrix modifier that raises the boiling temperature of analyte allows a higher charring temperature to be used to remove matrix without losing analyte.

It is important to monitor the absorption signal from a graphite furnace as a function of time, as in Figure 20-10b. Peak shapes help you decide how to adjust time and temperature for each step to obtain a clean signal from analyte. Also, a graphite furnace has a finite lifetime. Degradation of peak shape or a change in the slope of the calibration curve tell you that it is time to change the furnace.

## Inductively Coupled Plasmas

The inductively coupled plasma ${ }^{16}$ shown at the beginning of the chapter is twice as hot as a combustion flame (Figure 20-11). The high temperature, stability, and relatively inert Ar environment eliminate much of the interference encountered with flames. Simultaneous multielement analysis described in Section 20-4 is routine for inductively coupled plasma-atomic emission spectroscopy, which has replaced flame atomic absorption. The plasma instrument costs more to purchase and operate than a flame instrument.

The cross-sectional view of an inductively coupled plasma burner in Figure 20-12 shows two turns of a 27 - or $41-\mathrm{MHz}$ induction coil wrapped around the upper opening of the quartz apparatus. High-purity Ar gas is fed through the plasma gas inlet. After a spark from a Tesla coil ionizes Ar, free electrons are accelerated by the radio-frequency field. Electrons collide with atoms and transfer energy to the entire gas, maintaining a temperature of 6000 to 10000 K . The quartz torch is protected from overheating by Ar coolant gas.

The concentration of analyte needed for adequate signal is reduced by an order of magnitude with an ultrasonic nebulizer (Figure 20-13), in which sample solution is directed onto a

| Technique ${ }^{a}$ | Detection limits for <br> different instruments (ng/g) |
| :--- | :--- |
| ICP/atomic emission (pneumatic nebulizer) | $3-50$ |
| ICP/atomic emission (ultrasonic nebulizer) | $0.3-4$ |
| Graphite furnace/atomic absorption | $0.02-0.06$ |
| ICP/mass spectrometry | $0.001-0.2$ |

a. $I C P=$ inductively coupled plasma.
source: J. M. Mermet and E. Poussel, "ICP Emission Spectrometers: Analytical Figures of Merit," Appl. Spectros. 1995, 49, $12 A$.
piezoelectric crystal oscillating at 1 MHz . The vibrating crystal creates a fine aerosol that is carried by an Ar stream through a heated tube where solvent evaporates. In the next refrigerated zone, solvent condenses and is removed. Then the stream enters a desolvator containing a microporous polytetrafluoroethylene membrane in a chamber maintained at $160^{\circ} \mathrm{C}$. Remaining solvent vapor diffuses through the membrane and is swept away by flowing Ar. Analyte reaches the plasma flame as an aerosol of dry, solid particles. Plasma energy is not needed to evaporate solvent, so more energy is available for atomization. Also, a larger fraction of the sample reaches the plasma than with a conventional nebulizer.

Sensitivity with an inductively coupled plasma is further enhanced by a factor of 3 to 10 by observing emission along the length of the plasma (axial view) instead of across the diameter of the plasma. Additional sensitivity is obtained by detecting ions with a mass spectrometer instead of by optical emission (Table 20-2), as described in Section 20-6.

## 20-3 How Temperature Affects Atomic Spectroscopy

Temperature determines the degree to which a sample breaks down into atoms and the extent to which a given atom is found in its ground, excited, or ionized states. Each of these effects influences the strength of the signal we observe.

## The Boltzmann Distribution

Consider an atom with energy levels $E_{0}$ and $E^{*}$ separated by $\Delta E$ (Figure 20-14). An atom (or molecule) may have more than one state at a given energy. Figure 20-14 shows three states at $E^{*}$ and two at $E_{0}$. The number of states at each energy is called the degeneracy. We will call the degeneracies $g_{0}$ and $g^{*}$.

The Boltzmann distribution describes the relative populations of different states at thermal equilibrium. If equilibrium exists (which is not true in the blue cone of a flame but is probably true above the blue cone), the relative population ( $N^{*} / N_{0}$ ) of any two states is

$$
\text { Boltzmann distribution: } \quad \frac{N^{*}}{N_{0}}=\frac{g^{*}}{g_{0}} \mathrm{e}^{-\Delta E / k T}
$$

where $T$ is temperature $(\mathrm{K})$ and $k$ is Boltzmann's constant $\left(1.381 \times 10^{-23} \mathrm{~J} / \mathrm{K}\right)$.

## Effect of Temperature on Excited-State Population

The lowest excited state of a sodium atom lies $3.371 \times 10^{-19} \mathrm{~J} /$ atom above the ground state. The degeneracy of the excited state is 2 , whereas that of the ground state is 1 . The fraction of Na in the excited state in an acetylene-air flame at 2600 K is, from Equation 20-2,

$$
\frac{N^{*}}{N_{0}}=\left(\frac{2}{1}\right) \mathrm{e}^{-\left(3.371 \times 10^{-19} \mathrm{~J}\right) /\left[\left(1.381 \times 10^{-23} \mathrm{~J} / \mathrm{K}\right)(2600 \mathrm{~K})\right]}=1.67 \times 10^{-4}
$$

That is, less than $0.02 \%$ of the atoms are in the excited state.
If the temperature were 2610 K , the fraction of atoms in the excited state would be

$$
\frac{N^{*}}{N_{0}}=\left(\frac{2}{1}\right) \mathrm{e}^{-\left(3.371 \times 10^{-19} \mathrm{~J}\right) /\left[\left(1.381 \times 10^{-23} \mathrm{~J} / \mathrm{K}\right)(2610 \mathrm{~K})\right]}=1.74 \times 10^{-4}
$$

The fraction of atoms in the excited state is still less than $0.02 \%$, but that fraction has increased by $100(1.74-1.67) / 1.67=4 \%$.

A piezoelectric crystal is one whose dimensions change in an applied electric field. A sinusoidal voltage applied between two faces of the crystal causes it to oscillate. Quartz is the most common piezoelectric material.

FIGURE 20-14 Two energy levels with different degeneracies. Ground-state atoms that absorb light are promoted to the excited state. Excited-state atoms can emit light to return to the ground state.

The Boltzmann distribution applies to a system at thermal equilibrium.

A 10-K temperature rise changes the excitedstate population by $4 \%$ in this example.

Atomic absorption is not as sensitive to temperature as atomic emission, which is exponentially sensitive to temperature.

The linewidth of the source must be narrower than the linewidth of the atomic vapor for Beer's law to be obeyed. "Linewidth" and "bandwidth" are used interchangeably, but "lines" are narrower than "bands."
$\Delta E$ in Equation 20-2 is the difference in energy between ground and excited states. $\delta E$ in Equation $20-3$ is the uncertainty in $\Delta E$. $\delta E$ is a small fraction of $\Delta E$.

## The Effect of Temperature on Absorption and Emission

We see that more than $99.98 \%$ of the sodium atoms are in their ground state at 2600 K . Varying the temperature by 10 K hardly affects the ground-state population and would not noticeably affect the signal in atomic absorption.

How would emission intensity be affected by a 10 K rise in temperature? In Figure 20-14, absorption arises from ground-state atoms, but emission arises from excited-state atoms. Emission intensity is proportional to the population of the excited state. Because the excitedstate population changes by $4 \%$ when the temperature rises 10 K , emission intensity rises by 4\%. It is critical in atomic emission spectroscopy that the flame be very stable, or emission intensity will vary significantly. In atomic absorption spectroscopy, temperature variation is important but not as critical.

Almost all atomic emission is carried out with an inductively coupled plasma, whose temperature is more stable than that of a flame. Plasma is normally used for emission, not absorption, because it is so hot that there is a substantial population of excited-state atoms and ions. Table 20-3 compares excited-state populations for a flame at 2500 K and a plasma at 6000 K . Although the fraction of excited atoms is small, each atom emits many photons per second because it is rapidly promoted back to the excited state by collisions.

TABLE 20-3 Effect of energy difference and temperature on population of excited states

| Wavelength difference <br> of states $(\mathbf{n m})$ | Energy difference <br> of states $(\mathrm{J} /$ atom $)$ | $\frac{\text { Excited-state fraction }\left(N^{*} / N_{0}\right)^{a}}{\mathbf{2 5 0 0 \mathbf { K }}}$ |  | $\mathbf{6 0 0 0 \mathbf { K }}$ |

a. Based on the equation $N^{*} / N_{O}=\left(g^{*} / g_{0}\right) e^{-\Delta E k T}$ in which $g^{*}=g_{0}=1$.

Energy levels of halogen atoms ( $\mathrm{F}, \mathrm{Cl}, \mathrm{Br}, \mathrm{I}$ ) are so high that they emit ultraviolet radiation below 200 nm . This spectral region is called vacuum ultraviolet because radiation below 200 nm is absorbed by $\mathrm{O}_{2}$, so spectrometers for the far-ultraviolet were customarily evacuated. Some plasma emission spectrometers are purged with $\mathrm{N}_{2}$ to exclude air so that the region 130 to 200 nm is accessible and $\mathrm{Cl}, \mathrm{Br}, \mathrm{I}, \mathrm{P}$, and S can be analyzed. ${ }^{17}$ In another application, nitrogen in fertilizers is measured along with other major elements in the fertilizer. The torch is designed to be purged with Ar to exclude $\mathrm{N}_{2}$ from air. Unknowns are purged with He to remove dissolved air. Emission from N is observed near 174 nm .

## 20-4 Instrumentation

Fundamental requirements for an atomic absorption experiment are shown in Figure 20-2. Principal differences between atomic and ordinary molecular spectroscopy lie in the light source (or lack of a light source in atomic emission), the sample container (the flame, furnace, or plasma), and the need to subtract background emission.

## Atomic Linewidths ${ }^{18}$

Beer's law requires that the linewidth of the radiation source should be substantially narrower than the linewidth of the absorbing sample. Otherwise, the measured absorbance will not be proportional to the sample concentration. Atomic absorption lines are very sharp, with an intrinsic width of only $\sim 10^{-4} \mathrm{~nm}$.

Linewidth is governed by the Heisenberg uncertainty principle, which says that the shorter the lifetime of the excited state, the more uncertain is its energy:

Heisenberg uncertainty principle:

$$
\begin{equation*}
\delta E \delta t \gtrsim \frac{h}{4 \pi} \tag{20-3}
\end{equation*}
$$

where $\delta E$ is the uncertainty in the energy difference between ground and excited states, $\delta t$ is the lifetime of the excited state before it decays to the ground state, and $h$ is Planck's constant. Equation 20-3 says that the uncertainty in the energy difference between two states multiplied by the lifetime of the excited state is at least $h / 4 \pi$. If $\delta t$ decreases, then $\delta E$ increases. The
lifetime of an excited state of an isolated gaseous atom is $\sim 10^{-9} \mathrm{~s}$. Therefore, the uncertainty in its energy is

$$
\delta E \gtrsim \frac{h}{4 \pi \delta t}=\frac{6.6 \times 10^{-34} \mathrm{~J} \cdot \mathrm{~s}}{4 \pi\left(10^{-9} \mathrm{~s}\right)} \approx 10^{-25} \mathrm{~J}
$$

Suppose that the energy difference $(\Delta E)$ between the ground and the excited state of an atom corresponds to visible light with a wavelength of $\lambda=500 \mathrm{~nm}$. This energy difference is $\Delta E=h c / \lambda=4.0 \times 10^{-19} \mathrm{~J}$ (Equation 17-3, $c$ is the speed of light). The relative uncertainty in the energy difference is $\delta E / \Delta E \gtrsim\left(10^{-25} \mathrm{~J}\right) /\left(4.0 \times 10^{-19} \mathrm{~J}\right) \approx 2 \times 10^{-7}$. The relative uncertainty in wavelength $(\delta \lambda / \lambda)$ is the same as the relative uncertainty in energy:

$$
\begin{equation*}
\frac{\delta \lambda}{\lambda}=\frac{\delta E}{\Delta E} \gtrsim 2 \times 10^{-7} \Rightarrow \delta \lambda \gtrsim\left(2 \times 10^{-7}\right)(500 \mathrm{~nm})=10^{-4} \mathrm{~nm} \tag{20-4}
\end{equation*}
$$

The inherent linewidth of an atomic absorption or emission signal is $\sim 10^{-4} \mathrm{~nm}$ because of the short lifetime of the excited state.

Two mechanisms broaden the lines to $10^{-3}$ to $10^{-2} \mathrm{~nm}$ in atomic spectroscopy. One is the Doppler effect. An atom moving toward the radiation source experiences more oscillations of the electromagnetic wave in a given time period than one moving away from the source (Figure 20-15). That is, an atom moving toward the source "sees" higher frequency light than that encountered by one moving away. In the laboratory frame of reference, the atom moving toward the source absorbs lower frequency light than that absorbed by the one moving away. The linewidth, $\delta \lambda$, due to the Doppler effect, is

Doppler linewidth:

$$
\begin{equation*}
\delta \lambda \approx \lambda\left(7 \times 10^{-7}\right) \sqrt{\frac{T}{M}} \tag{20-5}
\end{equation*}
$$

where $T$ is temperature ( K ) and $M$ is the mass of the atom in atomic mass units. For an emission line near $\lambda=300 \mathrm{~nm}$ from $\mathrm{Fe}(M=56$ atomic mass units) at 2500 K in Figure 20-3, the Doppler linewidth is $(300 \mathrm{~nm})\left(7 \times 10^{-7}\right) \sqrt{2500 / 56}=0.0014 \mathrm{~nm}$, which is an order of magnitude greater than the natural linewidth.

Linewidth is also affected by pressure broadening from collisions between atoms. Collisions shorten the lifetime of the excited state. Uncertainty in the frequency of atomic absorption and emission lines is roughly numerically equal to the collision frequency between atoms and is proportional to pressure. The Doppler effect and pressure broadening are similar in magnitude and yield linewidths of $10^{-3}$ to $10^{-2} \mathrm{~nm}$ in atomic spectroscopy.

## Hollow-Cathode Lamp

Monochromators generally cannot isolate lines narrower than $10^{-3}$ to $10^{-2} \mathrm{~nm}$. To produce narrow lines of the correct frequency, we use a hollow-cathode lamp containing a vapor of the same element as that being analyzed.

The hollow-cathode lamp in Figure 20-16 is filled with Ne or Ar at a pressure of $\sim 130-700 \mathrm{~Pa}(1-5$ Torr). The cathode is made of the element whose emission lines we want. When $\sim 500 \mathrm{~V}$ is applied between the anode and the cathode, gas is ionized and positive ions are accelerated toward the cathode. After ionization occurs, the lamp is maintained at a constant current of 2-30 mA by a lower voltage. Cations strike the cathode with enough energy to "sputter" metal atoms from the cathode into the gas phase. Gaseous atoms excited by collisions with high-energy electrons emit photons. This atomic radiation has the same frequency absorbed by analyte in the flame or furnace. Atoms in the lamp are cooler than atoms in a flame, so lamp emission is sufficiently narrower than the absorption bandwidth of atoms in the flame to be nearly "monochromatic" (Figure 20-17). The purpose of a monochromator in

FIGURE 20-16 A hollow-cathode lamp.
$\delta \lambda$ is the width of an absorption or emission line measured at half the height of the peak.

FIGURE 20-15 The Doppler effect. A molecule moving (a) toward the radiation source "feels" the electromagnetic field oscillate more often than one moving (b) away from the source.

Doppler and pressure effects broaden the atomic lines by one to two orders of magnitude relative to their inherent linewidths.

FIGURE 20-17 Relative bandwidths of hollow-cathode emission, atomic absorption, and a monochromator. Linewidths are measured at half the signal height. The linewidth from the hollow cathode is relatively narrow because gas temperature in the lamp is lower than flame temperature (so there is less Doppler broadening) and pressure in the lamp is lower than pressure in a flame (so there is less pressure broadening).

## Capabilities of CID detector:

- pixels are individually addressed
- rapidly filling pixel can be read, re-zeroed, and read again
- filled pixel does not bloom into neighbors
atomic spectroscopy is to select one line from the hollow-cathode lamp and to reject as much emission from the flame or furnace as possible. A different lamp is usually required for each element, although some lamps are made with more than one element in the cathode.

## Multielement Detection with the Inductively Coupled Plasma

An inductively coupled plasma emission spectrometer does not require any lamps and can measure as many as 70 elements simultaneously. Color Plates 24 and 25 illustrate two designs for multielement analysis. In Color Plate 24, atomic emission enters the polychromator and is dispersed into its component wavelengths by the grating at the bottom. One photomultiplier detector (Figure 19-14) is required at the correct position for each element.

In Color Plate 25, atomic emission entering from the top right is reflected by a collimating mirror (which makes light rays parallel), dispersed in the vertical plane by a prism, and then dispersed in the horizontal plane by a grating. Dispersed radiation lands on a charge injection device (CID) detector, which is related to the charge coupled device (CCD) in Figure 19-17. Different wavelengths are spread over the 262000 pixels of the CID shown at the upper left of Color Plate 25. In a CCD detector, each pixel must be read one at a time in row-by-row order. Each pixel of a CID detector can be read individually at any time. Selectively reading relevant pixels eliminates time spent reading pixels that are of no interest. A given pixel can be monitored and read before it becomes full. The charge in the pixel is then neutralized to reset the pixel to zero. The pixel can then accumulate more charge and be read several times while other pixels are filling up at a slower pace. This process increases the dynamic range of the detector by allowing large signals to be measured in some pixels while small signals are measured in other pixels. Another advantage of the CID detector over the CCD detector is that strong signals in one pixel are less prone to spill over into neighboring pixels (a process called blooming in CCD detectors). CID detectors can therefore measure weak emission signals adjacent to strong signals. Figure 20-18 shows an actual spectrum as seen by a CID detector.

The spectrometer in Color Plate 25 is purged with $\mathrm{N}_{2}$ or Ar to exclude $\mathrm{O}_{2}$, thereby allowing ultraviolet wavelengths in the $100-200-\mathrm{nm}$ range to be observed. This spectral region permits more sensitive detection of some elements that are normally detected at longer wavelengths and allows halogens, $\mathrm{P}, \mathrm{S}$, and N to be measured (with poor detection limits of tens of

FIGURE 20-18 "Constellation image" of inductively coupled plasma emission from $200 \mu \mathrm{~g} \mathrm{Fe} / \mathrm{mL}$ seen by charge injection detector. Almost all peaks are from iron. Horizontally blurred "galaxies" near the top are Ar plasma emission. A prism spreads wavelengths of $200-400 \mathrm{~nm}$ over most of the detector. Wavelengths $>400 \mathrm{~nm}$ are bunched together at the top. A grating provides high resolution in the horizontal direction. Selected peaks are labeled with wavelength (in nanometers) and diffraction order ( $n$ in Equation 19-1) in parentheses. Two Fe peaks labeled in color at the lower left and lower right are both the same wavelength ( 238.204 nm ) diffracted into different orders by the grating. [Courtesy M. D. Seltzer, Michelson Laboratory, China Lake, CA.]

parts per million). These nonmetallic elements cannot be observed at wavelengths above 200 nm . The photomultiplier spectrometer in Color Plate 24 is more expensive and complicated than the CID spectrometer in Color Plate 25 but provides lower detection limits because a photomultiplier tube is more sensitive than a CID detector.

## Background Correction

Atomic spectroscopy must provide background correction to distinguish analyte signal from absorption, emission, and optical scattering of the sample matrix, the flame, plasma, or redhot graphite furnace. Figure 20-19 shows the spectrum of a sample analyzed in a graphite furnace. Sharp atomic signals with a maximum absorbance near 1.0 are superimposed on a broad background with an absorbance of 0.3 . If we did not subtract the background absorbance, significant errors would result. Background correction is critical for graphite furnaces, which tend to contain residual smoke from charring. Optical scatter from smoke must be distinguished from optical absorption by analyte.

Figure 20-20 shows how background is subtracted in an emission spectrum collected with a charge injection device detector. The figure shows 15 pixels from one row of the detector centered on an analytical peak. (The spectrum is manipulated by a computer algorithm to make it look smooth, even though the original data consist of a single reading for each pixel and would look like a bar graph.) Pixels 7 and 8 were selected to represent the peak. Pixels 1 and 2 represent the baseline at the left and pixels 14 and 15 represent the baseline at the right. The mean baseline is the average of pixels $1,2,14$, and 15 . The mean peak amplitude is the average of pixels 7 and 8 . The corrected peak height is the mean peak amplitude minus the mean baseline amplitude.

For atomic absorption, beam chopping or electrical modulation of the hollow-cathode lamp (pulsing it on and off) can distinguish the signal of the flame from the atomic line at the same wavelength. Figure 20-21 shows light from the lamp being periodically blocked by a rotating chopper. Signal reaching the detector while the beam is blocked must be from flame emission. Signal reaching the detector when the beam is not blocked is from the lamp and the flame. The difference between the two signals is the desired analytical signal.

Beam chopping corrects for flame emission but not for scattering. Most spectrometers provide an additional means to correct for scattering and broad background absorption. Deuterium lamps and Zeeman correction systems are most common.

For deuterium lamp background correction, broad emission from a $\mathrm{D}_{2}$ lamp (Figure 19-4) is passed through the flame in alternation with that from the hollow cathode. The monochromator bandwidth is so wide that a negligible fraction of $\mathrm{D}_{2}$ radiation is absorbed by the analyte atomic absorption line. Light from the hollow-cathode lamp is absorbed by analyte

Dougherty, F. R. Preli, Jr., J. T. McCaffrey, M. D. Seltzer, and R. G. Michel, "Instrumentation for Zeeman Electrothermal Atomizer Laser Excited Atomic Fluorescence Spectrometry," Anal. Chem. 1987, 59, 1112.]

FIGURE 20-23 Measurement of peak-topeak noise level and signal level. The signal is measured from its base at the midpoint of the noise along the slightly slanted baseline. This sample exhibits a signal-to-noise ratio of 2.4.

FIGURE 20-24 Flame, furnace, and inductively coupled plasma emission and inductively coupled plasma-mass spectrometry detection limits ( $\mathrm{ng} / \mathrm{g}=\mathrm{ppb}$ ) with instruments from GBC Scientific Equipment, Australia. Accurate quantitative analysis requires concentrations 10-100 times greater than the detection limit. [Flame, furnace, ICP from R. J. Gill, Am. Lab., November 1993, p. 24F. ICP-MS from T. T. Nham, Am. Lab., August 1998, 17A. Data for Cl, Br, and I are from reference 17.]
and absorbed and scattered by background. Light from the $\mathrm{D}_{2}$ lamp is absorbed and scattered only by background. The difference between absorbance measured with the hollow-cathode lamp and absorbance measured with the $\mathrm{D}_{2}$ lamp is the absorbance of analyte.

An excellent, but expensive, background correction technique for a graphite furnace for many elements relies on the Zeeman effect (pronounced ZAY-mon). When a magnetic field is applied parallel to the light path through a furnace, the absorption (or emission) line of analyte atoms is split into three components. Two are shifted to slightly lower and higher wavelengths (Figure 20-22), and one component is unshifted. The unshifted component does not have the correct electromagnetic polarization to absorb light traveling parallel to the magnetic field and is therefore "invisible."

To use the Zeeman effect for background correction, a strong magnetic field is pulsed on and off. Sample and background are observed when the field is off. Background alone is observed when the field is on. The difference is the corrected signal.

The advantage of Zeeman background correction is that it operates at the analytical wavelength. In contrast, $D_{2}$ background correction is made over a broad band. A structured or sloping background is averaged by this process, potentially misrepresenting the true background signal at the analytical wavelength. Background correction in Figure 20-20 is similar to $D_{2}$ background correction, but the wavelength range in Figure 20-20 is restricted to the immediate vicinity of the analytical peak.

## Detection Limits

One definition of detection limit is the concentration of an element that gives a signal equal to two times the peak-to-peak noise level of the baseline (Figure 20-23). The baseline noise level should be measured for a blank sample. ${ }^{19}$

Figure 20-24 compares detection limits for flame, furnace, and inductively coupled plasma analyses on instruments from one manufacturer. The detection limit for furnaces is typically two orders of magnitude lower than that observed with a flame because the sample is confined in the small volume of the furnace for a relatively long time. For instruments in Figure 20-24, detection limits for the inductively coupled plasma are intermediate between the flame and the furnace. With ultrasonic nebulization and axial plasma viewing, the sensitivity of the inductively coupled plasma is close to that of the graphite furnace.

Commercial standard solutions for flame atomic absorption are not necessarily suitable for plasma and furnace analyses. The latter methods require purer grades of water and acids for standard solutions and, especially, for dilutions. For the most sensitive analyses, solutions are prepared in a dust-free clean room or hood with a filtered air supply to reduce background contamination that will be detected by your instruments.

Any standard solution has a limited shelf life. High-density polyethylene plastic bottles containing standards for atomic spectroscopy are packaged in sealed, aluminized bags to retard evaporation. In one study, the concentration of standard not stored in an aluminized bag increased by $0.11 \%$ per year at $23^{\circ} \mathrm{C}$ and $0.26 \%$ per year at $30^{\circ} \mathrm{C}$ because water evaporated

## 20-5 Interference

Interference is any effect that changes the signal while analyte concentration remains unchanged. Interference can be corrected by removing the source of interference or by preparing standards that exhibit the same interference.

## Types of Interference

Spectral interference refers to the overlap of analyte signal with signals due to other elements or molecules in the sample or with signals due to the flame or furnace. Interference from the flame can be subtracted by using $\mathrm{D}_{2}$ or Zeeman background correction. The best means of dealing with overlap between lines of different elements in the sample is to choose another wavelength for analysis. High-resolution spectrometers eliminate interference from other elements by resolving closely spaced lines (Figure 20-25).

A single element such as Nb gives rise to over 1000 discrete emission lines, so some lines from different elements overlap-even at high resolution. Software in one commercial instrument measures each element from several different spectral lines. ${ }^{21}$ It converts each intensity to a concentration, using a different calibration curve for every line. If there were no spectral interference, all lines for one element would give the same concentration. Results that deviate more than a little from most results are attributed to spectral interference and are discarded.

Elements that form very stable diatomic oxides are incompletely atomized at the temperature of a flame or furnace. The spectrum of a molecule is much broader and more complex than that of an atom, because vibrational and rotational transitions are combined with electronic transitions (Section 17-6). The broad spectrum leads to spectral interference at many wavelengths. Figure 20-26 shows a plasma containing Y and Ba atoms as well as YO molecules. Note how broad the molecular emission is relative to the atomic emission.

When trace impurities in tungsten powder are analyzed by graphite furnace atomic absorption using direct solid sampling (Figure 20-9), $\mathrm{WO}_{3}$ from the surface of the powder sublimes and fills the furnace with vapor, creating spectral interference throughout the visible and ultraviolet regions. Heating the powder under $\mathrm{H}_{2}$ at $1000^{\circ}-1200^{\circ} \mathrm{C}$ in the furnace prior to atomization reduces $\mathrm{WO}_{3}$ to metallic tungsten and eliminates the interference. ${ }^{12}$

Chemical interference is caused by any component of the sample that decreases the extent of atomization of analyte. For example, $\mathrm{SO}_{4}^{2-}$ and $\mathrm{PO}_{4}^{3-}$ hinder the atomization of $\mathrm{Ca}^{2+}$, perhaps by forming nonvolatile salts. Releasing agents are chemicals added to a sample to decrease chemical interference. EDTA and 8-hydroxyquinoline protect $\mathrm{Ca}^{2+}$ from interference by $\mathrm{SO}_{4}^{2-}$ and $\mathrm{PO}_{4}^{3-} . \mathrm{La}^{3+}$ is a releasing agent, apparently because it preferentially reacts with $\mathrm{PO}_{4}^{3-}$ and frees the $\mathrm{Ca}^{2+}$. A fuel-rich flame reduces certain oxidized analyte species that would otherwise hinder atomization. Higher flame temperatures eliminate many kinds of chemical interference.

Ionization interference can be a problem in the analysis of alkali metals at relatively low temperature and in the analyses of other elements at higher temperature. For any element, we can write a gas-phase ionization reaction:

$$
\begin{equation*}
\mathrm{M}(g) \rightleftharpoons \mathrm{M}^{+}(g)+\mathrm{e}^{-}(g) \quad K=\frac{\left[\mathrm{M}^{+}\right]\left[\mathrm{e}^{-}\right]}{[\mathrm{M}]} \tag{20-6}
\end{equation*}
$$

Because alkali metals have low ionization potentials, they are most extensively ionized. At 2450 K and a pressure of 0.1 Pa , sodium is $5 \%$ ionized. With its lower ionization potential, potassium is $33 \%$ ionized. Ions have energy levels different from those of neutral atoms, so the desired signal is decreased. If there is a strong signal from the ion, you could use the ion signal rather than the atomic signal.

An ionization suppressor decreases the extent of ionization of analyte. In the analysis of potassium, it is recommended that solutions contain 1000 ppm of CsCl , because cesium is more easily ionized than potassium. By producing a high concentration of electrons in the flame, ionization of Cs suppresses ionization of K . Ionization suppression is desirable in a low-temperature flame in which we want to observe neutral atoms.

The method of standard addition (Section 5-3) compensates for many types of interference by adding known quantities of analyte to the unknown in its complex matrix. For example, Figure 20-27 shows the analysis of strontium in aquarium water by standard addition. The

## Types of interference:

- spectral: unwanted signals overlapping analyte signal
- chemical: chemical reactions decreasing the concentration of analyte atoms
- ionization: ionization of analyte atoms decreasing the concentration of neutral atoms

FIGURE 20-25 A Cd line at 228.802 nm causes spectral interference with the As line at 228.812 nm in most spectrometers. With sufficiently high resolution, peaks are separated and there is no interference. The instrument used for this spectrum has a 1-m Czerny-Turner monochromator (Figure 19-6) with a resolution of 0.005 nm from 160 to 320 nm and 0.010 nm from 320 to 800 nm. [Courtesy Jobin Yvon Horiba Group, Longjumeau Cedex, France.]

FIGURE 20-26 Emission from a plasma produced by laser irradiation of the hightemperature superconductor $\mathrm{YBa}_{2} \mathrm{Cu}_{3} \mathrm{O}_{7}$. Solid is vaporized by the laser, and excited atoms and molecules such as YO emit light at characteristic wavelengths. [From W. A. Weimer, "Plasma Emission from Laser Ablation of $\mathrm{YBa}_{2} \mathrm{Cu}_{3} \mathrm{O}_{7}$, " Appl. Phys. Lett. 1988, 52, 2171.]

Le Châtelier's principle tells us that adding electrons to the right side of Reaction 20-6 drives the reaction back to the left.

FIGURE 20-27 Atomic absorption calibration curve for Sr added to distilled water and standard addition of Sr to aquarium water. All solutions are made up to a constant volume, so the ordinate is the concentration of added Sr. [Data from L. D. Gilles de Pelichy, C. Adams, and E. T. Smith, "Analysis of Sr in Marine Aquariums by Atomic Absorption Spectroscopy," J. Chem. Ed. 1997, 74, 1192.]

slope of the standard addition curve is 0.0188 absorbance units/ppm. If, instead, Sr is added to distilled water, the slope is 0.0308 absorbance units/ppm. That is, in distilled water, the absorbance increases $0.0308 / 0.0188=1.64$ times more than it does in aquarium water for each addition of standard Sr . We attribute the lower response in aquarium water to interference by other species. The absolute value of the $x$-intercept of the standard addition curve, 7.41 ppm , is a reliable measure of Sr in the aquarium.

## Virtues of the Inductively Coupled Plasma

An inductively coupled argon plasma eliminates many common interferences. ${ }^{22}$ The plasma is twice as hot as a conventional flame, and the residence time of analyte in the plasma is about twice as long. Therefore, atomization is more complete and signal is enhanced. Formation of analyte oxides and hydroxides is negligible. The plasma is remarkably free of background radiation where sample emission is observed $15-35 \mathrm{~mm}$ above the load coil.

Concentrations of excited atoms in the cooler, outer part of the flame are lower than in the warmer, central part of the flame. Emission from the central region is absorbed in the outer region. This self-absorption increases with increasing concentration of analyte and gives nonlinear calibration curves. In a plasma, the temperature is more uniform, and selfabsorption is not nearly so important. Plasma emission calibration curves are linear over five orders of magnitude. In flames and furnaces, the linear range is two orders of magnitude. For inductively coupled plasma-mass spectrometry, the linear range is eight orders of magnitude (Table 20-4).

TABLE 20-4 Comparison of atomic analysis methods

|  | Flame absorption | Furnace absorption | Plasma emission | Plasma-mass spectrometry |

## Sampling by Laser Ablation

At the opening of this chapter, we saw an example of laser ablation-inductively coupled plasma-mass spectrometry ${ }^{23}$ for the analysis of teeth. In laser ablation, a pulsed laser beam is focused onto a microscopic spot on a solid sample, creating an explosion of particles, atoms, electrons, and ions into the gas phase. Most commonly, a Nd:YAG (neodymium-doped yttrium aluminum garnet) laser with a wavelength of $1.064 \mu \mathrm{~m}$ is used. A $10-\mathrm{ns}$ pulse with 10 mJ of energy focused onto a spot diameter of $50 \mu \mathrm{~m}$ delivers a power of $50 \mathrm{GW} / \mathrm{cm}^{2}$. Material is typically removed to a depth of 0.02 to $5 \mu \mathrm{~m}$ by each pulse (Figure 20-28). Each pulse ablates just nanograms of material, making the method almost nondestructive. Ablation product generated in a sealed chamber is swept by Ar or He through a Teflon-coated tube into the plasma for analysis by mass spectrometry or atomic emission. Depth profiling can be done by successive pulses probing deeper and deeper to measure elemental concentrations as a function of depth.

If the plasma is analyzed by observing atomic emission, the method is called laserinduced breakdown spectroscopy. Each laser pulse produces a short-lived plasma with a temperature of 10000 to 20000 K in which material dissociates into excited atoms and ions. Initial optical emission from the plasma is a continuum with little useful information. The plasma expands supersonically and cools to temperatures at which discrete atomic emission lines are observed after $\sim 1-10 \mu \mathrm{~s}$. The detector is gated to record atomic emission several microseconds after the laser pulse. One commercial system observes plasma emission through seven optical fibers directed to seven polychromators, each containing a linear 2 048-pixel charge coupled device to view a different spectral region. Spectral resolution is 0.1 nm over the range $200-980 \mathrm{~nm}$.

A major challenge for quantitative analysis by laser ablation is that elements can be selectively ablated, selectively transported to the plasma, or selectively atomized in the plasma. Therefore, the relative numbers of ions detected are not necessarily equal to relative quantities in the solid sample. The most reliable-but usually unattainable-calibration is a standard sample containing elements of interest in the same matrix as the unknown. Mussel shell in Figure 20-28 is composed principally of $\mathrm{CaCO}_{3}$. A calibration standard was made by dissolving known quantities of metals with a large excess of $\mathrm{Ca}^{2+}$ in acid and precipitating everything with $\mathrm{CO}_{3}^{2-}$. The carbonate precipitate was washed, dried, and pressed into a dense pellet whose ablation behavior is similar to that of mussel shell. In the absence of matrix-matched standards, results from laser ablation can be compared with results obtained by completely digesting a material and analyzing the homogeneous solution. The difficulty of calibration renders laser ablation methods semiquantitative, with accuracies of $\pm 10 \%$ or worse.

## 20-6 Inductively Coupled Plasma-Mass Spectrometry

The ionization energy of Ar is 15.8 electron volts (eV), which is higher than those of all elements except $\mathrm{He}, \mathrm{Ne}$, and F. In an Ar plasma, analyte elements can be ionized by collisions with $\mathrm{Ar}^{+}$, excited Ar atoms, or energetic electrons. The plasma can be directed into a mass spectrometer (Chapter 21), which separates and measures ions according to their mass-to-charge ratio. ${ }^{24}$ For the most accurate measurements of isotope ratios, the mass spectrometer has one detector for each desired isotope. ${ }^{25}$

The trace element profile of teeth at the opening of this chapter was obtained by inductively coupled plasma-mass spectrometry. Figure 20-29 shows an example in which coffee beans were extracted with trace-metal-grade nitric acid and the aqueous extract was analyzed by inductively coupled plasma-mass spectrometry. Coffee brewed from either Hawaiian or Cuban beans contains $\sim 15 \mathrm{ng} \mathrm{Pb} / \mathrm{mL}$. However, the Cuban beans also contain Hg at a concentration similar to that of Pb .

The difficulty in sampling anything with a mass spectrometer is that the spectrometer requires high vacuum to avoid collisions between ions and background gas molecules that divert the ions from their trajectory in a magnetic field. Figure 20-30 shows an interface between a horizontal Ar plasma and a mass spectrometer. The plasma at the left is directed onto a water-cooled Ni sampling cone with a 1-mm-diameter orifice through which a fraction of the plasma can pass. Behind the sampling cone is a water-cooled skimmer cone with an even smaller orifice. The extraction lens behind the skimmer cone has a high negative potential to attract positive ions from the plasma. Pressure is reduced in each successive section of the instrument. From the skimmer cone, ions enter a collision cell that might contain $\mathrm{H}_{2}$ or He or both. The collision cell guides ions to the entrance of the mass separator and reduces the

FIGURE 20-28 Microscopic crater ablated into a mussel shell by 10 pulses from a $266-\mathrm{nm}$ laser with a beam energy of 4.5 mJ per $10-\mathrm{ns}$ pulse and a repetition rate of 10 Hz . [From V. R. Bellotto and N. Miekely, "Improvements in Calibration Procedures for the Quantitative Determination of Trace Elements in Carbonate Material (Mussel Shells) by Laser Ablation ICP-MS," Fresenius J. Anal. Chem. 2000, 367, 635.]

FIGURE 20-29 Partial elemental profile of coffee beans by inductively coupled plasma-mass spectrometry. The Cuban beans have a much higher Hg content than the Hawaiian beans. A blank has not been subtracted from either spectrum, so the small amount of Hg in the upper spectrum could be in the blank. [Courtesy G. S. Ostrom and M. D. Seltzer, Michelson Laboratory, China Lake, CA.]

spread of ion kinetic energies by a factor of 10 . Following the collision cell, ions are separated by a mass spectrometer. Ions of selected mass-to-charge ratio are deflected into the detector (at the right of the diagram), where they are counted. Photons from the plasma do not hit the detector, or they would generate a signal.

Part per trillion detection limits for inductively coupled plasma-mass spectrometry are so low (Figure 20-24 and Table 20-2) as to tax the cleanliness of reagents, glassware, and procedures. Solutions must be made from extremely pure water and trace-metal-grade $\mathrm{HNO}_{3}$ in Teflon or polyethylene vessels protected from dust. HCl and $\mathrm{H}_{2} \mathrm{SO}_{4}$ are avoided because they create isobaric interferences discussed below. The plasma-mass spectrometer interface cannot tolerate high concentrations of dissolved solids that clog the orifice of the sampling cone. The plasma reduces organic matter to carbon that can clog the orifice. Organic material can be analyzed if some $\mathrm{O}_{2}$ is fed into the plasma to oxidize the carbon.

Matrix effects on the yield of ions in the plasma are important, so calibration standards should be in the same matrix as the unknown. Standard addition is highly appropriate to correct for matrix effects. For example, when trace elements in blood were measured by inductively coupled plasma-mass spectrometry, matrix interference produced values for ${ }^{75} \mathrm{As}^{+}$and ${ }^{78} \mathrm{Se}^{+}$

FIGURE 20-30 Interface between inductively coupled plasma and mass spectrometer. [Courtesy TJA Solutions, Franklin, MA.] Chapter 21 discusses mass spectrometry.
that were almost a factor of 2 above certified values for standard reference materials. ${ }^{26}$ Calibration by standard addition reduced the errors to $0-4 \%$.

Alternatively, internal standards can be used if they have nearly the same ionization energy as the analyte. For example, Tm can be used as an internal standard for U. The ionization energies of these two elements are 5.81 and 6.08 eV , respectively, so they should ionize to nearly the same extent in different matrices. If possible, internal standards with just one major isotope should be selected for maximum response.

## Isobaric Interference

Ar is an "inert" gas with virtually no chemistry. However, $\mathrm{Ar}^{+}$has the same electronic configuration as Cl , and their chemistry is analogous. The inductively couple plasma is a rich source of $\mathrm{Ar}^{+}$and ions such as $\mathrm{ArH}^{+}, \mathrm{ArC}^{+}, \mathrm{ArN}^{+}, \mathrm{ArNH}^{+}, \mathrm{ArO}^{+}, \mathrm{ArCl}^{+}$, and $\mathrm{Ar}_{2}^{+}$. These ions interfere with the measurement of analyte ions of the same mass-to-charge ratio.

For example, ${ }^{40} \mathrm{Ar}^{16} \mathrm{O}^{+}$has nearly the same mass as ${ }^{56} \mathrm{Fe}^{+}$, and ${ }^{40} \mathrm{Ar}_{2}^{+}$has nearly the same mass as ${ }^{80} \mathrm{Se}^{+}$. Interference by ions of similar mass-to-charge ratio is called isobaric interference. Doubly ionized ${ }^{138} \mathrm{Ba}^{2+}$ interferes with ${ }^{69} \mathrm{Ga}^{+}$because each has nearly the same mass-to-charge ratio $(138 / 2=69 / 1)$. High-resolution mass spectrometers ${ }^{27}$ eliminate interference by resolving species such as ${ }^{40} \mathrm{Ar}^{16} \mathrm{O}^{+}$and ${ }^{56} \mathrm{Fe}^{+}$, which differ by 0.02 atomic mass units, but most systems do not have high resolution.

For elements with multiple isotopes, you can check for isobaric interference by measuring isotope ratios. For example, if the ratio of Se isotopes agrees with those found in nature ( ${ }^{74} \mathrm{Se}:{ }^{76} \mathrm{Se}:{ }^{77} \mathrm{Se}:{ }^{.78} \mathrm{Se}:{ }^{80} \mathrm{Se}:{ }^{82} \mathrm{Se}=0.008$ 7:0.090:0.078:0.235:0.498:0.092), then it is unlikely that there is interference at any of these masses.

In the collision cell in Figure 20-30, collisions of high-velocity ions such as $\mathrm{ArO}^{+}$with $\mathrm{H}_{2}$ or He redistribute the kinetic energy of the ion into vibrational energy, which can cause $\mathrm{ArO}^{+}$to dissociate. Endothermic bond breaking derives its energy from the initial kinetic energy (the high velocity) of $\mathrm{ArO}^{+}$. However, the concentration of $\mathrm{ArO}^{+}$is not sufficiently reduced to eliminate isobaric interference.

A dynamic reaction cell, which can replace the collision cell in Figure 20-30, uses thermodynamically favorable reactions to reduce isobaric interference. ${ }^{29}$ The dynamic reaction cell contains a reactive gas such as $\mathrm{NH}_{3}, \mathrm{CH}_{4}, \mathrm{~N}_{2} \mathrm{O}, \mathrm{CO}$, or $\mathrm{O}_{2}$, and its electric field is configured to select lower and upper masses of ions to pass through the cell. Plasma species that
$\mathrm{Ar}^{+}$is similar to Cl in its chemical reactivity.

Box 20-2 gives an important environmental application of the dynamic reaction cell.

## BOX 20-2 GEOTRACES

A carousel of 12-L plastic bottles lowered on a Kevlar line from a research vessel is used to collect ocean water without introducing trace metal contamination during collection. Samples are removed from the bottles in a plastic-lined clean room inside a cargo container on the deck of the ship. [Courtesy Gregory A. Cutter, Old Dominion University, Norfolk, VA.]

GEOTRACES is an international program to characterize geographic and depth distributions of trace metals and their isotopes including $\mathrm{Al}, \mathrm{Mn}, \mathrm{Fe}, \mathrm{Cu}, \mathrm{Zn}, \mathrm{Cd}$, and a host of other elements at part per trillion levels $(\mathrm{ng} / \mathrm{kg})$ in ocean water around the globe. The goal is to establish a baseline and then monitor responses to changing environmental conditions such as global warming and ocean acidification, as well as reveal the chemical and biological processes affecting trace metals. Models suggest that Fe is a growth-limiting nutrient in the ocean, Al is a tracer for mineral dust, and Mn responds to redox processes. Measuring part per trillion levels requires preconcentration of the elements from seawater, described in Section $25-1 .{ }^{28}{ }^{55} \mathrm{Mn},{ }^{54} \mathrm{Fe}$, and ${ }^{56} \mathrm{Fe}$ are affected by isobaric interference from ${ }^{40} \mathrm{Ar}^{14} \mathrm{NH}^{+},{ }^{40} \mathrm{Ar}^{14} \mathrm{~N}^{+}$, and ${ }^{40} \mathrm{Ar}^{16} \mathrm{O}^{+}$in inductively coupled plasma-mass spectrometry analysis. Therefore, a dynamic reaction cell with $\mathrm{NH}_{3}$ gas is turned on for the analysis of Mn and Fe and then turned off for the analysis of other trace metals in the same sample. Detection limits for $\mathrm{Al}, \mathrm{Mn}, \mathrm{Fe}, \mathrm{Co}, \mathrm{Ni}, \mathrm{Cu}, \mathrm{Zn}, \mathrm{Cd}$, and Pb range from 0.1 to $7 \mathrm{ng} / \mathrm{kg}$. Concentrations of these metals in the open ocean range from $1 \mathrm{ng} / \mathrm{kg}$ for Co to $500 \mathrm{ng} / \mathrm{kg}$ for Ni . Another means used to overcome isobaric interference is to employ high resolution mass spectrometry.
interfere with some elements can be reduced by as many as nine orders of magnitude by reactions such as

Electron transfer from $\mathrm{NH}_{3}$ :

$$
\begin{array}{ll}
{ }^{40} \mathrm{Ar}^{+}+\mathrm{NH}_{3} \rightarrow \mathrm{NH}_{3}^{+}+\mathrm{Ar} & { }^{40} \mathrm{Ar}^{14} \mathrm{~N}^{+}+\mathrm{NH}_{3} \rightarrow \mathrm{NH}_{3}^{+}+\mathrm{Ar}+\mathrm{N} \\
{ }^{40} \mathrm{Ar}^{12} \mathrm{C}^{+}+\mathrm{NH}_{3} \rightarrow \mathrm{NH}_{3}^{+}+\mathrm{Ar}+\mathrm{C} & { }^{40} \mathrm{Ar}^{16} \mathrm{O}^{+}+\mathrm{NH}_{3} \rightarrow \mathrm{NH}_{3}^{+}+\mathrm{Ar}+\mathrm{O}
\end{array}
$$

Proton transfer to $\mathrm{NH}_{3}$ :

$$
\begin{array}{ll}
{ }^{40} \mathrm{ArH}^{+}+\mathrm{NH}_{3} \rightarrow \mathrm{NH}_{4}^{+}+\mathrm{Ar} & { }^{35,37} \mathrm{Cl}^{16} \mathrm{OH}^{+}+\mathrm{NH}_{3} \rightarrow \mathrm{NH}_{4}^{+}+\mathrm{ClO} \\
{ }^{40} \mathrm{Ar}^{14} \mathrm{NH}^{+}+\mathrm{NH}_{3} \rightarrow \mathrm{NH}_{4}^{+}+\mathrm{Ar}+\mathrm{N} &
\end{array}
$$

For example, ${ }^{40} \mathrm{Ar}^{12} \mathrm{C}^{+}$interferes with ${ }^{52} \mathrm{Cr}^{+}$and ${ }^{35} \mathrm{Cl}^{17} \mathrm{OH}^{+}$interferes with ${ }^{53} \mathrm{Cr}^{+}$. A dynamic reaction cell with $\mathrm{NH}_{3}$ permits the measurement of Cr by removing $\mathrm{ArC}^{+}$and $\mathrm{ClOH}^{+} .{ }^{40} \mathrm{Ar}^{16} \mathrm{O}^{+}$interferes with ${ }^{56} \mathrm{Fe}^{+}$. Either $\mathrm{ArO}^{+}$can be removed by reaction with $\mathrm{NH}_{3}$ or $\mathrm{Fe}^{+}$can be shifted to a different mass by reaction with $\mathrm{N}_{2} \mathrm{O}$ :

$$
\mathrm{Fe}^{+}+\mathrm{N}_{2} \mathrm{O} \rightarrow \mathrm{FeO}^{+}+\mathrm{N}_{2}
$$

In natural waters with traces of iron and high concentrations of calcium, ${ }^{40} \mathrm{Ca}^{16} \mathrm{O}^{+}$interferes with ${ }^{56} \mathrm{Fe}^{+}$. $\mathrm{CaO}^{+}$can be removed by reaction with CO :

$$
\mathrm{CaO}^{+}+\mathrm{CO} \rightarrow \mathrm{Ca}^{+}+\mathrm{CO}_{2}
$$

## Summary

In atomic spectroscopy, absorption, emission, or fluorescence from gaseous atoms is measured. Liquids may be atomized by a plasma, a furnace, or a flame. Flame temperatures are usually in the range $2300-3400 \mathrm{~K}$. The choice of fuel and oxidant determines the temperature of the flame and affects the extent of spectral, chemical, or ionization interference that will be encountered. Temperature instability affects atomization in atomic absorption and has an even larger effect on atomic emission, because the excited-state population is exponentially sensitive to temperature. An electrically heated graphite furnace requires less sample than a flame and has a lower detection limit. In an inductively coupled plasma, a radio-frequency induction coil heats $\mathrm{Ar}^{+}$ions to $6000-10000 \mathrm{~K}$. At this high temperature, emission is observed from electronically excited atoms and ions. There is little chemical interference in an inductively coupled plasma, the temperature is very stable, and little self-absorption is observed.

Plasma emission spectroscopy does not require a light source and is capable of measuring $\sim 70$ elements simultaneously with a charge injection device detector. Background correction for a given emission peak is based on subtracting the intensity of neighboring pixels in the detector. The lowest detection limits are obtained by directing the plasma into a mass spectrometer that separates and measures ions from the plasma. In flame and furnace atomic absorption spectroscopy, a hollow-cathode lamp made of the analyte element provides spectral lines sharper than those of the atomic vapor. The inherent linewidth of atomic lines is limited by the Heisenberg
uncertainty principle. Lines in a flame, furnace, or plasma are broadened by a factor of $10-100$ by the Doppler effect and by atomic collisions. Correction for background emission from the flame is possible by electrically pulsing the lamp on and off or mechanically chopping the beam. Light scattering and spectral background can be subtracted by measuring absorption with a deuterium lamp or by Zeeman background correction, in which the atomic energy levels are alternately shifted in and out of resonance with the lamp frequency by a magnetic field. Chemical interference can be reduced by addition of releasing agents, which prevent the analyte from reacting with interfering species. Ionization interference in flames is suppressed by adding easily ionized elements such as Cs.

In inductively coupled plasma-mass spectrometry, isobaric interference occurs between species with the same mass and charge. Interference can be eliminated if mass spectral resolution is sufficiently great, but this is not often the case. A dynamic reaction cell reduces isobaric interference by using an exothermic reaction of a gas such as $\mathrm{NH}_{3}, \mathrm{~N}_{2} \mathrm{O}$, or CO to remove interfering molecular ions such as $\mathrm{ArO}^{+}$or to transform analyte into a molecular ion that can be measured without interference.

For qualitative and semiquantitative analysis, solids and liquids can be sampled by laser ablation. Ablated material can be swept through an inductively coupled plasma into a mass spectrometer. In laser-induced breakdown spectroscopy, plasma emission is used to quantify elements. Matrix-matched standards are necessary for semiquantitative analysis.

20-A. Li was determined by atomic emission with the method of standard addition. Prepare a standard addition graph (Section 5-3) to find the concentration of Li and its uncertainty in pure unknown. The Li standard contained $1.62 \mu \mathrm{~g} \mathrm{Li} / \mathrm{mL}$.

| Unknown <br> $(\mathrm{mL})$ | Standard <br> $(\mathrm{mL})$ | Final volume <br> $(\mathrm{mL})$ | Emission <br> intensity <br> (arbitrary units) |
| :--- | :---: | :--- | :--- |
| 10.00 | 0.00 | 100.0 | 309 |
| 10.00 | 5.00 | 100.0 | 452 |
| 10.00 | 10.00 | 100.0 | 600 |
| 10.00 | 15.00 | 100.0 | 765 |
| 10.00 | 20.00 | 100.0 | 906 |

20-B. Mn was used as an internal standard for measuring Fe by atomic absorption. A standard mixture containing $2.00 \mu \mathrm{~g} \mathrm{Mn} / \mathrm{mL}$ and $2.50 \mu \mathrm{~g} \mathrm{Fe} / \mathrm{mL}$ gave a quotient ( Fe signal/Mn signal) $=$ 1.05/1.00. A mixture with a volume of 6.00 mL was prepared by mixing 5.00 mL of unknown Fe solution with 1.00 mL containing $13.5 \mu \mathrm{~g} \mathrm{Mn} / \mathrm{mL}$. The absorbance of this mixture at the Mn wavelength was 0.128 , and the absorbance at the Fe wavelength was 0.185 . Find the molarity of the unknown Fe solution.

20-C. (a) The atomic absorption signal shown here was obtained with $0.0485 \mu \mathrm{~g} \mathrm{Fe} / \mathrm{mL}$ in a graphite furnace. Estimate the detection limit for Fe , defined for this problem as the concentration of Fe that gives a signal-to-noise ratio of 2 .

(b) Seven replicate measurements of a standard containing 1.00 ng $\mathrm{Hg} / \mathrm{L}$ gave readings of $0.88,1.48,0.94,1.12,1.03,1.40$, and $1.14 \mathrm{ng} / \mathrm{L}$ in cold vapor atomic absorption (Box 20-1). From Equations 5-5 and 5-6, estimate the detection and quantitation limits. (Note that in Equations 5-5 and 5-6, the quotient $s / m$ is the standard deviation in concentration.)

20-D. The measurement of Li in brine (salt water) is used by geochemists to help determine the origin of this fluid in oil fields. Flame atomic emission and absorption of Li are subject to interference by scattering, ionization, and overlapping spectral emission from other elements. Atomic absorption analysis of replicate samples of a marine sediment gave results in the table

| Sample and <br> treatment | Li found <br> $(\mu \mathrm{g} / \mathrm{g})$ | Analytical <br> method | Flame <br> type |
| :--- | :--- | :--- | :--- |
| 1. None <br> 2. Dilute to $1 / 10$ <br> with $\mathrm{H}_{2} \mathrm{O}$ | 25.1 | standard curve | air/ $\mathrm{C}_{2} \mathrm{H}_{2}$ |
| 3. Dilute to $1 / 10$ <br> with $\mathrm{H}_{2} \mathrm{O}$ | 84.8 | standard curve | air/ $\mathrm{C}_{2} \mathrm{H}_{2}$ |
| 4. None | 77.3 | standard addition | air/ $\mathrm{C}_{2} \mathrm{H}_{2}$ |
| 5. Dilute to $1 / 10$ <br> with $\mathrm{H}_{2} \mathrm{O}$ | 79.6 | standard curve curve | $\mathrm{N}_{2} \mathrm{O} / \mathrm{C}_{2} \mathrm{H}_{2}$ |
| 6. Dilute to $1 / 10$ <br> with $\mathrm{H}_{2} \mathrm{O}$ | 80.4 | standard addition | $\mathrm{N}_{2} \mathrm{O} / \mathrm{C}_{2} \mathrm{H}_{2} \mathrm{O} / \mathrm{C}_{2} \mathrm{H}_{2}$ |

(a) Suggest a reason for the increasing apparent concentration of Li in samples 1 through 3.
(b) Why do samples 4 through 6 give an almost constant result?
(c) What value would you recommend for reporting the real concentration of Li in the sample?

## Problems

Techniques of Atomic Spectroscopy
20-1. In which technique, atomic absorption or atomic emission, is flame temperature stability more critical? Why?

20-2. State the advantages and disadvantages of a furnace compared with a flame in atomic absorption spectroscopy.

20-3. Figure 20-10 shows a temperature profile for a furnace atomic absorption experiment. Explain the purpose of each different part of the heating profile.

20-4. State the advantages and disadvantages of the inductively coupled plasma compared with a flame in atomic spectroscopy.
20-5. Explain what is meant by the Doppler effect. Rationalize why Doppler broadening increases with increasing temperature and decreasing mass in Equation 20-5.

20-6. Explain how the following background correction techniques work: (a) beam chopping; (b) deuterium lamp; (c) Zeeman.

20-7. Explain what is meant by spectral, chemical, ionization, and isobaric interference.

20-8. Bone consists of the protein collagen and the mineral hydroxyapatite, $\mathrm{Ca}_{10}\left(\mathrm{PO}_{4}\right)_{6}(\mathrm{OH})_{2}$. The Pb content of archaeological human skeletons measured by graphite furnace atomic absorption sheds light on customs and economic status of individuals in historical times. ${ }^{30}$ Explain why $\mathrm{La}^{3+}$ is added to bone samples to suppress matrix interference in Pb analysis.

20-9. (a) Explain the purpose of the collision cell in Figure 20-30.
(b) Explain the purpose of a dynamic reaction cell, which can replace the collision cell.
(c) In geologic strontium isotopic analysis, there is isobaric interference between ${ }^{87} \mathrm{Rb}^{+}$and ${ }^{87} \mathrm{Sr}^{+}$. A collision cell with $\mathrm{CH}_{3} \mathrm{~F}$ converts $\mathrm{Sr}^{+}$to $\mathrm{SrF}^{+}$but does not convert $\mathrm{Rb}^{+}$to $\mathrm{RbF}^{+}$. How does this reaction eliminate interference?

20-10. What is the purpose of a matrix-matched standard in laserinduced breakdown spectroscopy?
20-11. Laser atomic fluorescence excitation and emission spectra of sodium in an air-acetylene flame are shown here. In the excitation spectrum, the laser (bandwidth $=0.03 \mathrm{~nm}$ ) was scanned through various wavelengths, while the detector monochromator (bandwidth $=$ 1.6 nm ) was held fixed near 589 nm . In the emission spectrum, the laser was fixed at 589.0 nm , and the detector monochromator wavelength was varied. Explain why the emission spectrum gives one broad band, whereas the excitation spectrum gives two sharp lines. How can the excitation linewidths be much narrower than the detector monochromator bandwidth?

(a)

Fluorescence excitation and emission spectra of the two sodium $D$ lines in an air-acetylene flame. (a) In the excitation spectrum, the laser was scanned. (b) In the emission spectrum, the monochromator was scanned. The monochromator slit width was the same for both spectra. [From S. J. Weeks, H. Haraguchi, and J. D. Winefordner, "Improvement of Detection Limits in Laser-Excited Atomic Fluorescence Flame Spectrometry," Anal. Chem. 1978, 50, 360.]

20-12. Concentrations ( pg per g of snow) of metals by atomic fluorescence in the Agassiz Ice Cap in Greenland for the period 1988-1992 $\operatorname{are}^{31} \mathrm{~Pb}, 1.0_{4}\left( \pm 0.1_{7}\right) \times 10^{2} ; \mathrm{Tl}, 0.43 \pm 0.08_{7} ; \mathrm{Cd}, 3.5 \pm 0.8_{7}$; $\mathrm{Zn}, 1.7_{4}\left( \pm 0.2_{6}\right) \times 10^{2}$; and $\mathrm{Al}, 6.1( \pm 1.7) \times 10^{3}$. The mean annual snowfall was $11.5 \mathrm{~g} / \mathrm{cm}^{2}$. Calculate the mean annual flux of each metal in units of $\mathrm{ng} / \mathrm{cm}^{2}$. Flux means how much metal falls on each $\mathrm{cm}^{2}$.
20-13. Calculate the emission wavelength (nm) of excited atoms that lie $3.371 \times 10^{-19} \mathrm{~J}$ per molecule above the ground state.
20-14. Derive the entries for 500 nm in Table 20-3. Find $N^{*} / N_{0}$ at 6000 K if $g^{*}=3$ and $g_{0}=1$ ?

20-15. Calculate the Doppler linewidth for the $589-\mathrm{nm}$ line of Na and for the $254-\mathrm{nm}$ line of Hg , both at 2000 K .

20-16. The first excited state of Ca is reached by absorption of $422.7-\mathrm{nm}$ light.
(a) Find the energy difference $(\mathrm{kJ} / \mathrm{mol})$ between ground and excited states.
(b) The degeneracies are $g^{*} / g_{0}=3$ for Ca . Find $N^{*} / N_{0}$ at 2500 K .
(c) By what percentage will $N^{*} / N_{0}$ change with a $15-\mathrm{K}$ rise in temperature?
(d) Find $N^{*} / N_{0}$ at 6000 K .

20-17. An electron volt ( eV ) is the energy change of an electron moved through a potential difference of 1 volt: $\mathrm{eV}=(1.602 \times$ $\left.10^{-19} \mathrm{C}\right)(1 \mathrm{~V})=1.602 \times 10^{-19} \mathrm{~J}$ per electron $=96.49 \mathrm{KJ}$ per mole of electrons. Use the Boltzmann distribution to fill in the table and explain why Br is not readily observed in atomic absorption or atomic emission.

|  | Na | Cu | Br |
| :--- | :--- | :--- | :--- |
| Excited-state energy $(\mathrm{eV})$ <br> Wavelength $(\mathrm{nm})$ <br> Degeneracy ratio $\left(g^{*} / g_{0}\right)$ <br> 2.10 | 3.78 | 8.04 |  |
|  | 3 | 3 | $2 / 3$ |

$N^{*} / N_{0}$ at 2600 K in flame
$N^{*} / N_{0}$ at 6000 K in plasma
20-18. MgO prevents premature evaporation of Al in a furnace by maintaining the aluminum as $\mathrm{Al}_{2} \mathrm{O}_{3}$. Another type of matrix modifier prevents loss of signal from the atom X that readily forms the molecular carbide XC in a graphite furnace (a source of carbon). For example, adding yttrium to a sample containing barium increases the Ba signal by $30 \%$. The bond dissociation energy of YC is greater than that of BaC . Explain what is happening to increase the Ba signal.

20-19. The $20-\mu$ m-radius laser ablation pit in Figure 20-28 was created by a laser pulse with a duration of 10 ns and an energy of 2.4 mJ . Express the laser power density in units of $\mathrm{W} / \mathrm{cm}^{2}$. Recall that $1 \mathrm{~W}=1 \mathrm{~J} / \mathrm{s}$. If the depth of the pit is $1 \mu \mathrm{~m}$ and the density of the material is $4 \mathrm{~g} / \mathrm{mL}$, how much mass is removed by one pulse?

## Quantitative Analysis by Atomic Spectroscopy

20-20. Why is an internal standard most appropriate for quantitative analysis when unavoidable sample losses are expected during sample preparation?
20-21. Standard addition. To measure Ca in breakfast cereal, 0.5216 g of crushed Cheerios was ashed in a crucible at $600^{\circ} \mathrm{C}$ in air for $2 \mathrm{~h} .{ }^{32}$ The residue was dissolved in 6 M HCl , quantitatively transferred to a volumetric flask, and diluted to 100.0 mL . Then $5.00-\mathrm{mL}$ aliquots were transferred to $50-\mathrm{mL}$ volumetric flasks. Each was treated with standard $\mathrm{Ca}^{2+}$ (containing $20.0 \mu \mathrm{~g} / \mathrm{mL}$ ), diluted to volume with $\mathrm{H}_{2} \mathrm{O}$, and analyzed by flame atomic absorption. Construct a standard addition graph and use the method of least squares to find the $x$-intercept and its uncertainty. Find wt $\% \mathrm{Ca}$ in Cheerios and its uncertainty.

| $\mathrm{Ca}^{2+}$ <br> $(\mathrm{mL})$ standard | Absorbance | $\mathrm{Ca}^{2+}$ standard <br> $(\mathrm{mL})$ | Absorbance |
| :--- | :--- | :---: | :--- |
| 0 | 0.151 | 8.00 | 0.388 |
| 1.00 | 0.185 | 10.00 | 0.445 |
| 3.00 | 0.247 | 15.00 | 0.572 |
| 5.00 | 0.300 | 20.00 | 0.723 |

20-22. Internal standard. A solution was prepared by mixing 10.00 mL of unknown (X) with 5.00 mL of standard (S) containing $8.24 \mu \mathrm{~g}$ $\mathrm{S} / \mathrm{mL}$ and diluting the mixture to 50.0 mL . The measured signal quotient was (signal due to $\mathrm{X} /$ signal due to S ) $=1.690 / 1.000$.
(a) In a separate experiment, in which the concentrations of X and S were equal, the quotient was (signal due to $\mathrm{X} /$ signal due to S ) $=$ $0.930 / 1.000$. What is the concentration of X in the unknown?
(b) Answer the same question if, in a separate experiment in which the concentration of X was 3.42 times the concentration of S , the quotient was (signal due to $\mathrm{X} /$ signal due to S ) $=0.930 / 1.000$.

20-23. 张 Potassium standards gave the following emission intensities at 404.3 nm . Emission from the unknown was 417. Find $\left[\mathrm{K}^{+}\right]$and its uncertainty in the unknown.

| Sample ( $\mu \mathrm{g} \mathrm{K} / \mathrm{mL}$ ): | 0 | 5.00 | 10.00 | 20.00 | 30.00 |
| :--- | :--- | ---: | ---: | ---: | ---: |
| Relative emission: | 0 | 124 | 243 | 486 | 712 |

20-24. Quality assurance. Tin is leached (dissolved) into canned foods from the tin-plated steel can. ${ }^{33}$ For analysis by inductively coupled plasma-atomic emission, food is digested by microwave heating in a Teflon bomb (Figure 27-7) in three steps with $\mathrm{HNO}_{3}$, $\mathrm{H}_{2} \mathrm{O}_{2}$, and HCl .
(a) CsCl is added to the final solution at a concentration of $1 \mathrm{~g} / \mathrm{L}$. What is the purpose of the CsCl ?
(b) Calibration data are shown in the table. Find the slope and intercept and their standard deviations and $R^{2}$, which is a measure of the goodness of fit of the data to a line. Draw the calibration curve.

| Sn $(\mu \mathrm{g} / \mathrm{L})$ | Emission <br> at 189.927 nm | Sn $(\mu \mathrm{g} / \mathrm{L})$ | Emission <br> at 189.927 nm |
| :--- | :--- | :---: | :---: |
| 0 | 4.0 | 40.0 | 31.1 |
| 10.0 | 8.5 | 60.0 | 41.7 |
| 20.0 | 19.6 | 100.0 | 78.8 |
| 30.0 | 23.6 | 200.0 | 159.1 |

(c) Interference by high concentrations of other elements was assessed at different emission lines of Sn. Foods containing little tin were digested and spiked with Sn at $100.0 \mu \mathrm{~g} / \mathrm{L}$. Then other elements were deliberately added. The table shows selected results. Which elements interfere at each of the two wavelengths? Which wavelength is preferred for the analysis?

| Element added <br> at $50 \mathrm{mg} / \mathrm{L}$ | Sn found $(\mu \mathrm{g} / \mathrm{L})$ <br> with $189.927-\mathrm{nm}$ <br> emission line | Sn found $(\mu \mathrm{g} / \mathrm{L})$ <br> with $235.485-\mathrm{nm}$ <br> emission line |
| :--- | :--- | :--- |
| None | 100.0 | 100.0 |
| Ca | 96.4 | 104.2 |
| Mg | 98.9 | 92.6 |
| P | 106.7 | 104.6 |
| Si | 105.7 | 102.9 |
| Cu | 100.9 | 116.2 |
| Fe | 103.3 | intense emission |
| Mn | 99.5 | 126.3 |
| Zn | 105.3 | 112.8 |
| Cr | 102.8 | 76.4 |

(d) Limits of detection and quantitation. The slope of the calibration curve in part (b) is 0.782 units per ( $\mu \mathrm{g} / \mathrm{L}$ ) of Sn . Food containing little Sn gave a mean signal of 5.1 units for seven replicates. Food spiked with $30.0 \mu \mathrm{~g} \mathrm{Sn} / \mathrm{L}$ gave a mean signal of 29.3 units with a standard deviation of 2.4 units for seven replicates. Use Equations 5-5 and 5-6 to estimate the limits of detection and quantitation.
(e) A $2.0-\mathrm{g}$ food sample was digested and eventually diluted to 50 mL for analysis. Express the limit of quantitation from part (d) in terms of $\mathrm{mg} \mathrm{Sn} / \mathrm{kg}$ food.
20-25. Titanocene dichloride, $\left(\pi-\mathrm{C}_{5} \mathrm{H}_{5}\right)_{2} \mathrm{TiCl}_{2}$, is a potential antitumor drug thought to be carried to cancer cells by the protein transferrin (Figure 17-7). To measure the $\mathrm{Ti}(\mathrm{IV})$ binding capacity of transferrin, the protein was treated with excess titanocene dichloride. After allowing time for $\mathrm{Ti}(\mathrm{IV})$ binding to the protein, excess small molecules were removed by dialysis (Demonstration 26-1). The protein was then digested with $2 \mathrm{M} \mathrm{NH}_{3}$ and used to prepare a series of solutions with standard additions for chemical analysis. All solutions were made to the same total volume. Titanium and sulfur in each solution were measured by inductively coupled plasma-atomic emission spectrometry, with results in the table Each transferrin molecule contains 39 sulfur atoms. Find the molar ratio Ti/transferrin in the protein.

| Added Ti <br> $(\mathrm{mg} / \mathrm{L})$ | ICP-AES <br> signal | Added S <br> $(\mathrm{mg} / \mathrm{L})$ | ICP-AES <br> signal |
| :--- | :--- | :---: | :--- |
| 0 | 0.86 | 0 | 0.0174 |
| 3.00 | 1.10 | 37.0 | 0.0221 |
| 6.00 | 1.34 | 74.0 | 0.0268 |
| 12.0 | 1.82 | 148.0 | 0.0362 |

Data derived from A. Cardona and E. Meléndez, "Determination of the Titanium Content of Human Transferrin by Inductively-Coupled Plasma-Atomic-Emission Spectroscopy," Anal. Bioanal. Chem. 2006, 386, 1689.

## DROPLET ELECTROSPRAY

Deflection and disintegration of liquid droplets falling past a wire held at +6000 V . [From D. B. Hager and N. J. Dovichi, "Behavior of Microscopic Liquid Droplets Near a Strong Electrostatic Field: Droplet Electrospray," Anal. Chem. 1994, 66, 1593. See also D. B. Hager, N. J. Dovichi, J. Klassen, and P. Kebarle, "Droplet Electrospray Mass Spectrometry," Anal. Chem. 1994, 66, 3944.]

One method for expelling charged protein molecules into the gas phase for mass spectrometry is called electrospray. In the experiment shown here, droplets of acetone with a diameter of $16 \mu \mathrm{~m}$ fall past a Pt wire held at +6000 V with respect to the nozzle from which the droplets came. High voltage creates a glowing electric corona discharge (a plasma containing electrons and positive ions) around the wire, but the discharge is not visible in this photograph. Droplets falling through the discharge become positively charged and are repelled by the wire, thus deflecting their path to the right. When positively charged droplets come close to the wire, we see a fine stream of liquid jetting away from the positively charged wire. Microscopic droplets in the fine spray rapidly evaporate. If the liquid had been an aqueous protein solution, the water would evaporate, thereby leaving charged protein molecules in the gas phase.

Francis W. Aston (1877-1945) developed a "mass spectrograph" in 1919 that could separate ions differing in mass by $1 \%$ and focus them onto a photographic plate. Aston immediately found that neon consists of two isotopes $\left({ }^{20} \mathrm{Ne}\right.$ and $\left.{ }^{22} \mathrm{Ne}\right)$ and went on to discover 212 of the 281 naturally occurring isotopes. He received the Nobel Prize for chemistry in 1922.
ass spectrometry has long been used to measure isotopes and decipher organic structures. Hydrogen and oxygen isotopes in ice cores record the history of Earth's climate (Figure $0-6$ ). The constancy of the ${ }^{18} \mathrm{O} /{ }^{16} \mathrm{O}$ ratio in certain dinosaur bones strongly suggests that these species were warm blooded. ${ }^{1}$ Mass spectrometry can elucidate the amino acid sequence in a protein, ${ }^{2}$ the sequence of nucleic acids in DNA, the structure of a complex carbohydrate, and the types of lipids in a single organism. Mass spectrometry can measure masses of individual cells ${ }^{3}$ and viruses. ${ }^{4}$ Mass spectrometry is the most powerful detector for chromatography, offering both qualitative and quantitative information, providing high sensitivity, and distinguishing different substances with the same retention time.

## 21-1 What Is Mass Spectrometry?

Mass spectrometry is a technique for studying the masses of atoms or molecules or fragments of molecules. ${ }^{5,6}$ To obtain a mass spectrum, gaseous species desorbed from condensed phases are ionized, the ions are accelerated by an electric field and then separated according to their mass-to-charge ratio, $m / z$. If all charges are +1 , then $m / z$ is numerically equal to the mass. If an ion has a charge of +2 , for example, then $m / z$ is $1 / 2$ of the mass. The mass spectrum in Figure 21-1 displays detector response versus $m / z$, showing four natural isotopes of $\mathrm{Pb}^{+}$ions. The area of each peak is proportional to the abundance of each isotope. Box 21-1 defines nominal mass, which is the mass we usually speak of in this chapter.

Figure 21-2 shows a magnetic sector mass spectrometer, which uses a magnetic field to allow ions of a selected $m / z$ to pass from the ion source to the detector. ${ }^{7}$ Gaseous molecules entering at the upper left are converted into ions (usually positive ions), accelerated by an electric field, and expelled into the analyzer tube, where they encounter a magnetic field perpendicular to their direction of travel. The tube is maintained under high vacuum $\left(\sim 10^{-5} \mathrm{~Pa}\right.$, $\sim 10^{-7}$ Torr) so that ions are not deflected by collision with background gas molecules. The magnet deflects ions toward the detector at the far end of the tube (see Box 21-2). Heavy ions are not deflected enough and light ones are deflected too much to reach the detector. The spectrum of masses is obtained by varying the magnetic field strength.

At the electron multiplier detector ${ }^{8}$ in Figure 21-2, each arriving ion starts a cascade of electrons, just as a photon starts a cascade of electrons in a photomultiplier tube (Figure 19-14). A series of dynodes multiplies the number of electrons by $\sim 10^{5}$ before they reach the anode where current is measured. The mass spectrum shows detector current as a function of $\mathrm{m} / \mathrm{z}$ selected by the magnetic field.

Mass spectrometers can measure negative ions by reversing voltages where the ions are formed and detected. To detect negative ions, a conversion dynode with a positive potential is placed before the electron multiplier. When bombarded by negative ions, the dynode liberates positive ions that are accelerated into the electron multiplier, which amplifies the signal.

## Electron Ionization

Molecules entering the ion source in Figure 21-2 are converted into ions by electron ionization. Electrons emitted from a hot filament (like the one in a light bulb) are accelerated through 70 V before interacting with incoming molecules. Some ( $\sim 0.01 \%$ ) molecules (M)

FIGURE 21-1 Mass spectrum showing natural isotopes of Pb observed as an impurity in brass. The variability of isotopic abundances in Pb from natural sources creates a large uncertainty in the atomic mass $(207.2 \pm 0.1)$ in the periodic table. From Y. Su, Y. Duan, and Z. Jin, "Development and Evaluation of a Glow Discharge Microwave-Induced Plasma Tandem Source for Time-of-Flight Mass Spectrometry," Anal. Chem. 2000, 72,5600.]

FIGURE 21-2 Magnetic sector mass spectrometer. [Adapted from F. W. McLafferty, Interpretation of Mass Spectra (New York: Benjamin, 1966).]

Atomic mass is the weighted average of the masses of the isotopes of an element. Bromine consists of $50.69 \%{ }^{79} \mathrm{Br}$ with a mass of 78.91834 Da (daltons) and $49.31 \%{ }^{81} \mathrm{Br}$ with a mass of 80.91629 Da . Therefore, its atomic mass is $(0.5069)(78.91834)+(0.4931)(80.91629)=$ 79.904 Da . The unit of atomic mass is the dalton, Da , defined as $1 / 12$ of the mass of ${ }^{12} \mathrm{C}$. Mass spectrometrists prefer " $u$ " for "unified atomic mass unit." Da and $u$ are synonymous.

The molecular mass of a molecule or an ion is the sum of atomic masses listed in the periodic table. For bromoethane,
$\mathrm{C}_{2} \mathrm{H}_{5} \mathrm{Br}$, the molecular mass is $(2 \times 12.0107)+(5 \times 1.00794)+$ $(1 \times 79.904)=108.965$.

The nominal mass of a molecule or ion is the integer mass of the species with the most abundant isotope of each of the constituent atoms. For carbon, hydrogen, and bromine the most abundant isotopes are ${ }^{12} \mathrm{C},{ }^{1} \mathrm{H}$, and ${ }^{79} \mathrm{Br}$. Therefore, the nominal mass of $\mathrm{C}_{2} \mathrm{H}_{5} \mathrm{Br}$ is $(2 \times 12)+(5 \times 1)+(1 \times 79)=108$.

FIGURE 21-3 lonization energies (I.E.) of valence electrons in formaldehyde. [Data from C. R. Brundle, M. B. Robin, N. A. Kuebler, and H. Basch, "Perfluoro Effects in Photoelectron Spectroscopy," J. Am. Chem. Soc. 1972, 94, 1451.] Here are other first ionization energies:

| $\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{3}$ | 10.6 eV (sigma) |
| :--- | :--- |
| $\mathrm{CH}_{2}=\mathrm{CHCH}_{2} \mathrm{CH}_{3}$ | 9.6 eV (pi) |
| $\left(\mathrm{CH}_{3} \mathrm{CH}_{2}\right)_{2} \ddot{\mathrm{O}}$ | 9.6 eV (nonbonding) |
| $\square \dot{\mathrm{NH}}$ | 8.6 eV (nonbonding) |

9.2 eV (pi)
absorb as much as $12-15$ electron volts ( $1 \mathrm{eV}=96.5 \mathrm{~kJ} / \mathrm{mol}$ ), which is enough for ionization:

Almost all stable molecules have an even number of electrons. When one electron is lost, the resulting cation with one unpaired electron is designated $\mathrm{M}^{+\cdot}$, the molecular ion. After ionization, $\mathrm{M}^{+\cdot}$ usually has enough internal energy $(\sim 1 \mathrm{eV})$ to break into fragments.

A small positive potential on the repeller plate of the ion source pushes ions toward the analyzer tube, and a small potential on the ion focus plates creates a focused beam. High voltage ( $\sim 1000-10000 \mathrm{~V}$ ) between the ion acceleration plates imparts a high velocity to ions as they are expelled from the bottom of the ion source.

The electron kinetic energy of 70 eV is much greater than the ionization energy of molecules. Consider formaldehyde in Figure 21-3, whose molecular orbitals were shown in Figure 17-12. The most easily lost electron comes from a nonbonding ("lone pair") orbital centered on oxygen, with an ionization energy of 11.0 eV . To remove a pi bonding electron from neutral formaldehyde requires 14.1 eV , and to remove the highest energy sigma bonding electron from the neutral molecule requires 15.9 eV .

Interaction with a $70-\mathrm{eV}$ electron most likely removes the electron with lowest ionization energy. The resulting molecular ion, $\mathrm{M}^{+\bullet}$, can have so much extra energy that it breaks into fragments. There might be so little $\mathrm{M}^{+\boldsymbol{}}$ that its peak is small or absent in the mass spectrum.

## BOX 21-2 How lons of Different Masses Are Separated by a Magnetic Field

Electron ionization in the ion source of the mass spectrometer in Figure 21-2 creates positive ions, $\mathrm{M}^{z+}$, with different masses. Let the mass of an ion be $m$ and let its charge be $+z e$ (where $e$ is the magnitude of the charge of an electron). When the ion is accelerated through a potential difference $V$ by the ion acceleration plates, it acquires a kinetic energy equal to the electric potential difference:

$$
\begin{equation*}
\underset{\substack{\text { Kinetic energy } \\(\mathrm{v}=\text { velocity })}}{\frac{1}{2} m v^{2}} \quad \underset{\text { Potential energy }}{z e V} \Rightarrow \mathrm{v}=\sqrt{\frac{2 z e V}{m}} \tag{A}
\end{equation*}
$$

An ion with charge $z e$ and velocity v traveling perpendicular to a magnetic field $B$ experiences a force $z e v B$ that is perpendicular to both the velocity vector and the magnetic field vector. This force deflects the ion through a circular path of radius $r$. The centripetal force $\left(m \mathrm{v}^{2} / r\right)$ required to deflect the particle is provided by the magnetic field.

$$
\begin{equation*}
\underset{\text { Centripetal force }}{\frac{m \mathrm{v}^{2}}{r}}=\underset{\substack{\text { Magnetic force }}}{z e \mathrm{v} B} \Rightarrow \mathrm{v}=\frac{z e B r}{m} \tag{B}
\end{equation*}
$$

Equating velocities from Equations A and B gives

$$
\begin{equation*}
\frac{z e B r}{m}=\sqrt{\frac{2 z e V}{m}} \Rightarrow \frac{m}{z}=\frac{e B^{2} r^{2}}{2 V} \tag{C}
\end{equation*}
$$

Equation C tells us the radius of curvature of the path traveled by an ion with mass $m$ and charge $z$. The radius of curvature is fixed by the geometry of the hardware. Ions can be selected to reach the detector by adjusting the magnetic field, $B$, or the accelerating voltage, $V$. Normally, $B$ is varied to select ions and $V$ is fixed near 3000 V . Transmission of ions and detector response both decrease when $V$ is decreased.

FIGURE 21-4 Mass spectra of the sedative pentobarbital from electron ionization (left) or chemical ionization (right). The molecular ion ( $\mathrm{M}^{+\cdot}, \mathrm{m} / \mathrm{z} 226$ ) is not evident with electron ionization. The dominant ion from chemical ionization is $\mathrm{MH}^{+}$. The peak at $\mathrm{m} / \mathrm{z} 255$ in the chemical ionization spectrum is from $\mathrm{M}\left(\mathrm{C}_{2} \mathrm{H}_{5}\right)^{+}$. [Courtesy Varian Associates, Sunnyvale, CA.]

The electron ionization mass spectrum at the left side of Figure 21-4 does not exhibit an $\mathrm{M}^{+}$ peak that would be at $m / z 226$. Instead, there are peaks at $m / z 197,156,141,112,98,69$, and 55 , arising from fragmentation of $\mathrm{M}^{+\bullet}$. These peaks provide clues about the structure of the molecule. A computer search is commonly used to match the spectrum of an unknown to similar spectra in a library. ${ }^{10}$

If you lower the kinetic energy of electrons in the ionization source to, say, 20 eV , there will be a lower yield of ions and less fragmentation. You would likely observe a greater abundance of molecular ions. We customarily use 70 eV because it gives reproducible fragmentation patterns that can be compared with library spectra.

The most intense peak in a mass spectrum is called the base peak. Intensities of other peaks are expressed as a percentage of the base peak intensity. In the electron ionization spectrum in Figure 21-4, the base peak is at $m / z 141$.

Electrons with an energy near 70 eV almost exclusively create cationic molecular products. If the electron energy is lower, it is possible to form negative ions from molecules with a sufficiently great electron affinity:
Resonance capture:

$$
\mathrm{M}+\underset{<0.1 \mathrm{eV}}{\mathrm{e}^{-}} \rightarrow \mathrm{M}^{-\cdot}
$$

Dissociative capture: $\mathrm{XY}+\underset{\mathrm{e}}{ } \mathrm{e}^{-} \rightarrow \mathrm{X} \quad+\mathrm{Y}^{-}$
Chemical ionization produces less fragmentation than electron ionization. For chemical ionization, the ionization source is filled with a reagent gas such as methane, isobutane, or ammonia, at a pressure of $\sim 100 \mathrm{~Pa}(\sim 1 \mathrm{mbar}, \sim 1$ Torr). Energetic electrons ( $100-200 \mathrm{eV}$ ) convert $\mathrm{CH}_{4}$ into a variety of reactive products:

$$
\begin{gathered}
\mathrm{CH}_{4}+\mathrm{e}^{-} \rightarrow \mathrm{CH}_{4}^{+}+2 \mathrm{e}^{-} \\
\mathrm{CH}_{4}^{+}+\mathrm{CH}_{4} \rightarrow \mathrm{CH}_{5}^{+}+{ }^{\circ} \mathrm{CH}_{3} \\
\mathrm{CH}_{4}^{+\cdot} \rightarrow \mathrm{CH}_{3}^{+}+\mathrm{H}^{\cdot} \\
\mathrm{CH}_{3}^{+}+\mathrm{CH}_{4} \rightarrow \mathrm{C}_{2} \mathrm{H}_{5}^{+}+\mathrm{H}_{2}
\end{gathered}
$$

$\mathrm{CH}_{5}^{+}$is a potent proton donor that reacts with analyte to give the protonated molecule, $\mathrm{MH}^{+}$, which is usually the most abundant ion in the chemical ionization mass spectrum.

$$
\mathrm{CH}_{5}^{+}+\mathrm{M} \rightarrow \mathrm{CH}_{4}+\mathrm{MH}^{+}
$$

In the chemical ionization spectrum in Figure 21-4, $\mathrm{MH}^{+}$at $\mathrm{m} / \mathrm{z} 227$ is the second strongest peak and there are fewer fragments than in the electron ionization spectrum.

Ammonia or isobutane are used in place of $\mathrm{CH}_{4}$ to reduce the fragmentation of $\mathrm{MH}^{+}$. These reagents bind $\mathrm{H}^{+}$more strongly than $\mathrm{CH}_{4}$ does and impart less energy to $\mathrm{MH}^{+}$when the proton is transferred to M. Another mild, versatile ionization reagent is $\mathrm{NO}^{+}$generated from NO by radioactive ${ }^{210}$ Po. ${ }^{12}$

A reasonable match of the experimental spectrum to one in the computer library is not proof of molecular structure-it is just a clue. ${ }^{9}$ You must be able to explain all major peaks (and even minor peaks at high $\mathrm{m} / \mathrm{z}$ ) in the spectrum in terms of the proposed structure, and you should obtain a matching spectrum from an authentic sample before reaching a conclusion. The authentic sample must have the same chromatographic retention time as the proposed unknown. Many isomers produce nearly identical mass spectra.

$\mathrm{CH}_{5}^{+}$is described as a $\mathrm{CH}_{3}$ tripod with an added $\mathrm{H}_{2}$ unit. $[\mathrm{H}-\mathrm{C}-\mathrm{H}]$ is held together by two electrons distributed over three atoms. Atoms of the $\mathrm{H}_{2}$ unit rapidly exchange with atoms of the $\mathrm{CH}_{3}$ unit. ${ }^{11}$

The molecular ion, $\mathrm{M}^{+}$, can be formed by reactions such as

$$
\mathrm{CH}_{4}^{+\cdot}+\mathrm{M} \rightarrow \mathrm{CH}_{4}+\mathrm{M}^{+\cdot}
$$

$\mathrm{MH}^{+}$is the protonated molecule, not the molecular ion.

FIGURE 21-5 Resolving power. (a) By one definition, the resolving power is $m / \Delta m=500 / 1=500$. (b) By a second definition, the resolving power for the same pair of peaks is $m / m_{1 / 2}=500 / 0.481=$ 1 040. (c) With the second definition, two peaks at $\mathrm{m} / \mathrm{z} 500$ and 501 are just barely discernible if the resolving power is 500 .

Negative chemical ionization reagents include $\mathrm{O}_{2}^{-}, \mathrm{F}^{-}$, and $\mathrm{SF}_{6}^{-12}$ Anions such as $\mathrm{Cl}^{-}$ and $\mathrm{OH}^{-}$in solution can produce negative ions in the mass spectrum by reactions such as

$$
\begin{gathered}
\mathrm{M}+\mathrm{Cl}^{-} \rightarrow(\mathrm{M}+\mathrm{Cl})^{-} \\
\mathrm{M}+\mathrm{OH}^{-} \rightarrow(\mathrm{M}-\mathrm{H})^{-}+\mathrm{H}_{2} \mathrm{O}
\end{gathered}
$$

## Resolving Power

Mass spectra in Figure 21-4 are computer-generated bar graphs. In contrast, Figure 21-1 shows the actual detector signal. Each mass spectral peak has a width that limits how closely two peaks could be spaced and still be resolved. If peaks are too close, they appear to be a single peak.

The higher the resolving power of a mass spectrometer, the better it is able to separate two peaks with similar mass.

$$
\begin{array}{rlc}
\text { Resolving power } & =\frac{m}{\Delta m} & \text { or } \tag{21-1}
\end{array} \frac{m}{m_{1 / 2}}
$$

where $m$ is the smaller value of $m / z$. The denominator is defined in two different ways. In Figure 21-5a, the denominator is the separation of the two peaks $(\Delta m)$ when the overlap at their base is $10 \%$ of the maximum peak height. The resolving power in Figure 21-5a is $\mathrm{m} / \Delta \mathrm{m}=$ $500 / 1.00=5.00 \times 10^{2}$. In Figure 21-5b, the denominator is taken as $m_{1 / 2}$, the width of the peak at half the maximum height, which is 0.481 Da (dalton, see Box 21-1). By this definition, the resolving power is $\mathrm{m} / m_{1 / 2}=500 / 0.481=1.04 \times 10^{3}$ for the same two peaks. Figure $21-5 \mathrm{c}$ shows that, when the expression $\mathrm{m} / \mathrm{m}_{1 / 2}$ gives a resolving power of $5.00 \times 10^{2}$, two peaks at $\mathrm{m} / \mathrm{z} 500$ and 501 are barely discernible. Specify which definition you use when expressing resolving power.

## EXAMPLE Resolving Power

Using the ${ }^{208} \mathrm{~Pb}$ peak in Figure 21-1, find the resolving power from the expression $\mathrm{m} / \mathrm{m}_{1 / 2}$.
Solution The width at half-height is $0.146 \mathrm{~m} / \mathrm{z}$ units. Therefore,

$$
\text { Resolving power }=\frac{m}{m_{1 / 2}}=\frac{208}{0.146}=1.42 \times 10^{3}
$$

An instrument with a resolving power of $1.42 \times 10^{3}$ separates peaks well near $\mathrm{m} / z 200$ but gives a barely discernible separation at $m / z 1420$.

Test Yourself Measure the resolving power $m / m_{1 / 2}$ from the ${ }^{31} \mathrm{P}$ peak in Figure 21-9. (Answer: $\mathrm{m} / m_{1 / 2}=30.974 \mathrm{Da} / 0.0033 \mathrm{Da}=9400$ )

## 21-2 Oh, Mass Spectrum, Speak to Me!*

Each mass spectrum has a story to tell. The molecular ion, $\mathrm{M}^{+\cdot}$, tells us the molecular mass of an unknown. Unfortunately, with electron ionization, some compounds do not exhibit a molecular ion, because $\mathrm{M}^{+\bullet}$ breaks apart so efficiently. However, fragments provide clues to the structure of an unknown. To find the molecular mass, we can obtain a chemical ionization mass spectrum, which usually has a strong peak for $\mathrm{MH}^{+}$.

The nitrogen rule helps us propose compositions for molecular ions: If a compound has an odd number of nitrogen atoms-in addition to any number of $\mathrm{C}, \mathrm{H}$, halogens, $\mathrm{O}, \mathrm{S}, \mathrm{Si}$ and P -then $\mathrm{M}^{+\boldsymbol{\bullet}}$ has an odd nominal mass. For a compound with an even number of nitrogen atoms $(0,2,4, \ldots), \mathbf{M}^{+\bullet}$ has an even nominal mass. A molecular ion at $m / z 128$ can have 0 or 2 N atoms, but it cannot have 1 N atom.

## Molecular Ion and Isotope Patterns

Electron ionization of aromatic compounds (those containing benzene rings) usually gives significant intensity for $\mathrm{M}^{+\cdot} . \mathrm{M}^{+\cdot}$ is the base peak (most intense) in the spectra of benzene and biphenyl in Figure 21-6.

The next higher mass peak, $\mathrm{M}+1$, provides information on elemental composition. Table 21-1 lists the natural abundance of several isotopes. For carbon, $98.93 \%$ of atoms are ${ }^{12} \mathrm{C}$ and $1.07 \%$ are ${ }^{13} \mathrm{C}$. The ratio of the two isotopes is ${ }^{13} \mathrm{C} /{ }^{12} \mathrm{C}=1.07 / 98.93=0.0108$. Nearly all hydrogen is ${ }^{1} \mathrm{H}$, with $0.012 \%{ }^{2} \mathrm{H}$. Applying the factors in Table 21-2 to $\mathrm{C}_{n} \mathrm{H}_{m}$, the intensity of the $\mathrm{M}+1$ peak should be
Intensity of $M+1$
relative to molecular ion for $\mathrm{C}_{n} \mathrm{H}_{m}$ :

$$
\begin{equation*}
\text { Intensity }=\underbrace{n \times 1.08 \%}_{\text {From }{ }^{13} \mathrm{C}}+\underbrace{m \times 0.012 \%}_{\text {From }{ }^{2} \mathrm{H}} \tag{21-2}
\end{equation*}
$$

For benzene, $\mathrm{C}_{6} \mathrm{H}_{6}, \mathrm{M}^{+\boldsymbol{}}$ is observed at $\mathrm{m} / \mathrm{z} 78$. The predicted intensity at $\mathrm{m} / \mathrm{z} 79$ is $6 \times$ $1.08+6 \times 0.012=6.55 \%$ of the abundance of $\mathrm{M}^{+\cdot}$. The observed intensity in Figure 21-6 is $6.5 \%$. An intensity within $\pm 10 \%$ of the expected value ( 5.9 to 7.2 , in this case) is within the precision of ordinary mass spectrometers. For biphenyl $\left(\mathrm{C}_{12} \mathrm{H}_{10}\right)$, we predict that $\mathrm{M}+1$ should have $12 \times 1.08+10 \times 0.012=13.1 \%$ of the intensity of $\mathrm{M}^{+\bullet}$. The observed value is $12.9 \%$.

## EXAMPLE Listening to a Mass Spectrum

In the chemical ionization mass spectrum of pentobarbital in Figure 21-4, the peak with the most significant intensity at the high end of the mass spectrum at $\mathrm{m} / \mathrm{z} 227$ is suspected to be $\mathrm{MH}^{+}$. If this is so, then the nominal mass of M is 226 . The nitrogen rule tells us that a molecule with an even mass must have an even number of nitrogen atoms. If you know from elemental analysis that the compound contains only $\mathrm{C}, \mathrm{H}, \mathrm{N}$, and O , how many atoms of carbon would you suspect are in the molecule?

Solution The $m / z 228$ peak has $12.0 \%$ of the height of the $m / z 227$ peak. Table 21-2 tells us that $n$ carbon atoms will contribute $n \times 1.08 \%$ intensity at $m / z 228$ from ${ }^{13} \mathrm{C}$. Contributions from ${ }^{2} \mathrm{H}$ and ${ }^{17} \mathrm{O}$ are small. ${ }^{15} \mathrm{~N}$ makes a larger contribution, but there are probably few atoms of nitrogen in the compound. Our first guess is

Although we write the molecular ion as $\mathrm{M}^{+\boldsymbol{}}$, we use the notation $M+1$ and $M-29$ for other peaks, without indicating positive charge. $\mathrm{M}+1$ refers to an ion with a mass one unit greater than that of $\mathrm{M}^{+\bullet}$.

FIGURE 21-6 Electron ionization (70 eV) mass spectra of molecular ion region of benzene $\left(\mathrm{C}_{6} \mathrm{H}_{6}\right)$ and biphenyl $\left(\mathrm{C}_{12} \mathrm{H}_{10}\right)$. [From NIST/EPA/NIH Mass Spectral Database. ${ }^{10}$ ]

a. 1 dalton $(D a) \equiv 1 / 12$ of the mass of ${ }^{12} C=1.660538782(83) \times 10^{-27} \mathrm{~kg}$ (from http://physics.nist.gov/constants). Nuclide masses from G. Audi, A. H. Wapsta, and C. Thibault, Nucl. Phys. 2003, A729, 337, found at www.nndc.bnl.gov/masses. This source provides more significant figures for atomic mass than are cited in this table.
b. Abundance is representative of what is found in nature. Significant variations are observed. For example, ${ }^{18} \mathrm{O}$ in natural substances has been found in the range 0.188 to 0.222 atom $\%$. The latest list of isotope abundances, which is slightly different from this table, is found in J. K. Böhlke et al., "Isotopic Compositions of the Elements, 2001," J. Phys. Chem. Ref. Data 2005, 34, 57.

$$
\text { Number of } \mathrm{C} \text { atoms }=\frac{\text { observed peak intensity for } \mathrm{M}+1}{\text { contribution per carbon atom }}=\frac{12.0 \%}{1.08 \%}=11.1 \approx 11
$$

The actual composition of $\mathrm{MH}^{+}$at $m / z 227$ is $\mathrm{C}_{11} \mathrm{H}_{19} \mathrm{O}_{3} \mathrm{~N}_{2}$. From the factors in Table 21-2, the theoretical intensity at $m / z 228$ is

$$
\text { Intensity }=\underbrace{11 \times 1.08 \%}_{{ }^{13} \mathrm{C}}+\underbrace{19 \times 0.012 \%}_{{ }^{2} \mathrm{H}}+\underbrace{3 \times 0.038 \%}_{{ }^{17} \mathrm{O}}+\underbrace{2 \times 0.369 \%}_{{ }^{15} \mathrm{~N}}=13.0 \%
$$

The theoretical intensity is within the $10 \%$ uncertainty of the observed value of $12.0 \%$.

TABLE 21-2 Isotope abundance factors (\%) for interpreting mass spectra

| Element | X+1 | X+2 | X+3 | X+4 | X+5 | X+6 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| H | $0.012 n$ |  |  |  |  |  |
| C | $1.08 n$ | $0.0058 n(n-1)$ |  |  |  |  |
| N | $0.369 n$ |  |  |  |  |  |
| O | $0.038 n$ | $0.205 n$ |  |  |  |  |
| F | 0 |  |  |  |  |  |
| Si | $5.08 n$ | $3.35 n$ | $0.170 n(n-1)$ | $0.056 n(n-1)$ |  |  |
| P | 0 |  |  |  |  |  |
| S | $0.801 n$ | $4.52 n$ | $0.036 n(n-1)$ | $0.102 n(n-1)$ |  |  |
| Cl | - | $32.0 n$ | - | $5.11 n(n-1)$ | - | $0.544 n(n-1)(n-2)$ |
| Br | - | $97.3 n$ | - | $47.3 n(n-1)$ | - | $15.3 n(n-1)(n-2)$ |
| I | 0 |  |  |  |  |  |

EXAMPLE: For a peak at $m / z=X$ containing $n$ carbon atoms, the intensity from carbon at $X+1$ is $n \times 1.08 \%$ of the intensity at $X$.
The intensity at $X+2$ is $n(n-1) \times 0.0058 \%$ of the intensity at $X$. Contributions from isotopes of other atoms in the ion are additive.

Test Yourself A compound with a parent ion at $m / z 117$ has a peak at $m / z 118$ with a relative intensity of $9.3 \%$. Is there an odd or even number of N atoms? How many carbons are in the formula? (Answer: odd, 8C. It cannot be 9 C because mass of $\mathrm{C}_{9} \mathrm{~N}$ is 122 Da , which is $>117 \mathrm{Da}$.)

FIGURE 21-7 Calculated isotopic patterns for species containing Cl and Br .

Ions containing Cl or Br have distinctive isotopic peaks shown in Figure 21-7. ${ }^{16}$ In the mass spectrum of 1-bromobutane in Figure 21-8, two nearly equal peaks at $\mathrm{m} / \mathrm{z} 136$ and 138 are a strong indication that the molecular ion contains one Br atom. The fragment at $\mathrm{m} / \mathrm{z} 107$ has a nearly equal partner at $\mathrm{m} / \mathrm{z} 109$, strongly suggesting that this fragment ion contains Br . Box 21-3 describes other information available from isotope ratios.

FIGURE 21-8 Electron ionization mass spectrum ( 70 eV ) of 1-bromobutane. [From A. Illies, P. B. Shevlin, G. Childers, M. Peschke, and J. Tsai, "Mass Spectrometry for Large Undergraduate Laboratory Sections," J. Chem. Ed. 1995, 72, 717. Referee from Maddy Harris.]

## BOX 21-3 Isotope Ratio Mass Spectrometry

The opening of Chapter 23 describes the analysis of cholesterol from ancient human bones by isotope ratio mass spectrometry. ${ }^{13} \mathrm{~A}$ compound eluted from a gas chromatography column is passed through a combustion furnace loaded with a metal catalyst (such as $\mathrm{CuO} / \mathrm{Pt}$ at $820^{\circ} \mathrm{C}$ ) to oxidize organic compounds to $\mathrm{CO}_{2}$. The $\mathrm{H}_{2} \mathrm{O}$ combustion by-product is removed by passage through a Nafion fluorocarbon tube (page 384). Water diffuses through the membrane, but other combustion products are retained. $\mathrm{CO}_{2}$ then enters a mass spectrometer that monitors $\mathrm{m} / \mathrm{z} 44$ $\left({ }^{12} \mathrm{CO}_{2}\right)$ and $45\left({ }^{13} \mathrm{CO}_{2}\right)$. One detector is dedicated to each ion.

Natural carbon is composed of $98.9 \%{ }^{12} \mathrm{C}$ and $1.1 \%{ }^{13} \mathrm{C}$. The chart shows consistent, small variations in ${ }^{13} \mathrm{C}$ from natural sources.

The standard used to measure carbon isotope ratios is calcium carbonate from the Pee Dee belemnite (fossil shell) formation in South Carolina (designated PDB) with a ratio $\mathrm{R}_{\mathrm{PDB}}={ }^{13} \mathrm{C} /{ }^{12} \mathrm{C}=0.01123_{72}$. (The composition is accurate to four significant figures, but small differences are precise to six significant figures.) The $\delta^{13} \mathrm{C}$ scale expresses small variations in isotopic compositions:

$$
\delta^{13} \mathrm{C}(\text { parts per thousand, } \%)=1000\left(\frac{\mathrm{R}_{\text {sample }}-\mathrm{R}_{\mathrm{PDB}}}{\mathrm{R}_{\mathrm{PDB}}}\right)
$$

$\delta{ }^{13} \mathrm{C}$ of natural materials provides information about their biological and geographic origins. ${ }^{14,15}$

[^12]FIGURE 21-9 High-resolution double-focusing sector-field mass spectrum distinguishing ${ }^{31} \mathrm{P}^{+}$, ${ }^{15} \mathrm{~N}^{16} \mathrm{O}^{+}$, and ${ }^{14} \mathrm{~N}^{16} \mathrm{OH}^{+}$with a resolution of $m / \Delta m=4000$. The spectrum is a bar graph of detector counts $/ \mathrm{s}$ at each increment of $\mathrm{m} / \mathrm{z}$. [From J. S. Becker, S. F. Boulyga, C. Pickhardt, J. Becker, S. Buddrus, and M. Przybylski, "Determination of Phosphorus in Small Amounts of Protein Samples by ICP-MS," Anal. Bioanal. Chem. 2003, 375, 561.]

Predicted masses from Table 21-1 and masses observed by high-resolution mass spectrometry: $\mathrm{C}_{5} \mathrm{H}_{8} \mathrm{O}^{+\cdot}$ :

| 5 C | $5 \times$ | 12.00000 |
| :---: | :---: | :---: |
| 8H | +8× | 1.007825 |
| 10 | +1× | 15.99491 |
| $-\mathrm{e}^{-}$ | $-1 \times$ | 0.00055 |
|  |  | 84.05696 |
| observed: ${ }^{17}$ |  | 84.0591 |
| $\mathrm{C}_{6} \mathrm{H}_{12}^{+}$: |  |  |
| 6C | $6 \times$ | 12.00000 |
| 12 H | $12 \times$ | 1.007825 |
| $-\mathrm{e}^{-}$ | $-1 \times$ | 0.00055 |
|  |  | 84.09335 |
| observed: ${ }^{17}$ |  | 84.0939 |

If $P$ makes more than three bonds or if $S$ makes more than two bonds, then Equation 21-3 does not include these extra bonds. Examples that violate Equation 21-3:

## High-Resolution Mass Spectrometry

An ion at $\mathrm{m} / \mathrm{z} 84$ could have a variety of elemental compositions, such as $\mathrm{C}_{5} \mathrm{H}_{8} \mathrm{O}^{+}=84.05696 \mathrm{Da}$ or $\mathrm{C}_{6} \mathrm{H}_{12}^{+}=84.09335 \mathrm{Da}$. We can determine which composition is correct if the spectrometer can distinguish sufficiently small differences in mass. With a double-focusing mass spectrometer, a time-of-flight mass spectrometer, an orbitrap mass spectrometer, or a Fourier transform ion cyclotron resonance mass spectrometer (Section 21-3), we can resolve differences of 0.001 or less at $\mathrm{m} / \mathrm{z} 100$. Figure 21-9 shows a high-resolution spectrum that distinguishes ${ }^{31} \mathrm{P}^{+},{ }^{15} \mathrm{~N}^{16} \mathrm{O}^{+}$, and ${ }^{14} \mathrm{~N}^{16} \mathrm{OH}^{+}$- all with a nominal mass of 31 .

To ensure accurate mass measurement, spectrometers are calibrated with compounds such as perfluorokerosene $\left(\mathrm{CF}_{3}\left(\mathrm{CF}_{2}\right)_{n} \mathrm{CF}_{3}\right)$ or perfluorotributylamine $\left(\left(\mathrm{CF}_{3} \mathrm{CF}_{2} \mathrm{CF}_{2} \mathrm{CF}_{2}\right)_{3} \mathrm{~N}\right)$. In high-resolution spectra, the exact masses of fluorocarbon fragments are slightly lower than those of ions containing C, H, O, N, and S. For high-resolution work, standards should be run with the unknown.

## Rings + Double Bonds

If we know the composition of a molecular ion, and we want to propose its structure, a handy equation that gives the number of rings + double bonds $(R+D B)$ is
$\begin{aligned} & \text { Rings + double } \\ & \text { bonds formula: }\end{aligned} \quad \mathrm{R}+\mathrm{DB}=c-h / 2+n / 2+1$
where $c$ is the number of Group 14 atoms ( $\mathrm{C}, \mathrm{Si}$, and so on, which all make four bonds), $h$ is the number of $(\mathrm{H}+$ halogen $)$ atoms (which make one bond), and $n$ is the number of Group 15 atoms ( $\mathrm{N}, \mathrm{P}, \mathrm{As}$, and so on, which make three bonds). Group 16 atoms ( $\mathrm{O}, \mathrm{S}$, and so on, which make two bonds) do not enter the formula. Here is an example:

$$
\mathrm{R}+\mathrm{DB}=(14+1)-\frac{22+1+1}{2}+\frac{1+1}{2}+1=5
$$

The molecule has one ring + four double bonds. Note that $c$ includes $\mathrm{C}+\mathrm{Si}, h$ includes $\mathrm{H}+\mathrm{Cl}+\mathrm{Br}$, and $n$ includes $\mathrm{N}+$ As.

FIGURE 21-10 Electron ionization ( 70 eV ) mass spectra of isomeric ketones with the composition $\mathrm{C}_{6} \mathrm{H}_{12} \mathrm{O}$. [From NIST/EPA/NIH Mass Spectral Database. ${ }^{10}$ ]

## Identifying the Molecular Ion Peak

Figure 21-10 shows electron ionization mass spectra of isomers with the elemental composition $\mathrm{C}_{6} \mathrm{H}_{12} \mathrm{O} . \mathrm{M}^{+\cdot}$ is marked by the solid triangle at $\mathrm{m} / \mathrm{z} 100$.

If these spectra had been obtained from unknowns, how would we know that the peak at $\mathrm{m} / \mathrm{z} 100$ represents the molecular ion? Here are some guidelines:

1. $\mathrm{M}^{+\bullet}$ will be at the highest $m / z$ value of any of the "significant" peaks in the spectrum that cannot be attributed to isotopes or background. "Background" arises from sources such as pump oil in the spectrometer and stationary phase from a gas chromatography column. Experience is required to recognize these signals. With electron ionization, the molecular ion peak intensity is often no greater than $5-20 \%$ of the base peak and might not represent more than $1 \%$ of all ions.
2. Intensities of isotopic peaks at $\mathrm{M}+1, \mathrm{M}+2$, and so on, must be consistent with the proposed formula.
3. The peak for the heaviest fragment ion should not correspond to an improbable mass loss from $\mathrm{M}^{+\boldsymbol{}}$. It is rare to find a mass loss in the range 3-14 or 21-25 Da. Common losses include $15\left(\mathrm{CH}_{3}\right), 17\left(\mathrm{OH}\right.$ or $\left.\mathrm{NH}_{3}\right), 18\left(\mathrm{H}_{2} \mathrm{O}\right), 29\left(\mathrm{C}_{2} \mathrm{H}_{5}\right), 31\left(\mathrm{OCH}_{3}\right), 43 \mathrm{Da}$ $\left(\mathrm{CH}_{3} \mathrm{CO}\right.$ or $\left.\mathrm{C}_{3} \mathrm{H}_{7}\right)$, and many others. If you think that $\mathrm{m} / \mathrm{z} 150$ represents $\mathrm{M}^{+\cdot}$, but there is a significant peak at $m / z 145$, then $\mathrm{M}^{+\cdot}$ is not assigned correctly, because a mass loss of 5 Da is improbable. Alternatively, the two peaks represent ions from different compounds or both peaks represent fragments from a compound whose mass is greater than 150 Da .
4. If a fragment ion is known to contain, say, three atoms of element $X$, then there must be at least three atoms of X in the molecular ion.

In both spectra in Figure 21-10, the peak at highest $m / z$ with "significant" intensity is $m / z 100$. The next highest significant peak is $m / z 85$, representing a loss of $15 \mathrm{Da}\left(\right.$ probably $\left.\mathrm{CH}_{3}\right)$. Peaks at $m / z 85$ and 100 are consistent with $m / z 100$ representing $\mathrm{M}^{+\bullet}$. If $\mathrm{M}^{+\bullet}$ has an even mass, the nitrogen rule says there must be an even number of N atoms (which could be 0 ) in the molecule.

In both spectra, $\mathrm{M}+1$ has $6 \%$ of the intensity of $\mathrm{M}^{+\boldsymbol{}}$, with just one significant digit in the measurement. From the intensity of $\mathrm{M}+1$, we estimate the number of C atoms:

$$
\text { Number of } \mathrm{C} \text { atoms }=\frac{\text { observed }(\mathrm{M}+1) / \mathrm{M}^{+\bullet} \text { intensity }}{\text { contribution per carbon atom }}=\frac{6 \%}{1.08 \%}=5.6 \approx 6
$$

If there are six C atoms and no N atoms, a possible composition is $\mathrm{C}_{6} \mathrm{H}_{12} \mathrm{O}$. The expected intensity of $\mathrm{M}+1$ is

$$
\text { Intensity }=\underbrace{6 \times 1.08 \%}_{{ }^{13} \mathrm{C}}+\underbrace{12 \times 0.012 \%}_{{ }^{2} \mathrm{H}}+\underbrace{1 \times 0.038 \%}_{{ }^{17} \mathrm{O}}=6.7 \% \text { of } \mathrm{M}^{+\cdot}
$$

The observed intensity of $6 \%$ for $\mathrm{M}+1$ is within experimental error of $6.7 \%$, so $\mathrm{C}_{6} \mathrm{H}_{12} \mathrm{O}$ is consistent with the data so far. $\mathrm{C}_{6} \mathrm{H}_{12} \mathrm{O}$ requires one ring or double bond.

The small peak at $m / z 86$ is not a loss of 14 Da from $\mathrm{M}^{+\cdot}$. It is the isotopic partner of $\mathrm{m} / \mathrm{z} 85$ containing ${ }^{13} \mathrm{C}$.

We see no evidence at $M+1, M+2$, and $\mathrm{M}+3$ for the elements $\mathrm{Cl}, \mathrm{Br}, \mathrm{Si}$, or S .

Challenge What intensities would you see at $\mathrm{M}+2$ and $\mathrm{M}+3$ if there were one Cl , one Br , one Si , or one S in the molecule?

$$
\begin{aligned}
\mathrm{R}+\mathrm{DB} & =c-h / 2+n / 2+1 \\
& =6-12 / 2+0+1=1
\end{aligned}
$$

FIGURE 21-11 Four possible fragmentation pathways for the molecular ion of 2-hexanone.
$\sim$ is transfer of one electron
$\longrightarrow$ is transfer of two electrons

## Types of bond breaking:

- Homolytic cleavage: 1 electron remains with each fragment
- Heterolytic cleavage: Both electrons stay with one fragment
In general, the most intense peaks correspond to the most stable fragments.

Bond cleavages of 4-methyl-2-pentanone leading to $m / z 15,85,43$, and 57 :

Challenge Draw a rearrangement like Reaction D in Figure 21-11 to show how $m / z 58$ arises.

## Interpreting Fragmentation Patterns

Consider how the 2-hexanone molecular ion can break apart to give the many peaks in Figure 21-10. Reactions A and B in Figure 21-11 show $\mathrm{M}^{+\cdot}$ derived from loss of a nonbonding electron from oxygen, which has the lowest ionization energy. In Reaction A, the C-C bond adjacent to $\mathrm{C}=\mathrm{O}$ splits so that one electron goes to each C atom. The products are a neutral butyl radical $\left({ }^{\circ} \mathrm{C}_{4} \mathrm{H}_{9}\right)$ and $\mathrm{CH}_{3} \mathrm{CO}^{+\bullet}$. Only the ion is detected by the mass spectrometer, giving the base peak at $m / z 43$. Cleavage of the C - C bond in Reaction B gives an ion with $\mathrm{m} / z 85$, corresponding to loss of ${ }^{\circ} \mathrm{CH}_{3}$ from the molecular ion. Two other major peaks in the spectrum arise from $\mathrm{C}_{4}-\mathrm{C}_{5}$ bond cleavage to give $\mathrm{CH}_{3} \mathrm{CH}_{2}^{+}(\mathrm{m} / \mathrm{z} 29)$ and ${ }^{+} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{COCH}_{3}$ $(\mathrm{m} / \mathrm{z} 71)$. The nitrogen rule told us that molecules containing only $\mathrm{C}, \mathrm{H}$, halogens, $\mathrm{O}, \mathrm{S}$, $\mathrm{Si}, \mathrm{P}$, and an even number of N atoms (such as 0 ) have an even mass. A fragment of a neutral molecule that is missing an H atom must have an odd mass.

We have yet to account for the second-tallest peak at $m / z 58$, which is special because it has an even mass. The molecular ion has an even mass ( 100 Da ). Radical fragments, such as $\mathrm{CH}_{3} \mathrm{CH}_{2}^{+}$, have an odd mass. All of the fragments discussed so far have an odd mass. The peak at $\mathrm{m} / \mathrm{z} 58$ results from the loss of a neutral molecule with an even mass of 42 Da .

Reaction D in Figure 21-11 shows a common rearrangement that leads to loss of a neutral molecule with even mass. In ketones with an H atom on the $\gamma$ carbon atom, the H atom can be transferred to $\mathrm{O}^{+}$. Concomitantly, the $\mathrm{C}_{\alpha}-\mathrm{C}_{\beta}$ bond cleaves and a neutral molecule of propene $\left(\mathrm{CH}_{3} \mathrm{CH}=\mathrm{CH}_{2}, 42 \mathrm{Da}\right)$ is lost. The resulting ion has a mass of 58 Da .

The spectra in Figure 21-10 allow us to distinguish one isomer of $\mathrm{C}_{6} \mathrm{H}_{12} \mathrm{O}$ from the other. The main difference between the spectra is a peak at $\mathrm{m} / \mathrm{z} 71$ for 2-hexanone that is absent in 4-methyl-2-pentanone. The peak at $m / z 71$ results from loss of ethyl radical, $\mathrm{CH}_{3} \mathrm{CH}_{2}^{+}$, from $\mathrm{M}^{+\bullet}$. Ethyl radical is derived from carbon atoms 5 and 6 of 2-hexanone. There is no simple way for an ethyl radical to cleave from 4-methyl-2-pentanone. The diagram in the margin shows how peaks at $\mathrm{m} / \mathrm{z} 15,85,43$, and 57 can arise from breaking bonds in 4-methyl-2-pentanone. A rearrangement like that at the bottom of Figure 21-11 accounts for $\mathrm{m} / \mathrm{z} 58$.

Other major peaks in Figure 21-10 might be $\mathrm{CH}_{2}=\mathrm{C}=\mathrm{O}^{+\bullet}(\mathrm{m} / \mathrm{z} 42), \mathrm{C}_{3} \mathrm{H}_{5}^{+}(\mathrm{m} / \mathrm{z} 41)$, $\mathrm{C}_{3} \mathrm{H}_{3}^{+}(\mathrm{m} / \mathrm{z} 39), \mathrm{C}_{2} \mathrm{H}_{5}^{+}$or $\mathrm{HC} \equiv \mathrm{O}^{+}(\mathrm{m} / \mathrm{z} 29)$, and $\mathrm{C}_{2} \mathrm{H}_{3}^{+}(\mathrm{m} / z 27)$. Small fragments are common in many spectra and not very useful for structure determination.

Interpretation of mass spectra to elucidate molecular structure is an important field. ${ }^{18}$ Fragmentation patterns can even unravel the structures of large biological molecules.

## 21-3 Types of Mass Spectrometers

Figure 21-2 shows a magnetic sector mass spectrometer in which ions with different mass, but constant kinetic energy, are separated by their trajectories in a magnetic field. The kinetic energy is imparted to the ions by the voltage between the acceleration plates in the ion source.

FIGURE 21-12 Electric sector of a double-focusing mass spectrometer. Positive ions are attracted toward the negative plate. Trajectories of high-energy ions are changed less than trajectories of lowenergy ions. lons reaching the exit slit have a narrow range of kinetic energies.

Ions are created from the neutral molecule with a small spread of kinetic energies and are accelerated to different extents, depending on where in the ion source they were formed.

The resolving power of a mass spectrometer is limited by the variation in kinetic energy of ions emerging from the source, which is typically $\sim 0.1 \%$. This variation limits the resolving power to $\sim 1000$, corresponding to a resolution of 0.1 at $\mathrm{m} / \mathrm{z} 100$. In a double-focusing mass spectrometer, ions ejected from the source pass through an electric sector as well as a magnetic sector (Figure 21-12). With both sectors in series, it is possible to achieve a resolving power of $\sim 10^{5}$, corresponding to a resolution of 0.001 at $\mathrm{m} / \mathrm{z} 100$.

## Transmission Quadrupole Mass Spectrometer

Magnetic sector and double-focusing mass spectrometers are not detectors of choice for chromatography. Figure 21-13 shows a transmission quadrupole mass spectrometer ${ }^{19}$ connected to an open tubular gas chromatography column to record multiple spectra from each component as it is eluted. Species exiting the chromatography column pass through a heated connector into the electron ionization chamber, which is pumped to maintain a pressure of $\sim 10^{-4} \mathrm{~Pa}\left(\sim 10^{-9}\right.$ bar, $\sim 10^{-6}$ Torr), using a high-speed turbomolecular or oil diffusion pump. Ions are accelerated through a potential of $5-15 \mathrm{~V}$ before entering the quadrupole filter.

The quadrupole is a common mass separator because of its low cost. It consists of four parallel metal rods to which are applied both a constant voltage and a radio-frequency oscillating voltage. The electric field deflects ions in complex trajectories as they migrate from the ionization chamber toward the detector, allowing only ions with one particular mass-to-charge ratio to reach the detector. Other ions (nonresonant ions) collide with the rods and

FIGURE 21-13 Quadrupole mass spectrometer. Ideally, the rods should have a hyperbolic cross section on the surfaces that face one another.

FIGURE 21-14 Continuous-dynode electron multiplier, also known as a Channeltron ${ }^{\circledR}$. For each incident electron, $\sim 10^{5}$ electrons are detected at the far end of the horn. [Adapted from J. T. Watson and O. D. Sparkman, Introduction to Mass Spectrometry, 4th ed. (Chichester: Wiley, 2007).]

Ideally, the kinetic energy of an ion expelled from the source is zeV, where ze is the charge of the ion and $V$ is the voltage on the backplate.

FIGURE 21-15 Time-of-flight mass spectrometer. Positive ions are accelerated out of the source by voltage +V periodically applied to the backplate. Light ions travel faster and reach the detector sooner than heavier ions.
are lost before they reach the detector. Rapidly varying voltages select ions of different masses to reach the detector. Transmission quadrupoles can record $2-8$ spectra per second, covering a range as high as $4000 \mathrm{~m} / \mathrm{z}$ units. They typically can resolve peaks separated by $\mathrm{m} / \mathrm{z} 0.3$.

Magnetic sector and double-focusing instruments, as well as time-of-flight instruments described next, operate at constant resolving power, which means that the separation between peaks decreases as $m / z$ increases. Transmission quadrupoles (and other quadrupole instruments described later) operate at constant resolution. That is, ions of $m / z .100$ and 101 are separated to the same extent as ions of $m / z 500$ and 501.

In place of the discrete-dynode detector in Figure 21-2, we show a high-energy dynode and a continuous-dynode electron multiplier detector in Figure 21-13. A high-energy dynode is used with quadrupole mass separators and ion traps (described below) to ensure that all ions produce a similar electrical response at the detector; otherwise, the mass spectrum may exhibit mass discrimination in which ions of different $\mathrm{m} / \mathrm{z}$ produce different responses. Cations emerging from the quadrupole mass analyzer are attracted to the high-energy dynode held at -10 kV . Each cation striking the dynode liberates electrons, which are accelerated toward the mouth of the continuous-dynode electron multiplier. The electrically resistive lead-doped glass wall of the horn-shaped electron multiplier is at -2 kV at the mouth and at ground potential at the narrow end (Figure 21-14). An electron striking the wall of the electron multiplier liberates several electrons, which are accelerated toward more positive potential deeper into the horn. After many rebounds, each incident electron is multiplied to $\sim 10^{5}$ electrons at the narrow end of the horn.

## Time-of-Flight Mass Spectrometer

The principle of the time-of-flight mass spectrometer is shown in Figure 21-15. ${ }^{20}$ The ion source is at the upper left. About 3000 to 20000 times per second, a voltage of 5000 V is applied to the backplate to accelerate ions toward the right and expel them from the ion source into the drift region, where there is no electric or magnetic field and no further acceleration. Ideally, all ions have the same kinetic energy, which is $\frac{1}{2} m v^{2}$, where $m$ is the mass of the ion and v is its velocity. If ions have the same kinetic energy, but different masses, the lighter ones travel faster than the heavier ones. In its simplest incarnation, the time-of-flight mass spectrometer is just a long, straight, evacuated tube with the source at one end and the detector at the other end. Ions expelled from the source drift to the detector in order of increasing mass, because the lighter ones travel faster.

The instrument in Figure 21-15 is designed for improved resolving power. The main limitation on resolving power is that all ions do not emerge from the source with the same kinetic energy. An ion formed close to the backplate is accelerated through a higher voltage difference than one formed near the grid, so the ion near the backplate gains more kinetic energy. Also, there is some distribution of kinetic energies among the ions, even in the absence of the accelerating voltage. Heavier ions with more-than-average kinetic energy reach the detector at the same time as lighter ions with less-than-average energy.

Consider two ions expelled from the source with different speeds at different times. The ion formed close to the grid has less kinetic energy but is expelled first. The ion formed close to the backplate has more kinetic energy but is expelled later. Eventually, the faster ion catches up to the slower ion at the space focus plane at a distance $2 s$ from the grid (where $s$ is the distance between the backplate and the grid). It can be shown that all ions of a given mass reach the space focus plane at the same time. After the space focus plane, ions diverge again, with faster ions overtaking slower ones. In the absence of countermeasures, ions would be badly spread by the time they reach the detector and resolving power would be low.

To improve resolving power, ions are turned around by the "reflectron" at the right side of Figure 21-15. The reflectron is a series of hollow rings held at increasingly positive potential, terminated by a grid whose potential is more positive than the accelerating potential on the backplate of the source. Ions entering the reflectron are slowed down, stopped, and reflected back to the left. The more kinetic energy an ion had when it entered the reflectron, the further it penetrates before it is turned around. Reflected ions reach a new space focus plane at the grid in front of the detector. All ions of the same mass reach this grid at the same time, regardless of their initial kinetic energies.

Resolving power can be as high as 1000 to 25000 , and $\mathrm{m} / \mathrm{z}$ accuracy is $\sim 0.001$. Other advantages of the time-of-flight spectrometer are its high acquisition rate ( $10^{2}$ to $10^{4}$ spectra/s) and its capability for measuring very high masses ( $\mathrm{m} / \mathrm{z} \approx 10^{6}$ ). The time-of-flight mass spectrometer requires a lower operating pressure than do the transmission quadrupole and magnetic sector instruments ( $10^{-7} \mathrm{~Pa}$ versus $10^{-4} \mathrm{~Pa}$ or $10^{-9}$ Torr versus $10^{-6}$ Torr).

## Three-Dimensional Quadrupole Ion-Trap Mass Spectrometer

The three-dimensional quadrupole ion-trap mass spectrometer ${ }^{21}$ is a compact device that is well suited as a chromatography detector. In Figure 21-16, substances emerging from the chromatography column enter the cavity of the three-dimensional ion-trap mass analyzer from the lower left through a heated transfer line. In the implementation of the ion trap shown in Figure 21-16, the gate electrode periodically admits electrons from the filament at the top into the cavity through holes in the end cap. Molecules undergo electron ionization in the cavity formed by the two end caps and a ring electrode, all of which are electrically isolated from one another. Alternatively, chemical ionization is achieved by adding a reagent gas such as methane to the cavity, ionizing it with the electron beam to form reagent ions, and then allowing reagent ions to react with analyte molecules. Some gas chromatography-mass spectrometry systems and all liquid chromatography-mass spectrometry systems produce ions outside the ion trap and inject them into the trap.

A constant-frequency radio-frequency voltage applied to the central ring electrode causes ions to circulate in stable, three-dimensional orbits in the cavity, with the lowest $\mathrm{m} / \mathrm{z}$ in the outermost orbits. Increasing the amplitude of the radio-frequency voltage destabilizes the orbits of ions of one $m / z$ value at a time, sending them flying out of the two end caps. Ions expelled through the lower end cap in Figure 21-16b are detected by the electron multiplier with high sensitivity ( $\sim 1-10 \mathrm{pg}$ ). Scans from $\mathrm{m} / \mathrm{z} 10$ to 650 can be conducted eight times per second. Resolving power is $1000-4000, \mathrm{~m} / \mathrm{z}$ accuracy is 0.1 , and the maximum $\mathrm{m} / \mathrm{z}$ is $\sim 20000$.

At the University of Bonn, W. Paul showed in the 1950s that ions could be manipulated by quadrupole electric fields. He received the Nobel Prize for physics in 1989.

FIGURE 21-16 Three-dimensional quadrupole ion-trap mass spectrometer. (a) Mass analyzer consists of two end caps (left and right) and central ring electrode. (b) Schematic diagram. [Courtesy Varian Associates, Sunnyvale, CA.]

In other mass analyzers, a small fraction of ions reaches the detector. With a three-dimensional ion trap, half of the ions reach the detector, giving this device 10 to 100 times more sensitivity than the transmission quadrupole.

The quadrupole ion trap contains He gas at $10^{-1} \mathrm{~Pa}\left(10^{-3}\right.$ Torr), which is much higher than the allowed pressure in a transmission quadrupole $\left(10^{-4} \mathrm{~Pa}\right.$ or $\left.10^{-6} \mathrm{Torr}\right)$ or a time-of-flight instrument ( $10^{-7} \mathrm{~Pa}, 10^{-9}$ Torr). Gas in the ion trap cools the ions by collisions, which absorb excess vibrational and rotational energy from the ions. Cool ions have less random displacement from the ideal orbits established by the electric field of the quadrupole. Lower pressure is required in other mass filters to increase the mean free path of ions so that they are not diverted from the intended trajectory by collisions with background gas.

The capacity of the three-dimensional quadrupole to hold ions is limited by the small volume enclosed by the electrodes and by the total charge of the ions, which can alter the electric field inside the quadrupole. The field created by the ions is called the space charge. When the space charge is too great, performance of the ion trap is degraded. Mass spectrometers have feedback controls that limit the space charge to tolerable levels by controlling the number of ions allowed in the trap.

## Linear Quadrupole Ion-Trap Mass Spectrometer

The linear quadrupole ion-trap mass spectrometer, which has higher trapping efficiency and higher storage capacity than the three-dimensional quadrupole ion trap, is finding its way into many instruments. The quadrupole mass filter in Figure 21-13 used a direct current voltage and a radio-frequency voltage to select ions of a particular $\mathrm{m} / \mathrm{z}$ to be transmitted through the filter. The linear ion trap in Figure 21-17 adds sections at each end of the quadrupole to create a potential well. If the ends are sufficiently positive with respect to the center section, cations become trapped in the center section. Ions are confined in the radial direction (the $x y$ plane) by a radio-frequency field applied to the central section. By manipulating the voltages, ions of a specific $m / z$ value can be expelled through slits in the $x$ direction or out the ends in the $z$ direction to one or more detectors.

Three-dimensional quadrupole ion traps have low detection limits, but they are limited by the number of ions they can hold without exceeding the allowed space charge. Also, they only $\operatorname{trap} \sim 5 \%$ of injected ions. The linear ion trap has even lower detection limits because it can hold $\sim 30$ times more ions and can be more than 10 times as efficient at trapping injected ions.

Linear and three-dimensional quadrupole ion traps can trade spectral acquisition rate for resolution. They are commonly operated at unit resolution with scan rates on the order of $11000 \mathrm{~m} / \mathrm{z}$ units per second. At the expense of slowing the scan rate to $27 \mathrm{~m} / \mathrm{z}$ units per second, a resolution of $0.05 \mathrm{~m} / \mathrm{z}$ units can be attained.

Cooks, "Rectilinear Ion Trap: Concepts, Calculations, and Analytical Performance of a New Mass Analyzer," Anal. Chem. 2004, 76, 4595. Photograph of LTQ XL linear ion trip courtesy Thermo Fisher Scientific, San Jose, CA.]

## Orbitrap Mass Spectrometer

The orbitrap is a high-resolution mass analyzer that does not require a magnetic field or a radiofrequency field. In its commercial realization, the orbitrap mass spectrometer provides a resolving power of $\sim 150000, \mathrm{~m} / \mathrm{z}$ accuracy of $2-5 \mathrm{ppm}$ with external calibration, upper $\mathrm{m} / \mathrm{z}$ limit of 6000 , and a dynamic range of several thousand. With internal calibration standards,

FIGURE 21-18 (a) Cutaway drawing of orbitrap. [From A. Makarov, "Electrostatic Axially Harmonic Orbital Trapping: A High-Performance Technique of Mass Analysis," Anal. Chem. 2000, 72, 1156.] (b) Electric field in one longitudinal plane of orbitrap. (c) Initial path of ion entering the orbitrap and stable path for successive orbits. (d) Photograph of orbitrap with half of outer sheath removed. Inner diameter of outer electrodes is 30 mm and length of exposed section is 4 cm . [Courtesy Thermo Fisher Scientific, San Jose, CA.]
sub-part-per-million $m / z$ accuracy is attainable. The cutaway view in Figure 21-18a shows precisely machined central and outer electrodes. The central electrode is held at -5 kV while the two outer electrodes (Figure 21-18b) are close to ground potential and electrically isolated from each other. Figure 21-18b shows electric field vectors perpendicular to the axis of symmetry $(z)$ near the center of the orbitrap, but increasingly angled toward the center of the orbitrap at increasing distance from the center.

A packet of ions is introduced perpendicular to the plane of Figure 21-18b at the indicated point. The electric field pushes ions into an orbit toward the center of the orbitrap in Figure 21-18c. Initial momentum carries ions from the right side of the orbitrap to the left side until the electric field is strong enough to push the ions back to the right. When ions have traveled far enough to the right, they are pushed back to the left. They circle back and forth around the central electrode as long as they do not strike another molecule. Maintaining the unperturbed orbit long enough requires the best vacuum of any mass spectrometer at $\sim_{10^{-8}} \mathrm{~Pa}\left(\sim 10^{-10}\right.$ Torr)—providing a mean free path of 100 km . The frequency of oscillation of an ion between the right and left halves of the orbitrap is proportional to $1 / \sqrt{\mathrm{m} / z}$.

Ions oscillating between the two halves of the orbitrap induce an opposite charge called the image charge in the outer electrode. A packet of cations in the right half of the orbitrap attracts electrons in the outer right electrode. A packet of cations in the left half of the orbitrap attracts electrons in the outer left electrode. An amplifier connected to the two halves of the split outer electrode measures the image current oscillating in synchrony with the ions. The orbitrap contains ions with different $\mathrm{m} / \mathrm{z}$ values, each creating a component of current with a different frequency. The observed signal is the sum of currents from all $\mathrm{m} / \mathrm{z}$ values. After recording the current for a predetermined time ( $\sim 0.1$ to 1.5 s ), a computer decomposes the current into its component frequencies-and hence component $\mathrm{m} / \mathrm{z}$ values - through a Fourier transform (Section 19-5).

Ions must be injected into the orbitrap in one small packet. Figure 21-19 shows how this can be done. Ions from an electrospray source (Section 21-4) are accumulated in a linear ion trap and then transferred in one batch to a C-trap, which electrodynamically squeezes them into a small packet. The packet is ejected through ion optics into the orbitrap. During the $\sim 0.1-\mathrm{ms}$ injection period, the electric field in the orbitrap is ramped up in such a manner that the ions begin to orbit the central electrode. After the voltage on the central electrode reaches its constant level for stable orbits, detection begins.

FIGURE 21-19 Arrangement of linear ion trap and C-trap for collecting ions, compressing them into a small packet, and feeding the packet into the orbitrap. [From A. Makarov, E. Denisov, A. Kholomeev, W. Balschun, O. Lange, K. Strupat, and S. Horning, "Performance Evaluation of a Hybrid Linear Ion Trap/Orbitrap Mass Spectrometer," Anal. Chem. 2006, 78, 2113.]

## Ion Mobility Spectrometer ${ }^{22}$

More than $10^{4}$ ion mobility spectrometers are deployed at airport security checkpoints to detect explosives, and perhaps $10^{5}$ hand-portable devices are used by military and civil defense personnel. Although functionally similar to mass spectrometers, ion mobility spectrometers are operated in air at ambient pressure, and ion mobility spectrometry is not a form of mass spectrometry. Ion mobility spectrometry does not measure molecular mass and provides no structural information. However, it is so widely used that we introduce it here.

Electrophoresis, which is discussed in Chapter 25, is the migration of ions in solution under the influence of an electric field. Ion mobility spectrometry is gas-phase electrophoresis, which separates ions according to their size-to-charge ratio. Unlike mass spectrometry, ion mobility spectrometry is capable of separating isomers. Ion mobility can be used to study large protein assemblies with masses up to $50 \mathrm{MDa} .^{23}$

At first sight, the ion mobility spectrometer in Figure 21-20a reminds us of a time-of-flight spectrometer. In portable units, the drift tube is 5 to 10 cm long. Typically, sample adsorbed on a cotton swab is placed in the heated anvil at the left to desorb analyte vapor. Dry air doped with a chemical ionization reagent (such as $\mathrm{Cl}_{2}$ for anions and acetone or $\mathrm{NH}_{3}$ for cations) sweeps the vapor through a tube containing 10 millicuries of radioactive ${ }^{63} \mathrm{Ni}$. Reagent gas ionized by $\beta$-emission from ${ }^{63} \mathrm{Ni}$ reacts with analyte to generate analyte ions.

A spectral scan is initiated when a $\sim 250-\mu \mathrm{s}$ voltage pulse on a gating grid admits a packet of ions into the drift tube. An electric field of $200-300 \mathrm{~V} / \mathrm{cm}$ in the drift region is established by potential differences on the drift rings. The field causes either cations or anions to drift to the right at $\sim 1$ to $2 \mathrm{~m} / \mathrm{s}$. Ions are retarded by collisions with gas molecules at atmospheric pressure. Each ion travels at its own speed equal to $K E$, where $E$ is the electric field and $K$ is the mobility. Small ions have greater mobility than large ions of the same charge because large ions experience more drag.

The ion mobility "spectrum" in Figure 21-20b is a graph of detector response versus drift time for several explosives. Peak area is proportional to the number of ions. Peaks are identified by their mobility, which is reproducibly measured relative to that of an internal standard. Runs are repeated $\sim 20$ times per second. The displayed spectrum averages many runs and requires $2-5$ s to obtain.

Detection limits are 0.1 to 1 pg for compounds with favorable ionization chemistry. Mobility spectrometers have limited resolution, but false positives are minimized by combining mobility determinations with selective ionization. Resolution can be improved by operating in a closed chamber with pressures of $2-4$ bar. ${ }^{24}$ Ion mobility separations are now being combined with mass spectrometry to identify the separated components.

(a)

## 21-4 Chromatography-Mass Spectrometry

Mass spectrometry is widely used as the detector in chromatography to provide both qualitative and quantitative information. The spectrometer can be highly selective for the analyte of interest. This selectivity eases the requirements for sample preparation or complete chromatographic separation of components in a mixture, and it increases the signal-to-noise ratio.

Mass spectrometry requires high vacuum to prevent molecular collisions during ion separation. Chromatography is inherently a high-pressure technique. The problem in marrying the two techniques is to remove the huge excess of matter between the chromatograph and the spectrometer. Gas chromatography felicitously evolved to employ narrow capillary columns whose eluate does not overwhelm the pumping capabilities of the mass spectrometer vacuum system. The capillary column is connected directly to the inlet of the mass spectrometer through a heated transfer line, as in Figures 21-13 and 21-16. ${ }^{25}$

Liquid chromatography creates a huge volume of gas when solvent vaporizes at the interface between the column and the mass spectrometer. ${ }^{26}$ Most of this gas must be removed prior to ion separation. Nonvolatile mobile-phase additives (such as phosphate buffer), which are common in chromatography, must be avoided for mass spectrometry. Electrospray ionization and atmospheric pressure chemical ionization are dominant methods for introducing eluate from liquid chromatography into a mass spectrometer.

## Electrospray Ionization

Electrospray ionization, ${ }^{28}$ also called ion spray, is illustrated in Figure 21-21a. Liquid from the chromatography column enters the steel nebulizer capillary at the upper left, along with a coaxial flow of $\mathrm{N}_{2}$ gas. For positive ion mass spectrometry, the nebulizer is held at 0 V and

FIGURE 21-20 (a) Schematic illustration of ion mobility spectrometer. The aperture grid prevents serious line broadening. Ions approaching a bare detector plate induce current, which appears as signal before the arrival of the ions. The aperture grid protects the detector from induced current until ions are between the grid and the detector. (b) Negative ion mobility spectrum of explosives designated RDX, TNT, PETN, and so on. The calibrant 4-nitrobenzonitrile is an internal mobility standard. $\mathrm{Cl}_{2}$ is the reagent gas for generating anions by chemical ionization.
[Courtesy W. R. Stott, Smiths Detection, Toronto.]

Volatile buffer components and additives for liquid chromatography that are compatible with mass spectrometry include $\mathrm{NH}_{3}, \mathrm{HCO}_{2} \mathrm{H}$, $\mathrm{CH}_{3} \mathrm{CO}_{2} \mathrm{H}, \mathrm{CCl}_{3} \mathrm{CO}_{2} \mathrm{H},\left(\mathrm{CH}_{3}\right)_{3} \mathrm{~N}$, and $\left(\mathrm{C}_{2} \mathrm{H}_{5}\right)_{3} \mathrm{~N}$. Avoid additive concentrations $>20 \mathrm{mM}$ and detergent concentrations $>10 \mu \mathrm{M}$.
J. B. Fenn received part of the Nobel Prize in chemistry in $2002{ }^{27}$ for electrospray ionization. K. Tanaka received part of the same prize for matrix-assisted laser desorption/ionization, described in Box 21-4.

FIGURE 21-21 (a) Pneumatically assisted electrospray interface for mass spectrometry. (b) Gas-phase ion formation. [Adapted from E. C. Huang, T. Wachs, J. J. Conboy, and J. D. Henion, "Atmospheric Pressure Ionization Mass Spectrometry," Anal. Chem. 1990, 62, 713A and P. Kebarle and L. Tang, "From lons in Solution to lons in the Gas Phase," Anal. Chem. 1993, 65, 972A.] (c) Electrospray from a silica capillary. [Courtesy R. D. Smith, Pacific Northwest Laboratory, Richland, WA.]
the spray chamber is held at -3500 V . For negative ion mass spectrometry, all voltages are reversed. The strong electric field at the nebulizer outlet, combined with the coaxial flow of $\mathrm{N}_{2}$ gas, creates a fine aerosol of charged particles.

Typically, but not always, ions that vaporize from aerosol droplets were already in solution in the chromatography column. For example, protonated bases $\left(\mathrm{BH}^{+}\right)$and ionized acids $\left(\mathrm{A}^{-}\right)$ can be observed. Other gas-phase ions arise from complexation between analyte, M (which could be neutral or charged), and stable ions from the solution. Examples include

$$
\begin{aligned}
& \mathrm{MH}^{+}(\text {mass }=\mathrm{M}+1) \\
& \mathrm{M}\left(\mathrm{NH}_{4}^{+}\right)(\text {mass }=\mathrm{M}+18) \\
& \mathrm{M}\left(\mathrm{Na}^{+}\right)(\text {mass }=\mathrm{M}+23)
\end{aligned}
$$

$$
\begin{aligned}
& \mathrm{M}\left(\mathrm{~K}^{+}\right)(\text {mass }=\mathrm{M}+39) \\
& \mathrm{M}\left(\mathrm{HCO}_{2}^{-}\right)(\text {mass }=\mathrm{M}+45) \\
& \mathrm{M}\left(\mathrm{CH}_{3} \mathrm{CO}_{2}^{-}\right)(\text {mass }=\mathrm{M}+59)
\end{aligned}
$$

For protein electrospray, it is common to find multiply charged ions such as $[\mathrm{M}+n \mathrm{H}]^{n+}$ and, sometimes, $[\mathrm{M}+n \mathrm{Na}]^{n+}$ or $\left[\mathrm{M}+n \mathrm{NH}_{4}\right]^{n+}$. There is little fragmentation in electrospray.

Positive ions from the aerosol are attracted toward the glass capillary leading into the mass spectrometer by an even more negative potential of -4500 V . Gas flowing from atmospheric pressure in the spray chamber transports ions to the right through the capillary to the exit, where the pressure is reduced to $\sim 300 \mathrm{~Pa}$ ( $\sim 2$ Torr) by a vacuum pump.

Figure 21-21b provides more detail on ionization. Voltage imposed between the steel nebulizer capillary and the inlet to the mass spectrometer creates excess charge in the liquid by redox reactions. If the nebulizer is positively biased, oxidation enriches the liquid in positive ions by reactions such as

$$
\begin{aligned}
\mathrm{Fe}(s) & \rightarrow \mathrm{Fe}^{2+}+2 \mathrm{e}^{-} \\
\mathrm{H}_{2} \mathrm{O}(l) & \rightarrow \frac{1}{2} \mathrm{O}_{2}+2 \mathrm{H}^{+}+2 \mathrm{e}^{-}
\end{aligned}
$$

Electrons from the oxidation flow through the external circuit and eventually neutralize gaseous positive ions at the inlet to the mass spectrometer. It is possible for analyte to be chemically altered by species such as $\mathrm{HO}^{\circ}$ generated during electrospray. ${ }^{29}$

Charged liquid exiting the capillary forms a cone and then a fine filament and finally breaks into a spray of fine droplets (see Figure 21-21c and the opening of this chapter). It is thought that a droplet shrinks to $\sim 1 \mu \mathrm{~m}$ by solvent evaporation until the repulsive force of the excess charge equals the cohesive force of surface tension. At that point, the droplet breaks up by ejecting tiny droplets with diameters of $\sim 10 \mathrm{~nm}$. They evaporate, leaving their cargo of ions in the gas phase. Aerodynamic forces might also contribute to droplet breakup. ${ }^{30}$

In electrospray, little fragmentation of analyte occurs and mass spectra are simple. Fragmentation can be intentionally increased by collisionally activated dissociation (also referred to as collision-induced dissociation) in the region between the glass capillary and the skimmer cone in Figure 21-21a. The pressure in this region is $\sim 300 \mathrm{~Pa}$ ( $\sim 2$ Torr) and the background gas is mainly $\mathrm{N}_{2}$. In Figure 21-21a, the outlet of the glass capillary is coated with a metal layer that is held at +40 V . The potential difference between the metal skimmer cone and the capillary is $-20-(40)=-60 \mathrm{~V}$. Positive ions accelerated through 60 V collide with $\mathrm{N}_{2}$ molecules with enough energy to break into a few fragments. Adjusting the skimmer cone voltage controls the degree of fragmentation. A small voltage difference favors molecular ions, whereas a large voltage difference creates fragments that aid in identification of analyte. Collisionally activated dissociation also tends to break apart complexes such as $\mathrm{M}\left(\mathrm{Na}^{+}\right)$.

For example, with a cone voltage difference of -20 V , the positive ion spectrum of the drug acetaminophen exhibits a base peak at $m / z 152$ for the protonated molecule, $[\mathrm{M}+\mathrm{H}]^{+}$ (colored species in the margin). A smaller peak at $m / z 110$ probably corresponds to the fragment shown in the margin. When the cone voltage difference is -50 V , collisionally activated dissociation decreases the peak at $\mathrm{m} / \mathrm{z} 152$ and increases the fragment peak at $\mathrm{m} / \mathrm{z}$ 110. The negative ion spectrum has a large peak at $m / z 150$ for $[\mathrm{M}-\mathrm{H}]^{-}$. As the cone voltage difference is raised from +20 V to +50 V , this peak decreases and a fragment at $\mathrm{m} / \mathrm{z} 107$ increases.

Figure 21-22 shows an electrospray interface for capillary electrophoresis. The silica capillary is contained in a stainless steel capillary held at the required outlet potential for electrophoresis. The steel makes electrical contact with the liquid inside the silica by a liquid sheath flowing between the capillaries. The sheath liquid, which is typically a mixed organic/aqueous solvent, constitutes $\sim 90 \%$ of the aerosol.

You, the chemist, need to adjust the pH of the chromatography solvent to favor $\mathrm{BH}^{+}$or $\mathrm{A}^{-}$ for mass spectrometric detection.

Electrospray requires low buffer concentration so that buffer ions do not overwhelm analyte ions in the mass spectrum. Low-surfacetension organic solvent is better than water. In reversed-phase chromatography (Section 24-1), it is good to use a stationary phase that strongly retains analyte so that a high fraction of organic solvent can be used. A flow rate of 0.05 to $0.4 \mathrm{~mL} / \mathrm{min}$ is best for electrospray.

Collisionally activated dissociation of acetaminophen:

FIGURE 21-23 (a) Atmospheric pressure chemical ionization interface between a liquid chromatography column and a mass spectrometer. A fine aerosol is produced by the nebulizing gas flow and the heater. The electric discharge from the corona needle creates gaseous ions from the analyte. [Adapted from E. C. Huang, T. Wachs, J. J. Conboy, and J. D. Henion, "Atmospheric Pressure lonization Mass Spectrometry," Anal. Chem. 1990, 62, 713A.] (b) Atmospheric pressure chemical ionization probe. [Courtesy Shimadzu Scientific Instruments, Columbia, MD.]

## Atmospheric Pressure Chemical Ionization

In atmospheric pressure chemical ionization, heat and a coaxial flow of $\mathrm{N}_{2}$ convert eluate into a fine mist from which solvent and analyte evaporate (Figure 21-23). Like chemical ionization in the ion source of a mass spectrometer, atmospheric pressure chemical ionization creates new ions from gas-phase reactions between ions and molecules. The distinguishing feature of this technique is that a high voltage is applied to a metal needle in the path of the aerosol. An electric corona (a plasma containing charged particles) forms around the needle, injecting electrons into the aerosol and creating ions. For example, protonated analyte, $\mathrm{MH}^{+}$, can be formed in the following manner:

$$
\begin{aligned}
\mathrm{N}_{2}+\mathrm{e}^{-} & \rightarrow \mathrm{N}_{2}^{+\cdot}+2 \mathrm{e}^{-} \\
\mathrm{N}_{2}^{+\cdot}+2 \mathrm{~N}_{2} & \rightarrow \mathrm{~N}_{4}^{+\cdot}+\mathrm{N}_{2} \\
\mathrm{~N}_{4}^{+\cdot}+\mathrm{H}_{2} \mathrm{O} & \rightarrow \mathrm{H}_{2} \mathrm{O}^{+\cdot}+2 \mathrm{~N}_{2} \\
\mathrm{H}_{2} \mathrm{O}^{+\cdot}+\mathrm{H}_{2} \mathrm{O} & \rightarrow \mathrm{H}_{3} \mathrm{O}^{+}+{ }^{\bullet} \mathrm{OH} \\
\mathrm{H}_{3} \mathrm{O}^{+}+n \mathrm{H}_{2} \mathrm{O} & \rightarrow \mathrm{H}_{3} \mathrm{O}^{+}\left(\mathrm{H}_{2} \mathrm{O}\right)_{n} \\
\mathrm{H}_{3} \mathrm{O}^{+}\left(\mathrm{H}_{2} \mathrm{O}\right)_{n}+\mathrm{M} & \rightarrow \mathrm{MH}^{+}+(n+1) \mathrm{H}_{2} \mathrm{O}
\end{aligned}
$$

Analyte M might also form a negative ion by electron capture:

$$
\mathrm{M}+\mathrm{e}^{-} \quad \rightarrow \quad \mathrm{M}^{-}
$$

A molecule, $\mathrm{X}-\mathrm{Y}$, in the eluate might create a negative ion by the reaction

$$
\mathrm{X}-\mathrm{Y}+\mathrm{e}^{-} \quad \rightarrow \quad \mathrm{X}^{\cdot}+\mathrm{Y}^{-}
$$

The species $\mathrm{Y}^{-}$could abstract a proton from a weakly acidic analyte, AH :

$$
\mathrm{AH}+\mathrm{Y}^{-} \quad \rightarrow \quad \mathrm{A}^{-}+\mathrm{HY}
$$

Atmospheric pressure chemical ionization handles a variety of analytes and accepts chromatography flow rates up to $2 \mathrm{~mL} / \mathrm{min}$. Generally, to be observed, analyte M must be capable of forming the protonated ion, $\mathrm{MH}^{+}$. Atmospheric pressure chemical ionization tends to produce single-charge ions and is unsuitable for macromolecules such as proteins. There is little fragmentation, but the skimmer cone voltage difference can be adjusted to favor collisionally activated dissociation into a small number of fragments.

## Selected Ion Monitoring and Extracted Ion Monitoring

Selected ion monitoring and extracted ion monitoring increase the selectivity of mass spectrometry for individual analytes and decrease the response to everything else (decreasing

FIGURE 21-24 Chromatograms of herbicides (designated 1-6) spiked into river water at a level near 1 ppb demonstrate increased signal-to-noise ratio in selected ion monitoring. (a) Ultraviolet detection at 240 nm . (b) Electrospray reconstructed total ion chromatogram. (c) Electrospray selected ion monitoring at $m / z$ 312. [From A. Laganà, G. Fago, and A. Marino, "Simultaneous Determination of Imidazolinone Herbicides from Soil and Natural Waters," Anal. Chem. 1998, 70, 121.]
background noise). Figure 21-24a shows a liquid chromatogram with ultraviolet absorbance detection of a mixture of herbicides (designated 1-6) spiked at a level near 1 ppb into river water. (Spiked means deliberately added.) The broad hump underlying the analytes represents many natural substances in the river water. The simplest way to use a mass spectrometer as a chromatographic detector is to substitute it for the ultraviolet monitor and add up the total current of all ions of all masses detected above a selected value. This reconstructed total ion chromatogram is shown in Figure 21-24b, which is just as congested as the ultraviolet chromatogram because all substances emerging at any moment contribute to the signal. This chromatogram is "reconstructed" by a computer from individual mass spectra recorded during chromatography.

To be more selective, we use selected ion monitoring in which the mass spectrometer is set to monitor just a few values of $\mathrm{m} / \mathrm{z}$ (never more than four or five in any time interval). Figure 21-24c shows the selected ion chromatogram for which just $\mathrm{m} / \mathrm{z} 312$ is monitored. The signal corresponds to $\mathrm{MH}^{+}$from herbicide 6 , which is imazaquin. The signal-to-noise ratio in selected ion monitoring is greater than the signal-to-noise ratio in chromatograms $a$ or $b$ because (1) most of the spectral acquisition time is spent collecting data in a small mass range and (2) little but the intended analyte gives a signal at $\mathrm{m} / \mathrm{z} 312$.

An extracted ion chromatogram is like a selected ion chromatogram, but the extracted ion chromatogram does not benefit from taking all available time to measure just one or a few mass spectral peaks. To create an extracted ion chromatogram, the entire mass spectrum is

FIGURE 21-25 (a) Total ion chromatogram of pesticides from fruit-based soft drinks from London's Gatwick Airport. (b) Extracted ion chromatogram set for thiabendazole with $m / z$ window $202.043 \pm 0.01$. Inset shows mass spectrum of thiabendazole peak at 9.31 min . [From J. F. García-Reyes, B. Gilbert-López, A. MolinaDíaz, and A. R. Fernández-Alba, "Determination of Pesticide Residues in Fruit-Based Soft Drinks," Anal. Chem. 2008, 80, 8966.]

Selected reaction monitoring is one of several techniques carried out by consecutive mass filters. These techniques are collectively called tandem mass spectrometry or mass spectrometry/mass spectrometry or simply MS/MS.

recorded repeatedly during chromatography. Then one value of $\mathrm{m} / \mathrm{z}$ is taken from each spectrum for display. For example, the chromatogram might display the intensity of $\mathrm{m} / \mathrm{z} 312$ observed as a function of time. In selected ion monitoring, only the $m / z 312$ signal would be collected. For the extracted ion chromatogram, all values of $\mathrm{m} / \mathrm{z}$ are measured, but only $\mathrm{m} / \mathrm{z}$ 312 intensity is displayed. You should collect the entire mass spectrum when you do not know what you are looking for and you want to observe everything.

Figure 21-25 shows an important example of an extracted ion chromatogram. By using liquid chromatography-high resolution time-of-flight mass spectrometry, it is possible to search for 100 pesticides at once in food extracts. The time-of-flight spectrometer provides nearly unique identification of small molecules, such as pesticides, by exact mass measurement with uncertainties of $\sim 1-2$ parts per million in $m / z$. Components of fruit-based soft drinks isolated by solid-phase extraction (Section 27-3) were separated by liquid chromatography to obtain the complex total ion chromatogram in the upper part of Figure 21-25. When the extracted ion chromatogram window was set for $m / z 202.043 \pm 0.01$ to find the pesticide thiabendazole, one major peak at 9.31 min was observed. Combined levels of several pesticides found in the majority of tested soft drinks from several countries exceeded European allowed maximum residue levels for drinking water by factors of 10 to 35 .

## Selected Reaction Monitoring

Selectivity and signal-to-noise ratio in a chromatogram is increased markedly by selected reaction monitoring, illustrated in Figure 21-26 with a triple quadrupole mass spectrometer. A mixture of ions enters quadrupole Q 1 , which passes just one selected precursor ion to the second stage, Q2. The second stage passes all ions of all masses straight on to the third stage, Q3. However, while inside Q2, which is called a collision cell, the precursor ion collides with $\mathrm{N}_{2}$ or Ar at a pressure of $\sim 10^{-3}$ to $10^{-1} \mathrm{~Pa}\left(\sim 10^{-5}\right.$ to $\left.10^{-3} \mathrm{Torr}\right)$ and breaks into fragments called product ions. Quadrupole Q3 allows only specific product ions to reach the detector.

Selected reaction monitoring is highly selective for the analyte of interest. An example is provided by the analysis of human estrogens in sewage at parts per trillion levels (ng/L).

column

(b)

FIGURE 21-26 (a) Principle of selected reaction monitoring, also called tandem mass spectrometry, mass spectrometry/mass spectrometry, or MS/MS. (b) Cutaway view of triple quadrupole mass spectrometer. [Courtesy Agilent Technologies, Santa Clara, CA.]

Estrogens are hormones in the ovarian cycle. The synthetic estrogen, $17 \alpha$-ethinylestradiol (designated $\mathrm{EE}_{2}$ ) is a contraceptive. Even at parts per trillion levels, some estrogens can provoke reproductive disturbances in fish.

A project in Italy measured the estrogens entering the aquatic environment from human waste. Now think about this problem. Sewage contains thousands of organic compoundsmany at high concentrations. To measure nanograms of one analyte was beyond the capabilities of analytical chemistry until recently. Some sample preparation was necessary to remove polar compounds from the less polar analyte and to preconcentrate analyte. Raw sewage ( 150 mL ) was filtered to remove particles $>1.5 \mu \mathrm{~m}$ and then passed through a solid-phase extraction cartridge (Section 27-3) containing carbon adsorbent that retained analyte. The cartridge was washed with polar solvents to remove polar materials. Estrogens were washed from the cartridge by a mixture of dichloromethane and methanol. Solvent was evaporated and the residue was dissolved in $200 \mu \mathrm{~L}$ of aqueous solution containing another estrogen as internal standard. A volume of $50 \mu \mathrm{~L}$ was injected for chromatography.

Figure 21-27a shows the collisionally activated dissociation mass spectrum of the deprotonated molecule of estrogen $\mathrm{EE}_{2}$. The precursor ion $[\mathrm{M}-\mathrm{H}]^{-}(\mathrm{m} / \mathrm{z} 295)$ obtained by electrospray was isolated by mass separator Q1 in Figure 21-26 and sent into Q2 for collisionally activated dissociation. Then all fragments $>m / z 140$ were analyzed by Q3 to give the mass spectrum in Figure 21-27a. For subsequent selected reaction monitoring, only the product ions at $\mathrm{m} / \mathrm{z} 159$ and 145 would be selected by Q3. The chromatogram in Figure 21-27b shows the signal from these product ions when $m / z 295$ was selected by Q1. From the area of the peak for $\mathrm{EE}_{2}$, its concentration in the sewage is calculated to be $3.6 \mathrm{ng} / \mathrm{L}$. Amazingly, there are other compounds that contribute mass spectral signals for this same set of masses $(295 \rightarrow 159+145)$ at elution times of $15-18 \mathrm{~min} . \mathrm{EE}_{2}$ was identified by its retention time and its complete mass spectrum.

Since the pioneering study, the widespread problem of pharmaceuticals and illegal drugs in municipal wastewater has been recognized. ${ }^{32}$ Wastes that we generate find their way from wastewater into drinking water and the environment.

Other combinations of mass separators can be used for selected reaction monitoring. For example, in Figure 21-19, the linear ion trap can select the precursor ion and carry out collisionally activated dissociation. Product ions would be analyzed in the orbitrap.

The process in Q2 is called collisionally activated dissociation.

In preconcentration, analyte collected from 150 mL was dissolved in $200 \mu \mathrm{~L}$. The concentration increased by a factor of

$$
\frac{150 \times 10^{-3} \mathrm{~L}}{200 \times 10^{-6} \mathrm{~L}}=750
$$

$3.6 \mathrm{ng} / \mathrm{L}$ in sewage became $750 \times 3.6 \mathrm{ng} / \mathrm{L}=$ $2.7 \mu \mathrm{~g} / \mathrm{L}$ for chromatography.

FIGURE 21-27 (a) Electrospray tandem mass spectrum of pure estrogen $\mathrm{EE}_{2}$. The ion $[\mathrm{M}-\mathrm{H}]^{-}(\mathrm{m} / \mathrm{z} 295)$ was selected by quadrupole Q1 in Figure 21-26 and dissociated in Q2; the full spectrum of fragments was measured by Q3. (b) Selected reaction monitoring chromatogram showing the elution of $3.6 \mathrm{ng} / \mathrm{L}$ of estrogen $E E_{2}$ extracted from sewage. The signal is the sum of $m / z 159+145$ from Q 3 when $m / z 295$ was selected by Q1. [From C. Baronti, R. Curini, G. D'Ascenzo, A. di Corcia, A. Gentili, and R. Samperi, "Monitoring Estrogens at Activated Sludge Sewage Treatment Plants and in a Receiving River Water," Environ. Sci. Tech. 2000, 34, 5059.]

The three-dimensional quadrupole ion-trap mass spectrometer in Figure 21-16 can perform selected reaction monitoring without additional hardware. After a collection of ions of different $m / z$ is injected into the ion trap, all but one $m / z$ are intentionally ejected. Precursor ions with the single $\mathrm{m} / \mathrm{z}$ remaining in the ion trap are then given increased kinetic energy by increasing the amplitude of the applied radio-frequency electric field. Increased energy promotes collisional dissociation with background He atoms in the ion trap. Product ions are retained in the trap but do not have enough kinetic energy for further collisional dissociation. After a period of dissociation of the precursor ion, product ions are expelled to the detector to record a mass spectrum.

This process can be repeated by selecting a product ion for further dissociation. The repeated process is called $\mathrm{MS}^{n}$, which denotes multiple repetitions of selected reaction monitoring. The beauty of $\mathrm{MS}^{n}$ with a three-dimensional quadrupole ion trap is that the entire process takes place in one piece of hardware under software control. To conduct more cycles of selected reaction monitoring with the equipment in Figure 21-26, it would be necessary to add another Q2 and Q3 chamber for each cycle, which is not practical.

## Electrospray of Proteins

Electrospray is well suited for the study of charged macromolecules such as proteins. ${ }^{35,36}$ It has been used to study intact viruses with masses up to 40 MDa . ${ }^{37}$ A typical protein has carboxylic acid and amine side chains (Table 9-1) that give it a net positive or negative charge, depending on pH . Electrospray (Figure 21-21) ejects preexisting ions from solution into the gas phase.

Each peak in the mass spectrum of the protein transferrin in Figure 21-28 arises from molecules with different numbers of protons, $\mathrm{MH}_{n}^{n+} .38$ Although we have already labeled charges

$m / z \rightarrow$

FIGURE 21-28 Electrospray time-of-flight mass spectrum of one anion-exchange chromatographic peak containing the protein transferrin with one particular set of carbohydrate substituents. Peaks arise from species with different numbers of protons, $M_{n}^{n+}$. [From M. E. Del Castillo Busto, M. Montes-Bayón, E. Blanco-González, J. Meija, and A. Sanz-Medel, "Strategies to Study Human Serum Transferrin Isoforms Using Integrated Liquid Chromatography ICPMS, MALDI-TOF, and ESI-Q-TOF Detection: Application to Chronic Alcohol Abuse," Anal. Chem. 2005, 77, 5615.]

Major methods for introducing proteins and other macromolecules into mass spectrometers are electrospray and matrix-assisted laser desorption/ionization (MALDI). ${ }^{20,33}$ Most often, MALDI is used with a time-of-flight mass spectrometer, which can measure $m / z$ up to $10^{6}$. Typically, $1 \mu \mathrm{~L}$ of a $10-\mu \mathrm{M}$ solution of analyte is mixed with $1 \mu \mathrm{~L}$ of a 1 - to $100-\mathrm{mM}$ solution of an ultraviolet-absorbing compound such as 2,5 -dihydroxybenzoic acid (the matrix) directly on a probe that fits into the source of the spectrometer. Evaporation of the liquid leaves an intimate mixture of fine crystals of matrix plus analyte.

To introduce ions into the gas phase for mass spectrometry, a brief infrared or ultraviolet pulse ( 600 ps ) from a laser is directed
onto the sample. The matrix vaporizes and expands into the gas phase, carrying analyte along with it. The high matrix/sample ratio inhibits association between analyte molecules and provides protonated or ionic species that transfer charge to analyte, much of which carries a single charge. Shortly after ions expand into the source, a voltage pulse applied to the backplate expels ions into the spectrometer. The resolving power is $10^{3}-10^{4}$, and mass accuracy can be $0.005-0.05 \%$. The spectrum below shows proteins from milk that has not undergone any sample preparation except for mixing with the matrix. It is possible to map differences in chemical composition in different regions by directing a laser at different parts of fixed cells, such as neurons. ${ }^{34}$

(b1) Enlarged view of laser pulse striking sample. (b2) Matrix is ionized and vaporized by laser and transfers some charge to analyte. (b3) Vapor expands in a supersonic plume.

Partial mass spectrum of cow's milk (containing $2 \%$ milk fat) observed by MALDI/time-of-flight mass spectrometry. [From R. M. Whittal and L. Li, "Time-Lag Focusing MALDI-TOF Mass Spectrometry," Am. Lab., December 1997, p. 30.]
on several peaks, we do not know what these charges are before analyzing the spectrum. If we can find the charge for each species, we can find the molecular mass, $M$, of the neutral protein.

To find the charge, consider a peak with $\mathrm{m} / z=m_{n}$ derived from the neutral molecule plus $n$ protons:

$$
\begin{equation*}
m_{n}=\frac{\text { mass }}{\text { charge }}=\frac{M+n(1.008)}{n}=\frac{M}{n}+1.008 \Rightarrow m_{n}-1.008=\frac{M}{n} \tag{21-4}
\end{equation*}
$$

Mass $=$ mass of protein $(M)+$ mass of $n$ atoms of $\mathrm{H}(n \times 1.008)$.

The next peak at lower $m / z$ should have $n+1$ protons and a charge of $n+1$. For this peak,

$$
m_{n+1}=\frac{M+(n+1)(1.008)}{n+1}=\frac{M}{n+1}+1.008 \Rightarrow m_{n+1}-1.008=\frac{M}{n+1} \text { (21-5) }
$$

source: M. E. Del Castillo Busto, M. Montes-Bayón, E. Blanco-González, J. Meija, and A. Sanz-Medel, "Strategies to Study Human Serum Transferrin Isoforms Using Integrated Liquid Chromatography ICPMS, MALDI-TOF, and ESI-Q-TOF Detection: Application to Chronic Alcohol Abuse," Anal. Chem. 2005, 77, 5615.

Forming the quotient of the expressions in the boxes, we get

$$
\begin{equation*}
\frac{m_{n}-1.008}{m_{n+1}-1.008}=\frac{M / n}{M /(n+1)}=\frac{n+1}{n} \tag{21-6}
\end{equation*}
$$

Solving Equation 21-6 for $n$ gives the charge on peak $m_{n}$ :

$$
\begin{equation*}
n=\frac{m_{n+1}-1.008}{m_{n}-m_{n+1}} \tag{21-7}
\end{equation*}
$$

The fourth column in Table 21-3 shows the charge of each peak, $n$, calculated with Equation 21-7. The charge of the peak at $m / z 2652.7227$ is $n=30$. We assign this peak as $\mathrm{MH}_{30}^{30+}$. The next peak at $m / z 2567.2205$ is $\mathrm{MH}_{31}^{31+}$, and so on. We find highly protonated species because the chromatography solvent was acidic ( $95 \mathrm{vol} \%$ acetonitrile $+5 \mathrm{vol} \%$ $\mathrm{H}_{2} \mathrm{O}+0.2 \mathrm{vol} \%$ formic acid). Even without adding formic acid, electrolysis in positive-ion electrospray produces $\mathrm{H}^{+}$by oxidation of $\mathrm{H}_{2} \mathrm{O}$.

From any peak, we can find the mass of the neutral molecule by rearranging the right side of Equation 21-4:

$$
\begin{equation*}
M=n \times\left(m_{n}-1.008\right) \tag{21-8}
\end{equation*}
$$

Reproducible masses computed with Equation 21-8 appear in the last column of Table 21-3. A limitation on the accuracy of molecular mass determination is the accuracy of the $\mathrm{m} / \mathrm{z}$ scale. For this work, $m / z$ was calibrated with an external standard of poly(propylene glycol).

## Electron-Transfer Dissociation for Protein Sequencing

We saw at the opening of Chapter 9 that proteins are chains of amino acids held together by amide (also called peptide) bonds. Proteins are synthesized on ribosomes, which are assemblies of RNA and protein whose job is to translate the sequence of DNA into a corresponding sequence of amino acids. After synthesis, some proteins are specifically modified by enzymes to add groups such as acetate, phosphate, carbohydrates, and lipids to specific amino acid side chains. A branch of biochemistry called proteomics seeks to characterize the structure and function of the full complement of proteins in an organism.

Mass spectrometry is a principal tool for deducing the sequence of amino acids in a protein. Protein is digested into shorter chains by enzymatic cleavage. Individual chains are cleaved to make fragments of all possible lengths. High-resolution mass spectrometry allows us to deduce which amino acids are in each fragment. A computer can use this information to reconstruct the sequence of amino acids.

Electron-transfer dissociation is a selective way to cleave polypeptides into fragments in a mass spectrometer. ${ }^{39}$ This process involves the exothermic transfer of an electron from a
gas-phase anion to a gas-phase polypeptide cation with concomitant bond breaking. In the chain of amino acids below,

cleavage occurs at each indicated position to form 10 possible charged fragments designated $c_{1}$ to $c_{5}$ and $z_{1}$ to $z_{5}$. In the $c$ fragments, charge resides on the fragment to the left of the broken bond. In the z fragments, charge resides on the fragment to the right of the broken bond. Unlike collisionally activated dissociation, electron-transfer dissociation does not break other bonds in the peptide chain or the side groups, including groups such as phosphate or carbohydrates bound to side chains.

The mass spectrometer in Figure 21-19, when equipped with two electrospray sources, can carry out electron-transfer dissociation for polypeptide sequencing. ${ }^{40}$ Polypeptide cations produced by electrospray for 0.2 s are collected in the linear ion trap and stored in the downstream section by application of appropriate voltages. The polypeptide source is then turned off and, after $0.4 \mathrm{~s}, 9$-anthracenecarboxylic acid solution is electrosprayed from a second source for 0.2 s . Anthracenecarboxylate anions are collected in the upstream section of the linear ion trap. Collisionally activated decarboxylation in the ion trap produces anion $\mathrm{A}^{-}$:

Potentials are then adjusted to allow anions and cations that had been at opposite ends of the ion trap to mix with one another. $\mathrm{A}^{-}$transfers an electron to a polypeptide $\mathrm{P}^{n+}$, thereby inducing electron-transfer dissociation of one peptide bond:

$$
\mathrm{A}^{-}+\mathrm{P}^{n+} \rightarrow \mathrm{A}+\mathrm{P}^{(n-1)+} \rightarrow \text { cleavage of one poptide bond }
$$

Different bonds are cleaved in individual molecules to make all possible c and z fragments drawn above. The reaction is quenched by ejecting anions from the ion trap. Finally, peptide cations are expelled and exact $m / z$ values are measured with the orbitrap in Figure 21-19. With $\mathrm{m} / \mathrm{z}$ accuracy of 1 part per million, the majority of electron-transfer dissociation product ions with $m / z<1000$ can be uniquely assigned and identified as N - or C-terminal peptides. ${ }^{41}$

## 21-5 Open-Air Sampling for Mass Spectrometry

Since 2004, new mass spectral sampling techniques have been introduced to vaporize and ionize analytes directly from the surface of an object in the open air with little harm to the object. This sampling capability opens up new vistas for mass spectrometry in qualitative analysis.

## Direct Analysis in Real Time (DART)

A direct analysis in real time (DART) source produces electronically excited He or vibrationally excited $\mathrm{N}_{2}$, which are directed at the surface of an object to be sampled in open air. In Figure 21-29, heated gas flows through a needle electrode held at +1 to +5 kV with respect to a grounded counterelectrode in the form of a perforated disk. The glow discharge plasma contains electrons, ions, and excited neutral species. Electrodes 1 and 2 are held at positive potentials for positive ion mass spectrometry and at negative potentials for negative ion mass spectrometry. At positive potential, electrodes 1 and 2 prevent cations from exiting the DART source. At negative potential, anions and electrons are retained.

The DART gun is directed at an object to be sampled. With a helium source, excited He atoms with an energy of 19.8 eV (designated $2^{3} \mathrm{~S}$ and shown as $\mathrm{He} *$ in the margin) react with atmospheric water vapor to create protonated water clusters. These clusters can react with analyte M on the surface of an object to create $\mathrm{MH}^{+}$. Other chemistry can produce $(\mathrm{M}-\mathrm{H})^{-}, \mathrm{M}^{-}$, or adducts such as $\left(\mathrm{M}+\mathrm{NH}_{4}\right)^{+}$or $(\mathrm{M}+\mathrm{Cl})^{-}$.

$$
\begin{aligned}
& \mathrm{He}^{*}+\mathrm{H}_{2} \mathrm{O} \rightarrow \mathrm{H}_{2} \mathrm{O}^{+}+\mathrm{He}+\mathrm{e}^{-} \\
& \mathrm{H}_{2} \mathrm{O}^{+}+\mathrm{H}_{2} \mathrm{O} \rightarrow \mathrm{H}_{3} \mathrm{O}^{+}+\mathrm{OH} \\
& \mathrm{H}_{3} \mathrm{O}^{+}+(n-1) \mathrm{H}_{2} \mathrm{O} \rightarrow\left(\mathrm{H}_{2} \mathrm{O}\right)_{n} \mathrm{H}^{+}
\end{aligned}
$$

FIGURE 21-30 Low-temperature plasma for sampling a surface in the open air. [From J. D. Harper, N. A. Charipar, C. C. Mulligan, X. Zhang, R. G. Cooks, and Z. Ouyang, "Low-Temperature Plasma Probe for Ambient Desorption Ionization," Anal. Chem 2008, 80, 9097.]

FIGURE 21-29 Direct Analysis in Real Time (DART) source. [Adapted from R. B. Cody, J A. Laramée, and H. D. Durst, "Versatile New lon Source for the Analysis of Materials in Open Air Under Ambient Conditions," Anal. Chem. 2005, 77, 2297 and JEOL USA, Peabody, MA.]

If the sample is a poppy seed from a bagel, two major species observed by a high-resolution time-of-flight mass spectrometer are the protonated molecules, (morphine) $\mathrm{H}^{+}$ $\left(\mathrm{C}_{17} \mathrm{H}_{19} \mathrm{NO}_{3} \mathrm{H}^{+}\right.$at $\mathrm{m} / \mathrm{z} 286.144$ 3) and (codeine) $\mathrm{H}^{+}\left(\mathrm{C}_{18} \mathrm{H}_{21} \mathrm{NO}_{3} \mathrm{H}^{+}\right.$at $\left.\mathrm{m} / \mathrm{z} 300.1611\right) .{ }^{42}$ Separate quantitative analysis shows that poppy seeds contain $\sim 33$ and $\sim 14 \mu \mathrm{~g} / \mathrm{g}(\mathrm{ppm})$ of morphine and codeine, respectively.

## Low-Temperature Plasma

In a technique related to DART, a low-temperature plasma is created by passing $\mathrm{He}, \mathrm{Ar}, \mathrm{N}_{2}$, or ambient air through a glass tube with a grounded wire at the center (Figure 21-30 and Color Plate 26). The tube is wrapped on the outside with a copper sheath to which is applied a $3-\mathrm{kV}$ alternating current. Excited-state species in the plasma ionize and dislodge molecules from a surface such as human skin into the source of a mass spectrometer. There is no electrical shock to the surface under study.

## Desorption Electrospray Ionization (DESI)

In desorption electrospray ionization (DESI), micron-sized, charged droplets created by electrospray of analyte-free solvent (Figure 21-21) are directed onto the surface of an object under study. ${ }^{43}$ Analyte on the surface dissolves in the droplets. Further bombardment knocks droplets into the air toward a mass spectrometer inlet. As in conventional electrospray, it is common to observe multiply charged ions and alkali metal adducts in the mass spectrum.

Figure 21-31 shows DESI mapping of inks on a page. A mixture of methanol and water is electrosprayed toward the paper, just 2 mm away from the spray tip. The mass spectrum ( $\mathrm{m} / \mathrm{z}, 150-600$ ) of rebounded droplets is recorded every 0.67 s . The paper is translated in small steps to make a two-dimensional map. The mass spectral signal observed at a blank area of the paper is subtracted from the signal observed from an inked area to obtain the spectrum of the ink.

In this example, the date " 1432 " was written with a blue pen. Then a second blue pen was used to change 4 to 9 and 3 to 8 , so that the date would be "1982." The second pen had a blue ink different from that in the first pen, but the difference is subtle. The objective of the demonstration was to show that the original date had been altered.
$\mathrm{CH}_{3} \mathrm{OH} / \mathrm{H}_{2} \mathrm{O}$
solvent in

FIGURE 21-31 Desorption ElectroSpray Ionization (DESI) mapping of inks. Images A, B, and C at the right are maps made by scanning the page in the $x$ and $y$ directions beneath the electrospray source. D is an optical image of the surface. [From D. R. Ifa, L. M. Gumaelius, L. S. Eberlin, N. E. Manicke, and R. G. Cooks, "Forensic Analysis of Inks by Imaging Desorption Electrospray Ionization (DESI) Mass Spectrometry," Analyst 2007, 132, 461.]

The first ink was Basic Violet 3, with a parent ion $\mathrm{M}^{+}$at $m / z 372.243$. The second ink was Solvent Blue 2, with a parent ion at $m / z$ 484.275. Map A in Figure 21-31 shows extracted-ion monitoring of $m / z 372.4$ with unit mass resolution. White shows where $m / z 372.4$ is maximal and black shows where $m / z 372.4$ is minimal. Therefore, map A shows where Basic Violet 3 ink is located. Map B is made from extracted-ion monitoring of $m / z 484.5$ with unit resolution to show where Solvent Blue 2 ink is located. We see that the second ink was written over the first ink to change " 1432 " to "1982." Map C is the sum of maps A and B. Frame D is an optical image of the writing.

## Summary

Ions are created or desorbed in the ion source of a mass spectrometer. Neutral molecules are converted into ions by electron ionization (which produces a molecular ion, $\mathrm{M}^{+\bullet}$, and many fragments) or by chemical ionization (which tends to create $\mathrm{MH}^{+}$and few fragments). A magnetic sector mass spectrometer separates gaseous ions by accelerating them in an electric field and deflecting ions of different mass-to-charge $(\mathrm{m} / \mathrm{z})$ ratio through different arcs. Ions are detected by an electron multiplier, which works like a photomultiplier tube. The mass spectrum is a graph of detector response versus $\mathrm{m} / \mathrm{z}$ value. A double-focusing mass spectrometer attains high resolution by employing an electric sector with the magnetic sector to select ions with a narrow range of kinetic energy. Other mass separators include the transmission quadrupole mass spectrometer, the time-of-flight mass spectrometer, the threedimensional quadrupole ion trap, the linear ion trap, and the orbitrap.

The time-of-flight instrument is capable of high acquisition rates and has a nearly unlimited upper mass range. Resolving power is defined as $m / \Delta m$ or $m / m_{1 / 2}$, where $m$ is the mass being measured, $\Delta m$ is the difference in mass between two peaks that are separated with a $10 \%$ valley between them, and $m_{1 / 2}$ is the width of a peak at half-height. Time-of-flight and orbitrap spectrometers can provide high-resolution spectra. An ion mobility spectrometer separates gas-phase ions by their different mobilities in an electric field at atmospheric pressure.

In a mass spectrum, the molecular ion is found from the highest $\mathrm{m} / \mathrm{z}$ value of any "significant" peak that cannot be attributed to isotopes or background signals. For a given composition, you should be able to predict the relative intensities of the isotopic peaks at $\mathrm{M}+1$, $\mathrm{M}+2$, and so on. Among common elements, Cl and Br have particularly diagnostic isotope patterns. From a molecular composition,
the rings + double bonds equation helps us propose structures. An organic compound with an odd number of nitrogen atoms will have an odd mass. Fragment ions arising from bond cleavage and rearrangements provide clues to molecular structure.

Gas emerging from a capillary gas chromatography column can go directly into the ion source of a well-pumped mass spectrometer to provide qualitative and quantitative information about the components of a mixture. For liquid chromatography, atmospheric pressure chemical ionization utilizes a corona discharge needle to create a variety of gaseous ions. Alternatively, electrospray employs high voltage at the exit of the column, combined with coaxial $\mathrm{N}_{2}$ gas flow, to create a fine aerosol containing charged species that were already present in the liquid phase. Analyte is often associated with other ions to give species such as $[\mathrm{MNa}]^{+}$or $\left[\mathrm{M}\left(\mathrm{CH}_{3} \mathrm{CO}_{2}\right)\right]^{-}$. Control of pH helps ensure that selected analytes are in anionic or cationic form. Both atmospheric pressure chemical ionization and electrospray tend to produce unfragmented ions. Collisionally activated dissociation to produce fragment ions is controlled by the cone voltage at the mass spectrometer inlet. Electrospray of proteins typically creates an array of highly charged ions such as $\mathrm{MH}_{n}^{n+}$. Matrix-assisted laser desorp-
tion/ionization is a gentle way to produce predominantly singly charged, intact protein ions for mass spectrometry.

A reconstructed total ion chromatogram shows the signal from all ions above a chosen $\mathrm{m} / \mathrm{z}$ emerging from chromatography as a function of time. An extracted ion chromatogram shows the signal for one ion taken from the complete mass spectrum. Selected ion monitoring of one or a few values of $\mathrm{m} / \mathrm{z}$ improves signal-to-noise because all of the time is spent measuring just that one or a few ions. In selected reaction monitoring, a precursor ion isolated by one mass filter passes into a collision cell in which it breaks into products. One (or more) product ion is then selected by a second mass filter for passage to the detector. This process is extremely selective for just one analyte and vastly increases the signal-to-noise ratio for this analyte. Electrontransfer dissociation is employed in protein sequencing to break amide bonds in a polypeptide without breaking other bonds.

Several methods can ionize molecules from the surface of an object in ambient atmosphere. Direct analysis in real time (DART) and a low-temperature plasma use excited-state helium or nitrogen to ionize analytes. Desorption electrospray ionization (DESI) directs electrosprayed solvent onto a surface to dislodge ions.

## Exercises

21-A. Measure the width at half-height of the peak at $m / z 53$ and calculate the resolving power of the spectrometer from the expression $\mathrm{m} / \mathrm{m}_{1 / 2}$. Would you expect to be able to resolve two peaks at 100 and 101 Da ?

Mass spectrum. [From V. J. Angelico, S. A. Mitchell, and V. H. Wysocki, "Low-Energy Ion-Surface Reactions of Pyrazine with Two Classes of Self-Assembled Monolayers," Anal. Chem. 2000, 72, 2603.]
21-B. What resolving power is required to distinguish $\mathrm{CH}_{3} \mathrm{CH}_{2}^{+}$ from $\mathrm{HC} \equiv \mathrm{O}^{+}$?
21-C. Isotope patterns. Consider an element with two isotopes whose natural abundances are $a$ and $b(a+b=1)$. If there are $n$ atoms of the element in a compound, the probability of finding each combination of isotopes is derived from the expansion of the binomial $(a+b)^{n}$. For carbon, the abundances are $a=0.9893$ for ${ }^{12} \mathrm{C}$ and $b=0.0107$ for ${ }^{13} \mathrm{C}$. The probability of finding $2{ }^{12} \mathrm{C}$ atoms in acetylene, $\mathrm{HC} \equiv \mathrm{CH}$, is given by the first term of the expansion of $(a+b)^{2}=a^{2}+2 a b+b^{2}$. The value of $a^{2}$ is $(0.9893)^{2}=0.9787$, so the probability of finding two ${ }^{12} \mathrm{C}$ atoms in acetylene is 0.978 7. The probability of finding $1{ }^{12} \mathrm{C}+1{ }^{13} \mathrm{C}$ is $2 a b=2(0.9893)(0.0107)=0.0212$. The probability of finding $2{ }^{13} \mathrm{C}$ is $(0.0107)^{2}=0.000114$. The molecular ion, by definition, contains $2{ }^{12} \mathrm{C}$ atoms. The $\mathrm{M}+1$ peak contains $1{ }^{12} \mathrm{C}+1{ }^{13} \mathrm{C}$. The intensity of $\mathrm{M}+1$ relative to $\mathrm{M}^{+\cdot}$ will be $(0.0212) /(0.9787)=0.021$ 7. (We are ignoring ${ }^{2} \mathrm{H}$ because its natural abundance is small.) Predict the relative amounts of $\mathrm{C}_{6} \mathrm{H}_{4}{ }^{35} \mathrm{Cl}_{2}, \mathrm{C}_{6} \mathrm{H}_{4}{ }^{35} \mathrm{Cl}^{37} \mathrm{Cl}$, and $\mathrm{C}_{6} \mathrm{H}_{4}{ }^{37} \mathrm{Cl}_{2}$ in 1,2-dichlorobenzene. Draw a stick diagram of the distribution, like Figure 21-6.

21-D. (a) Find the number of rings plus double bonds in a molecule with the composition $\mathrm{C}_{14} \mathrm{H}_{12}$ and draw one plausible structure.
(b) For an ion or radical, the rings + double bonds formula gives noninteger answers because the formula is based on valences in neutral molecules with all electrons paired. How many rings plus double bonds are predicted for $\mathrm{C}_{4} \mathrm{H}_{10} \mathrm{NO}^{+}$? Draw one structure for $\mathrm{C}_{4} \mathrm{H}_{10} \mathrm{NO}^{+}$.

21-E. (a) Spectra A and B belong to the isomers of $\mathrm{C}_{6} \mathrm{H}_{12} \mathrm{O}$ below. Explain how you can tell which isomer goes with each spectrum.

Mass spectra of isomeric ketones with the composition $\mathrm{C}_{6} \mathrm{H}_{12} \mathrm{O}$. [From NIST/ EPA/NIH Mass Spectral Database. ${ }^{10}$ ]
(b) The intensity of the $\mathrm{M}+1$ peak at $\mathrm{m} / \mathrm{z} 101$ must be incorrect in both spectra. It is entirely missing in spectrum A and too intense ( $15.6 \%$ of intensity of $\mathrm{M}^{+\cdot}$ ) in spectrum B. What should be the intensity of $\mathrm{M}+1$ relative to $\mathrm{M}^{+\cdot}$ for the composition $\mathrm{C}_{6} \mathrm{H}_{12} \mathrm{O}$ ?

21-F. (This is a long exercise suitable for group work.) Relative intensities for the molecular ion region of several compounds are listed in parts (a)-(d) and shown in the figure. Suggest a composition for each molecule and calculate the expected isotopic peak intensities.
(a) $m / z$ (intensity): 94 (999), 95 (68), 96 (3)
(b) $m / z$ (intensity): 156 (566), 157 (46), 158 (520), 159 (35)
(c) $m / z$ (intensity): 224 (791), 225 (63), 226 (754), 227 (60),

228 (264), 229 (19), 230 (29)
(d) $m / z$ (intensity): 154 (122), 155 (9), 156 (12) (Hint: Contains sulfur.)

Caffeine ( $\mathrm{M}=194 \mathrm{Da}$ )

Caffeine- $\mathrm{D}_{3}(\mathrm{M}=197 \mathrm{Da})$

Suppose that the following data were obtained for standard mixtures:

| Caffeine <br> $(\mathrm{mg} / \mathrm{L})$ | Caffeine-D <br> $(\mathrm{mg} / \mathrm{L})$ | Caffeine <br> peak area | Caffeine-D <br> peak area |
| :---: | :---: | :---: | :---: |
| $13.60 \times 10^{2}$ | $3.70 \times 10^{2}$ | 11438 | 2992 |
| $6.80 \times 10^{2}$ | $3.70 \times 10^{2}$ | 6068 | 3237 |
| $3.40 \times 10^{2}$ | $3.70 \times 10^{2}$ | 2755 | 2819 |

NOTE: Injected volume was different in all three runs.
(a) Compute the mean response factor in the equation

$$
\frac{\text { Area of analyte signal }}{\text { Area of standard signal }}=F\left(\frac{\text { concentration of analyte }}{\text { concentration of standard }}\right)
$$

(b) For analysis of a cola beverage, 1.000 mL of beverage was treated with $50.0 \mu \mathrm{~L}$ of standard solution containing $1.11 \mathrm{~g} / \mathrm{L}$ caffeine- $\mathrm{D}_{3}$ in methanol. The combined solution was passed through a solid-phase extraction cartridge that retains caffeine. Polar solutes were washed off with water. Then the caffeine was washed off the cartridge with an organic solvent and the solvent was evaporated to dryness. The residue was dissolved in $50 \mu \mathrm{~L}$ of methanol for gas chromatography. Peak areas were 1144 for $\mathrm{m} / \mathrm{z} 197$ and 1733 for $\mathrm{m} / \mathrm{z}$ 194. Find the concentration of caffeine ( $\mathrm{mg} / \mathrm{L}$ ) in the beverage.

## Problems

What Is Mass Spectrometry?
21-1. Briefly describe how a magnetic sector mass spectrometer works.
21-2. How are ions created for each of the mass spectra in Figure 21-4? Why are the two spectra so different?

21-3. Define the unit dalton. From this definition, compute the mass of 1 Da in grams. The mean of 60 measurements of the mass of individual $E$. coli cells vaporized by MALDI and measured with a quadrupole ion trap was $5.03( \pm 0.14) \times 10^{10} \mathrm{Da}^{3}$ Express this mass in femtograms.

21-4. Nickel has two major and three minor isotopes. For the purpose of this problem, suppose that the only isotopes are ${ }^{58} \mathrm{Ni}$ and ${ }^{60} \mathrm{Ni}$. The atomic mass of ${ }^{58} \mathrm{Ni}$ is 57.9353 Da and the mass of ${ }^{60} \mathrm{Ni}$ is 59.9332 Da . From the amplitude of the peaks in the following spectrum, calculate the atomic mass of Ni and compare your answer with the value in the periodic table.

Mass spectrum. [From Y. Su, Y. Duan, and Z. Jin, "Helium Plasma Source Time-of-Flight Mass Spectrometry: Off-Cone Sampling for Elemental Analysis," Anal. Chem. 2000, 72, 2455.]
21-5. Measure the width at half-height of the tallest peak in the spectrum below and calculate the resolving power of the spectrometer from the expression $\mathrm{m} / m_{1 / 2}$. Would you expect to be able to distinguish two peaks at 10000 and 10001 Da ?

MALDI mass spectrum of the peptide melittin. [From P. B. O'Connor and C. E. Costello, "Application of Multishot Acquisition in Fourier Transform Mass Spectrometry," Anal. Chem. 2000, 72, 5125.]

21-6. The two peaks near $m / z 31.00$ in Figure 21-9 differ in mass by 0.010 Da . Estimate the resolving power of the spectrometer from the expression $m / \Delta m$ without making any measurements in the figure.
21-7. The highest resolution mass spectra are obtained by Fourier transform ion cyclotron resonance mass spectrometry. ${ }^{45}$ Molecular ions of two peptides (chains of seven amino acids) differing in mass by 0.00045 Da were separated with a $10 \%$ valley between them. The ions each have a mass of 906.49 Da and a width at half-height of 0.00027 Da . Compute the resolving power by the $10 \%$ valley formula and by the half-width formula, both in Equation 21-1. Compare the difference in mass of these two compounds with the mass of an electron.

## The Mass Spectrum

21-8. The mass of a fragment ion in a high-resolution spectrum is 83.0865 Da . Which composition, $\mathrm{C}_{5} \mathrm{H}_{7} \mathrm{O}^{+}$or $\mathrm{C}_{6} \mathrm{H}_{11}^{+}$, better matches the observed mass?

21-9. Calculate the theoretical masses of the species in Figure 21-9 and compare your answers with the values observed in the figure.
21-10. Isotope patterns. Referring to Exercise 21-C, predict the relative amounts of $\mathrm{C}_{2} \mathrm{H}_{2}{ }^{79} \mathrm{Br}_{2}, \mathrm{C}_{2} \mathrm{H}_{2}{ }^{79} \mathrm{Br}^{81} \mathrm{Br}$, and $\mathrm{C}_{2} \mathrm{H}_{2}{ }^{81} \mathrm{Br}_{2}$ in 1,2-dibromoethylene. Compare your answer with Figure 21-7.
21-11. Isotope patterns. Referring to Exercise 21-C, predict the relative abundances of ${ }^{10} \mathrm{~B}_{2} \mathrm{H}_{6},{ }^{10} \mathrm{~B}^{11} \mathrm{BH}_{6}$, and ${ }^{11} \mathrm{~B}_{2} \mathrm{H}_{6}$ for diborane $\left(\mathrm{B}_{2} \mathrm{H}_{6}\right)$.
21-12. Find the number of rings plus double bonds in molecules with the following compositions and draw one plausible structure for each: (a) $\mathrm{C}_{11} \mathrm{H}_{18} \mathrm{~N}_{2} \mathrm{O}_{3}$; (b) $\mathrm{C}_{12} \mathrm{H}_{15} \mathrm{BrNPOS}$; (c) fragment in a mass spectrum with the composition $\mathrm{C}_{3} \mathrm{H}_{5}^{+}$.
21-13. (Each part of this problem is quite long and best worked by groups of students.) Peak intensities of the molecular ion region are listed in parts (a)-(g) and shown in the figure. Identify which peak represents the molecular ion, suggest a composition for it, and calculate the expected isotopic peak intensities. Restrict your attention to elements in Table 21-1.
(a) $m / z$ (intensity): 112 (999), 113 (69), 114 (329), 115 (21)
(b) $m / z$ (intensity): 146 (999), 147 (56), 148 (624), 149 (33), 150 (99), 151 (5)
(c) $m / z$ (intensity): 90 (2), 91 (13), 92 (96), 93 (999), 94 (71), 95 (2)
(d) $m / z$ (intensity): 226 (4), 227 (6), 228 (130), 229 (215), 230 (291), 231 (168), 232 (366), 233 (2), 234 (83) (Calculate expected intensities from isotopes of the major element present.)
(e) $m / z$ (intensity): 172 (531), 173 (12), 174 (999), 175 (10), 176 (497)
(f) $m / z$ (intensity): 177 (3), 178 (9), 179 (422), 180 (999), 181 (138), 182 (9)
(g) m/z (intensity): 182 (4), 183 (1), 184 (83), 185 (16), 186 (999), 187 (132), 188 (10)

Mass spectra for Problem 21-13. [From NIST/EPA/NIH Mass Spectral Database. ${ }^{10}$ ]

21-14. Suggest a composition for the halogen compound whose mass spectrum is shown in the figure. Assign each of the major peaks.

21-15. Box 21-3 (page 509) shows that $\mathrm{CO}_{2}$ in human breath in the United States has a value of $\delta{ }^{13} \mathrm{C}$ different from that of $\mathrm{CO}_{2}$ in human breath in mainland Europe. Suggest an explanation.
21-16. (a) The mass of ${ }^{1} \mathrm{H}$ in Table 21-1 is 1.007825 Da . Compare it with the sum of the masses of a proton and an electron given in the table. (b) ${ }^{2} \mathrm{H}$ (deuterium) contains one proton, one neutron, and one electron. Compare the sum of the masses of these three particles with the mass of ${ }^{2} \mathrm{H}$.
(c) The discrepancy in part (b) comes from the conversion of mass into binding energy that holds the nucleus together. The relation of mass, $m$, to energy, $E$, is $E=m c^{2}$, where $c$ is the speed of light. From the discrepancy in part (b), calculate the binding energy of ${ }^{2} \mathrm{H}$ in joules and in $\mathrm{kJ} / \mathrm{mol}$. ( $1 \mathrm{Da}=1.6605 \times 10^{-27} \mathrm{~kg}$ )
(d) The binding energy (ionization energy) of the electron in a hydrogen or deuterium atom is 13.6 eV . Use Table 1-4 to convert this number into $\mathrm{kJ} / \mathrm{mol}$ and compare it with the binding energy of the ${ }^{2} \mathrm{H}$ nucleus.
(e) A typical bond dissociation energy in a molecule is $400 \mathrm{~kJ} / \mathrm{mol}$. How many times larger is the nuclear binding energy of ${ }^{2} \mathrm{H}$ than a bond energy?
21-17. Isotope patterns. From the natural abundance of ${ }^{79} \mathrm{Br}$ and ${ }^{81} \mathrm{Br}$, predict the relative amounts of $\mathrm{CH}^{79} \mathrm{Br}_{3}, \mathrm{CH}^{79} \mathrm{Br}_{2}{ }^{81} \mathrm{Br}^{2} \mathrm{CH}^{79} \mathrm{Br}^{81} \mathrm{Br}_{2}$, and $\mathrm{CH}^{81} \mathrm{Br}_{3}$. As in Exercise 21-C, the fraction of each isotopic molecule comes from the expansion of $(a+b)^{3}$, where $a$ is the abundance of ${ }^{79} \mathrm{Br}$ and $b$ is the abundance of ${ }^{81} \mathrm{Br}$. Note that $(a+b)^{n}=$ $a^{n}-n a^{n-1} b+\frac{n(n-1)}{2!} a^{n-2} b^{2}+\frac{n(n-1)(n-2)}{3!} a^{n-3} b^{3}+\cdots$. Compare your answer with Figure 21-7.

21-18. Isotope patterns. (Caution: This problem could lead to serious brain injury.) For an element with three isotopes with abundances $a, b$, and $c$, the distribution of isotopes in a molecule with $n$ atoms is based on the expansion of $(a+b+c)^{n}$. Predict what the mass spectrum of $\mathrm{Si}_{2}$ will look like.

## Mass Spectrometers

21-19. Explain how a double-focusing mass spectrometer achieves high resolution.
21-20. A limitation on how many spectra per second can be recorded by a time-of-flight mass spectrometer is the time it takes the slowest ions to go from the source to the detector. Suppose we want to scan up to $\mathrm{m} / \mathrm{z} 500$. Calculate the speed of this heaviest ion if it is accelerated through 5.00 kV in the source. How long would it take to drift 2.00 m through a spectrometer? At what frequency could you record spectra if a new extraction cycle were begun each
time this heaviest ion reached the detector? What would be the frequency if you wanted to scan up to $\mathrm{m} / \mathrm{z} 1000$ ?
21-21. What is the purpose of the reflectron in a time-of-flight mass spectrometer?
21-22. (a) The mean free path is the average distance a molecule travels before colliding with another molecule. The mean free path, $\lambda$, is given by $\lambda=k T /(\sqrt{2} \sigma P)$, where $k$ is Boltzmann's constant, $T$ is temperature (K), $P$ is pressure (Pa), and $\sigma$ is the collision cross section. For a molecule with a diameter $d$, the collision cross section is $\pi d^{2}$. The collision cross section is the area swept out by the molecule within which it will strike any other molecule it encounters. The magnetic sector mass spectrometer is maintained at a pressure of $\sim 10^{-5} \mathrm{~Pa}$ ( $\sim 10^{-7}$ Torr) so that ions do not collide with (and deflect) one another as they travel through the mass analyzer. What is the mean free path of a molecule with a diameter of 1 nm at 300 K in the mass analyzer?
(b) The vacuum in an orbitrap mass separator is $\sim 10^{-8} \mathrm{~Pa}\left(\sim 10^{-13}\right.$ bar, $\sim 10^{-10}$ Torr). Find the mean free path in the orbitrap for the same conditions as (a).

## Chromatography/Mass Spectrometry

21-23. Which liquid chromatography/mass spectrometry interface, atmospheric pressure chemical ionization or electrospray, requires analyte ions to be in solution prior to the interface? How does the other interface create gaseous ions from neutral species in solution?
21-24. What is collisionally activated dissociation? At what points in a mass spectrometer does it occur?
21-25. What is the difference between a reconstructed total ion chromatogram, an extracted ion chromatogram, and a selected ion chromatogram?
21-26. What is selected reaction monitoring? Why is it also called MS/MS? Why does it improve the signal/noise ratio for a particular analyte?
21-27. (a) To detect the drug ibuprofen by liquid chromatography/mass spectrometry, would you choose the positive or negative ion mode for the spectrometer? Would you choose acidic or neutral chromatography solvent? State your reasons.

Ibuprofen (FM 206)
(b) If the unfragmented ion has an intensity of 100 , what should be the intensity of $\mathrm{M}+1$ ?

21-28. An electrospray/transmission quadrupole mass spectrum of the $\alpha$ chain of hemoglobin from acidic solution exhibits nine peaks corresponding to $\mathrm{MH}_{n}^{n+}$. Find the charge, $n$, for peaks A-I. Calculate the molecular mass of the neutral protein, M, from peaks $\mathrm{A}, \mathrm{B}, \mathrm{G}, \mathrm{H}$, and I , and find the mean value.

| Peak | $m / z$ | Amplitude | Peak | $\mathrm{m} / \mathrm{z}$ | Amplitude |
| :--- | :--- | :--- | :--- | :--- | :--- |
| A | 1261.5 | 0.024 | F | not stated | 1.000 |
| B | 1164.6 | 0.209 | G | 834.3 | 0.959 |
| C | not stated | 0.528 | H | 797.1 | 0.546 |
| D | not stated | 0.922 | I | 757.2 | 0.189 |
| E | not stated | 0.959 |  |  |  |

21-29. The molecular ion region in the mass spectrum of a large molecule, such as a protein, consists of a cluster of peaks differing by 1 Da . This pattern occurs because a molecule with many atoms has a high probability of containing one or several atoms of ${ }^{13} \mathrm{C}$, ${ }^{15} \mathrm{~N},{ }^{18} \mathrm{O},{ }^{2} \mathrm{H}$, and ${ }^{34} \mathrm{~S}$. In fact, the probability of finding a molecule with only ${ }^{12} \mathrm{C},{ }^{14} \mathrm{~N},{ }^{16} \mathrm{O},{ }^{1} \mathrm{H}$, and ${ }^{32} \mathrm{~S}$ may be so small that the nominal molecular ion is not observed. The electrospray mass spectrum of the rat protein interleukin- 8 consists of a series of clusters of peaks arising from intact molecular ions with different charges. One cluster has peaks at $m / z 1961.12,1961.35,1961.63,1961.88$, 1962.12 (tallest peak), $1962.36,1962.60,1962.87,1963.10$, $1963.34,1963.59,1963.85$, and 1964.09 . These peaks correspond to isotopic ions differing by 1 Da . From the observed peak separation, find the charge of the ions in this cluster. From $\mathrm{m} / \mathrm{z}$ of the tallest peak, estimate the molecular mass of the protein.
21-30. Phytoplankton at the ocean surface maintain the fluidity of their cell membranes by altering their lipid (fat) composition when the temperature changes. When the ocean temperature is high, plankton synthesize relatively more 37:2 than 37:3. ${ }^{46}$

After they die, plankton sink to the ocean floor and end up buried in sediment. The deeper we sample a sediment, the further back into time we delve. By measuring the relative quantities of cell-membrane compounds at different depths in the sediment, we can infer the temperature of the ocean long ago.

The molecular ion regions of the chemical ionization mass spectra of $37: 2$ and $37: 3$ are listed in the table. Predict the expected intensities of $\mathrm{M}, \mathrm{M}+1$, and $\mathrm{M}+2$ for each of the four species listed. Include contributions from C, H, O, and N, as appropriate. Compare your predictions with the observed values. Discrepant intensities in these data are typical unless care is taken to obtain high-quality data.

|  | Species in <br> Compound | Relative intensities   <br>    <br> mass spectrum   | M | $\mathrm{M}+1$ |
| :--- | :--- | :--- | :--- | :--- |
| $\mathrm{M}+2$ |  |  |  |  |
| $37: 3$ | $\left[\mathrm{MNH}_{4}\right]^{+}(\mathrm{m} / \mathrm{z} 546)^{a}$ | 100 | 35.8 | 7.0 |
| $37: 3$ | $[\mathrm{MH}]^{+}(m / z 529)^{b}$ | 100 | 23.0 | 8.0 |
| $37: 2$ | $\left[\mathrm{MNH}_{4}\right]^{+}(m / z 548)^{a}$ | 100 | 40.8 | 3.7 |
| $37: 2$ | $[\mathrm{MH}]^{+}(m / z 531)^{b}$ | 100 | 33.4 | 8.4 |

a. Chemical ionization with ammonia.
b. Chemical ionization with isobutane.

21-31. Chlorate $\left(\mathrm{ClO}_{3}^{-}\right)$, chlorite $\left(\mathrm{ClO}_{2}^{-}\right)$, bromate $\left(\mathrm{BrO}_{3}^{-}\right)$, and iodate $\left(\mathrm{IO}_{3}^{-}\right)$can be measured in drinking water at the 1-ppb level with $1 \%$ precision by selected reaction monitoring. ${ }^{47}$ Chlorate and chlorite arise from $\mathrm{ClO}_{2}$ used as a disinfectant. Bromate and iodate can be formed from $\mathrm{Br}^{-}$or $\mathrm{I}^{-}$when water is disinfected with ozone $\left(\mathrm{O}_{3}\right)$. For the highly selective measurement of chlorate, the negative ion selected by Q1 in Figure 21-26 is $\mathrm{m} / \mathrm{z} 83$ and the negative ion selected by Q3 is $\mathrm{m} / \mathrm{z}$ 67. Explain how this measurement works and how it distinguishes $\mathrm{ClO}_{3}^{-}$from $\mathrm{ClO}_{2}^{-}, \mathrm{BrO}_{3}^{-}$, and $\mathrm{IO}_{3}^{-}$.
21-32. Quantitative analysis by isotope dilution. In isotope dilution, a known amount of an unusual isotope (called the spike) is added to an unknown as an internal standard for quantitative analysis. After the mixture has been homogenized, some of the element of interest must be isolated. The ratio of the isotopes is then measured. From this ratio, the quantity of the element in the original unknown can be calculated.

Natural vanadium has atom fractions ${ }^{51} \mathrm{~V}=0.9975$ and ${ }^{50} \mathrm{~V}=0.002$ 5. The atom fraction is defined as

$$
\text { Atom fraction of }{ }^{51} \mathrm{~V}=\frac{\text { atoms of }{ }^{51} \mathrm{~V}}{\text { atoms of }{ }^{50} \mathrm{~V}+\text { atoms of }{ }^{51} \mathrm{~V}}
$$

A spike enriched in ${ }^{50} \mathrm{~V}$ has atom fractions ${ }^{51} \mathrm{~V}=0.6391$ and ${ }^{50} \mathrm{~V}=$ 0.3609.
(a) Let isotope A be ${ }^{51} \mathrm{~V}$ and isotope B be ${ }^{50} \mathrm{~V}$. Let $A_{x}$ be the atom fraction of isotope $\mathrm{A}(=$ atoms of $\mathrm{A} /[$ atoms of $\mathrm{A}+$ atoms of B$])$ in an unknown. Let $B_{x}$ be the atom fraction of B in an unknown. Let $A_{s}$ and $B_{s}$ be the corresponding atom fractions in a spike. Let $C_{x}$ be the total concentration of all isotopes of vanadium ( $\mu \mathrm{mol} / \mathrm{g}$ ) in the unknown and let $C_{s}$ be the concentration in the spike. Let $m_{x}$ be the mass of unknown and $m_{s}$ be the mass of spike. After $m_{x}$ grams of unknown are mixed with $m_{s}$ grams of spike, the ratio of isotopes in the mixture is found to be $R$. Show that

$$
\begin{equation*}
R=\frac{\mathrm{mol} \mathrm{~A}}{\mathrm{~mol} \mathrm{~B}}=\frac{A_{x} C_{x} m_{x}+A_{s} C_{s} m_{s}}{B_{x} C_{x} m_{x}+B_{s} C_{s} m_{s}} \tag{A}
\end{equation*}
$$

(b) Solve Equation A for $C_{x}$ to show that

$$
\begin{equation*}
C_{x}=\left(\frac{C_{s} m_{s}}{m_{x}}\right)\left(\frac{A_{s}-R B_{s}}{R B_{x}-A_{x}}\right) \tag{B}
\end{equation*}
$$

(c) A $0.40167-\mathrm{g}$ sample of crude oil containing an unknown concentration of natural vanadium was mixed with 0.41946 g of spike containing $2.2435 \mu \mathrm{~mol} \mathrm{~V} / \mathrm{g}$ enriched with ${ }^{50} \mathrm{~V}$ (atom fractions: $\left.{ }^{51} \mathrm{~V}=0.6391,{ }^{50} \mathrm{~V}=0.3609\right) .{ }^{48}$ After dissolution and equilibration of the oil and the spike, some of the vanadium was isolated by ion-exchange chromatography. The measured isotope ratio in the isolated vanadium was $R={ }^{51} \mathrm{~V} /{ }^{50} \mathrm{~V}=10.545$. Find the concentration of vanadium ( $\mu \mathrm{mol} / \mathrm{g}$ ) in the crude oil.
(d) Examine the calculation in part (c) and express the answer with the correct number of significant figures.
21-33. A literature project. Until the 1960s, dinosaurs were thought to be cold-blooded animals, which means they could not regulate their body temperature. Reference 1 describes how the ${ }^{18} \mathrm{O} /{ }^{16} \mathrm{O}$ ratio in dinosaur bones suggests that some species were warm blooded. Find reference 1, preferably at http://pubs.acs.org/ac if your institution has an electronic subscription to Analytical Chemistry. Explain how the ${ }^{18} \mathrm{O} /{ }^{16} \mathrm{O}$ ratio implies that an animal is warm or cold blooded. Explain the criteria that were used to determine the likelihood that ${ }^{18} \mathrm{O} /{ }^{16} \mathrm{O}$ in bone phosphate was altered after the dinosaur died. Describe how bone samples were prepared for analysis of oxygen isotopes and state the results of the measurements.

## Introduction to Analytical Separations

MEASURING SILICONES LEAKING FROM BREAST IMPLANTS

High-molecular-mass poly(dimethylsiloxane), $\left[\left(\mathrm{CH}_{3}\right)_{2} \mathrm{SiO}\right]_{n}$, is used as a stationary phase in gas chromatography (Table 23-1) and as the gel in breast implants. Approximately $1-2 \%$ of silicones in breast implants are low-molecular-mass materials that can leak from intact implants and travel through the circulatory and lymph systems to take up residence in lipid-rich tissues.

Gas chromatography with selected ion mass spectrometric detection (Section 21-4) provides a specific, sensitive means to measure silicones. Analytes were extracted with hexane from 1 mL of blood plasma to which the internal standard, $\left[\left(\mathrm{CH}_{3}\right)_{3} \mathrm{SiO}\right]_{4} \mathrm{Si}$, was added. Each analyte was monitored at the mass of its most abundant fragment. The chromatogram on this page would be enormously more complex if detection were not by selected ion monitoring. By setting the mass spectrometer to observe only each intended analyte near its known retention time, everything else eluted from the column becomes invisible.

The observation of silicones at part per billion levels in human tissue does not necessarily imply a health risk. Risk must be assessed in medical studies that make use of the analytical data.

Two liquids are miscible if they form a single phase when they are mixed in any ratio. Immiscible liquids remain in separate phases. Organic solvents with low polarity are generally immiscible with water, which is highly polar.

FIGURE 22-1 Partitioning of a solute between two liquid phases.

For simplicity, we assume that the two phases are not soluble in each other. A more realistic treatment considers that most liquids are partially soluble in each other. ${ }^{1}$

The larger the partition coefficient, the less solute remains in phase 1 .

Example: If $q=\frac{1}{4}$, then $\frac{1}{4}$ of the solute remains in phase 1 after one extraction. A second extraction reduces the concentration to $\left(\frac{1}{4}\right)\left(\frac{1}{4}\right)=\frac{1}{16}$ of initial concentration.
n the vast majority of real analytical problems, we must separate, identify, and measure one or more components from a complex mixture. This chapter discusses fundamentals of analytical separations, and the next three chapters describe specific methods.

## 22-1 Solvent Extraction

Extraction is the transfer of a solute from one phase to another. Common reasons to carry out an extraction in analytical chemistry are to isolate or concentrate the desired analyte or to separate it from species that would interfere in the analysis. The most common case is the extraction of an aqueous solution with an organic solvent. Diethyl ether, toluene, and hexane are common solvents that are immiscible with and less dense than water. They form a separate phase that floats on top of the aqueous phase. Chloroform, dichloromethane, and carbon tetrachloride are common solvents that are denser than water. ${ }^{\dagger}$ In the two-phase mixture, one phase is predominantly water and the other phase is predominantly organic.

Suppose that solute $S$ is partitioned between phases 1 and 2, as depicted in Figure 22-1. The partition coefficient, $K$, is the equilibrium constant for the reaction

$$
\mathrm{S}(\text { in phase } 1) \rightleftharpoons \mathrm{S}(\text { in phase } 2)
$$

Partition coefficient:

$$
\begin{equation*}
K=\frac{\mathcal{A}_{\mathrm{S}_{2}}}{\mathcal{A}_{\mathrm{S}_{1}}} \approx \frac{[\mathrm{~S}]_{2}}{[\mathrm{~S}]_{1}} \tag{22-1}
\end{equation*}
$$

where $\mathcal{A}_{\mathrm{S}_{1}}$ refers to the activity of solute in phase 1 . Lacking knowledge of the activity coefficients, we will write the partition coefficient in terms of concentrations.

Suppose that solute S in $V_{1} \mathrm{~mL}$ of solvent 1 (water) is extracted with $V_{2} \mathrm{~mL}$ of solvent 2 (toluene). Let $m$ be the moles of S in the system and let $q$ be the fraction of S remaining in phase 1 at equilibrium. The molarity in phase 1 is therefore $q m / V_{1}$. The fraction of total solute transferred to phase 2 is $(1-q)$, and the molarity in phase 2 is $(1-q) m / V_{2}$. Therefore,

$$
K=\frac{[\mathrm{S}]_{2}}{[\mathrm{~S}]_{1}}=\frac{(1-q) m / V_{2}}{q m / V_{1}}
$$

from which we can solve for $q$ :

$$
\begin{align*}
& \text { Fraction remaining in phase } 1  \tag{22-2}\\
& \text { after } 1 \text { extraction }
\end{align*}=q=\frac{V_{1}}{V_{1}+K V_{2}}
$$

Equation 22-2 says that the fraction of solute remaining in the water (phase 1 ) depends on the partition coefficient and the volumes. If the phases are separated and fresh toluene (solvent 2) is added, the fraction of solute remaining in the water at equilibrium will be

$$
\begin{aligned}
& \text { Fraction remaining in phase } 1 \\
& \quad \text { after } 2 \text { extractions }
\end{aligned}
$$

After $n$ extractions, each with volume $V_{2}$, the fraction remaining in the water is
$\begin{aligned} & \text { Fraction remaining in phase } 1 \\ & \quad \text { after } n \text { extractions }\end{aligned}=q^{n}=\left(\frac{V_{1}}{V_{1}+K V_{2}}\right)^{n}$

## EXAMPLE Extraction Efficiency

Solute A has a partition coefficient of 3 between toluene and water, with three times as much in the toluene phase. Suppose that 100 mL of a 0.010 M aqueous solution of A are extracted with toluene. What fraction of A remains in the aqueous phase (a) if one extraction with 500 mL is performed or $(\mathbf{b})$ if five extractions with 100 mL are performed?

Solution (a) With water as phase 1 and toluene as phase 2, Equation 22-2 says that, after a $500-\mathrm{mL}$ extraction, the fraction remaining in the aqueous phase is

$$
q=\frac{100}{100+(3)(500)}=0.062 \approx 6 \%
$$

[^13](b) With five $100-\mathrm{mL}$ extractions, the fraction remaining is given by Equation 22-3:
$$
\text { Fraction remaining }=\left(\frac{100}{100+(3)(100)}\right)^{5}=0.00098 \approx 0.1 \%
$$

## It is more efficient to do several small extractions than one big extraction.

Test Yourself If the partition coefficient is 10, what fraction remains in 100 mL of water after 1 and 5 extractions with 20 mL of toluene? (Answer: $33 \%, 0.41 \%$ )

## pH Effects

If a solute is an acid or base, its charge changes as the pH is changed. Usually, a neutral species is more soluble in an organic solvent and a charged species is more soluble in aqueous solution. Consider a basic amine whose neutral form, B , has partition coefficient $K$ between aqueous phase 1 and organic phase 2 . Suppose that the conjugate acid, $\mathrm{BH}^{+}$, is soluble only in aqueous phase 1. Let's denote its acid dissociation constant as $K_{\mathrm{a}}$. The distribution coefficient, $D$, is defined as

Distribution coefficient:

$$
\begin{equation*}
D=\frac{\text { total concentration in phase } 2}{\text { total concentration in phase } 1} \tag{22-4}
\end{equation*}
$$

which becomes

$$
\begin{equation*}
D=\frac{[\mathrm{B}]_{2}}{[\mathrm{~B}]_{1}+\left[\mathrm{BH}^{+}\right]_{1}} \tag{22-5}
\end{equation*}
$$

Substituting $K=[\mathrm{B}]_{2} /[\mathrm{B}]_{1}$ and $K_{\mathrm{a}}=\left[\mathrm{H}^{+}\right][\mathrm{B}]_{1} /\left[\mathrm{BH}^{+}\right]_{1}$ into Equation 22-5 leads to
Distribution of base
between two phases:

$$
\begin{equation*}
D=\frac{K \cdot K_{\mathrm{a}}}{K_{\mathrm{a}}+\left[\mathrm{H}^{+}\right]}=K \cdot \alpha_{\mathrm{B}} \tag{22-6}
\end{equation*}
$$

where $\alpha_{\mathrm{B}}$ is the fraction of weak base in the neutral form, B , in the aqueous phase. The distribution coefficient $D$ is used in place of the partition coefficient $K$ in Equation 22-2 when dealing with a species that has more than one chemical form, such as $B$ and $B H^{+}$.

Charged species tend to be more soluble in water than in organic solvent. To extract a base into water, use a pH low enough to convert B into $\mathrm{BH}^{+}$(Figure 22-2). To extract the acid HA into water, use a pH high enough to convert HA into $\mathrm{A}^{-}$.

Challenge Suppose that the acid HA (with dissociation constant $K_{\mathrm{a}}$ ) is partitioned between aqueous phase 1 and organic phase 2. Calling the partition coefficient $K$ for HA and assuming that $\mathrm{A}^{-}$is not soluble in the organic phase, show that the distribution coefficient is given by

$$
\begin{align*}
& \text { Distribution of acid } \\
& \text { between two phases: }
\end{align*} \quad D=\frac{K \cdot\left[\mathrm{H}^{+}\right]}{\left[\mathrm{H}^{+}\right]+K_{\mathrm{a}}}=K \cdot \alpha_{\mathrm{HA}}
$$

where $\alpha_{H A}$ is the fraction of weak acid in the form HA in the aqueous phase.

## EXAMPLE Effect of pH on Extraction

Suppose that the partition coefficient for an amine, B, is $K=3.0$ and the acid dissociation constant of $\mathrm{BH}^{+}$is $K_{\mathrm{a}}=1.0 \times 10^{-9}$. If 50 mL of 0.010 M aqueous amine are extracted with 100 mL of solvent, what will be the formal concentration remaining in the aqueous phase (a) at pH 10.00 and (b) at pH 8.00 ?
Solution (a) At pH 10.00, $D=K K_{\mathrm{a}} /\left(K_{\mathrm{a}}+\left[\mathrm{H}^{+}\right]\right)=(3.0)\left(1.0 \times 10^{-9}\right) /\left(1.0 \times 10^{-9}+\right.$ $\left.1.0 \times 10^{-10}\right)=2.73$. Using $D$ in place of $K$, Equation 22-2 says that the fraction remaining in the aqueous phase is

$$
q=\frac{50}{50+(2.73)(100)}=0.15 \Rightarrow 15 \% \text { left in water }
$$

The concentration of amine in the aqueous phase is $15 \%$ of $0.010 \mathrm{M}=0.0015 \mathrm{M}$.

Many small extractions are more effective than a few large extractions.
The limit for extracting solute $S$ from phase 1 (volume $V_{1}$ ) into phase 2 (volume $V_{2}$ ) is attained by dividing $V_{2}$ into an infinite number of infinitesimally small portions for extraction. With $K=[\mathrm{S}]_{2} /[\mathrm{S}]_{1}$, the limiting fraction of solute remaining in phase 1 is $^{2}$

$$
q_{\text {limit }}=e^{-\left(v_{2} / V_{1}\right) K}
$$

$$
\alpha_{\mathrm{B}}=\frac{[\mathrm{B}]_{\mathrm{aq}}}{[\mathrm{~B}]_{\mathrm{aq}}+\left[\mathrm{BH}^{+}\right]_{\mathrm{aq}}}
$$

$\boldsymbol{\alpha}_{\mathrm{B}}$ is the same as $\boldsymbol{\alpha}_{A^{-}}$in Equation 9-18.

FIGURE 22-2 Effect of pH on the distribution coefficient for the extraction of a base into an organic solvent. In this example, $K=3.0$ and $\mathrm{P} K_{\mathrm{a}}$ for $\mathrm{BH}^{+}$is 9.00 .

$\boldsymbol{\beta}$ is the overall formation constant defined in Box 6-2.
(b) At pH 8.00, $D=(3.0)\left(1.0 \times 10^{-9}\right) /\left(1.0 \times 10^{-9}+1.0 \times 10^{-8}\right)=0.273$. Therefore,

$$
q=\frac{50}{50+(0.273)(100)}=0.65 \Rightarrow 65 \% \text { left in water }
$$

The concentration in the aqueous phase is 0.0065 M . At pH 10 , the base is predominantly in the form B and is extracted into the organic solvent. At pH 8 , it is in the form $\mathrm{BH}^{+}$and remains in the water.

Test Yourself Consider an acid HA with $K=3.0$ and $K_{\mathrm{a}}=1.0 \times 10^{-9}$. What will be the formal concentration remaining in the aqueous phase at pH 10.00 and at pH 8.00 ? Explain why the acid and base have opposite answers. (Answer: 65\% at pH 10 and $15 \%$ at pH 8 ; neutral species HA or B are more soluble in organic phase)

## Extraction with a Metal Chelator

Most complexes that can be extracted into organic solvents are neutral. Charged complexes, such as $\mathrm{Fe}(\mathrm{EDTA})^{-}$or $\mathrm{Fe}(1,10 \text {-phenanthroline })_{3}^{2+}$, are not very soluble in organic solvents. One scheme for separating metal ions from one another is to selectively complex one ion with an organic ligand and extract it into an organic solvent. Ligands such as dithizone (Demonstration 22-1), 8-hydroxyquinoline, and cupferron are commonly employed. Each is a weak acid, HL, which loses a proton when it binds to a metal ion through atoms shown in bold type.

$$
\begin{align*}
\mathrm{HL}(a q) \rightleftharpoons \mathrm{H}^{+}(a q)+\mathrm{L}^{-}(a q) & K_{\mathrm{a}}=\frac{\left[\mathrm{H}^{+}\right]_{\mathrm{aq}}\left[\mathrm{~L}^{-}\right]_{\mathrm{aq}}}{[\mathrm{HL}]_{\mathrm{aq}}}  \tag{22-8}\\
n \mathrm{~L}^{-}(a q)+\mathrm{M}^{n+}(a q) \rightleftharpoons \mathrm{ML}_{n}(a q) & \beta=\frac{\left[\mathrm{ML}_{n}\right]_{\mathrm{aq}}}{\left[\mathrm{M}^{n+}\right]_{\mathrm{aq}}\left[\mathrm{~L}^{-}\right]_{\mathrm{aq}}^{n}} \tag{22-9}
\end{align*}
$$

## DEMONSTRATION 22-1 Extraction with Dithizone

Dithizone (diphenylthiocarbazone) is a green compound that is soluble in nonpolar organic solvents and insoluble in water below $\mathrm{pH} 7.3^{3}$ In alkaline aqueous solution, it forms a soluble yellow ion. It forms red, hydrophobic complexes with di- and trivalent metals. Dithizone is used for analytical extractions and for colorimetric determinations of metal ions.

You can demonstrate the equilibrium between green ligand and red complex by using three large test tubes sealed with tightly fitting rubber stoppers. Place some hexane plus a few milliliters of dithizone solution (prepared by dissolving 1 mg of dithizone in 100 mL of $\mathrm{CHCl}_{3}$ ) in each test tube. Add distilled water to tube A, tap water to tube B , and $2 \mathrm{mM} \mathrm{Pb}\left(\mathrm{NO}_{3}\right)_{2}$ to tube C . After shaking and settling, tubes B and C contain a red upper phase, whereas A remains green.

Proton equilibrium in the dithizone reaction is shown by adding a few drops of 1 M HCl to tube C. After shaking, the dithizone turns green again. Competition with a stronger ligand is shown by adding a few drops of 0.05 M EDTA solution to tube B. Again, shaking causes a reversion to the green color.

## Practicing "Green" Chemistry

Chemical procedures that produce less waste or less hazardous waste are said to be "green" because they reduce harmful environmental effects. In chemical analyses with dithizone, you can substitute aqueous micelles (Box 25-1) for the organic phase (which has traditionally been chloroform, $\mathrm{CHCl}_{3}$ ) to eliminate chlorinated solvent and the tedious extraction. ${ }^{4}$ For example, a solution containing $5.0 \mathrm{wt} \%$ of the micelle-forming surfactant Triton X-100 dissolves $8.3 \times 10^{-5} \mathrm{M}$ dithizone at $25^{\circ} \mathrm{C}$ and $\mathrm{pH}<7$. The concentration of dithizone inside the micelles, which constitute a small fraction of the volume of solution, is much greater than $8.3 \times 10^{-5} \mathrm{M}$. Aqueous micellar solutions of dithizone can be used for the spectrophotometric analysis of metals such as $\mathrm{Zn}(\mathrm{II}), \mathrm{Cd}$ (II), Hg (II), $\mathrm{Cu}($ II $)$, and Pb (II) with results comparable to those obtained with an organic solvent.

Each ligand can react with many different metal ions, but some selectivity is achieved by controlling the pH .

Let's derive an equation for the distribution coefficient of a metal between two phases when essentially all the metal in the aqueous phase $(a q)$ is in the form $\mathrm{M}^{n+}$ and all the metal in the organic phase (org) is in the form $\mathrm{ML}_{n}$ (Figure 22-3). We define the partition coefficients for ligand and complex as follows:

$$
\begin{array}{rlrl}
\mathrm{HL}(a q) & \rightleftharpoons \mathrm{HL}(\text { org }) & K_{\mathrm{L}}=\frac{[\mathrm{HL}]_{\mathrm{org}}}{[\mathrm{HL}]_{\mathrm{aq}}} \\
\mathrm{ML}_{n}(a q) \rightleftharpoons \mathrm{ML}_{n}(\text { org }) & K_{\mathrm{M}}=\frac{\left[\mathrm{ML}_{n}\right]_{\mathrm{org}}}{\left[\mathrm{ML}_{n}\right]_{\mathrm{aq}}} \tag{22-11}
\end{array}
$$

The distribution coefficient we seek is

$$
\begin{equation*}
D=\frac{[\text { total metal }]_{\text {org }}}{[\text { total metal }]_{\mathrm{aq}}} \approx \frac{\left[\mathrm{ML}_{n}\right]_{\mathrm{org}}}{\left[\mathrm{M}^{n+}\right]_{\mathrm{aq}}} \tag{22-12}
\end{equation*}
$$

From Equations 22-11 and 22-9, we can write

$$
\left[\mathrm{ML}_{n}\right]_{\mathrm{org}}=K_{\mathrm{M}}\left[\mathrm{ML}_{n}\right]_{\mathrm{aq}}=K_{\mathrm{M}} \beta\left[\mathrm{M}^{n+}\right]_{\mathrm{aq}}\left[\mathrm{~L}^{-}\right]_{\mathrm{aq}}^{n}
$$

Using $\left[\mathrm{L}^{-}\right]_{\mathrm{aq}}$ from Equation 22-8 gives

$$
\left[\mathrm{ML}_{n}\right]_{\mathrm{org}}=\frac{K_{\mathrm{M}} \beta\left[\mathrm{M}^{n+}\right]_{\mathrm{aq}} K_{\mathrm{a}}^{n}[\mathrm{HL}]_{\mathrm{aq}}^{n}}{\left[\mathrm{H}^{+}\right]_{\mathrm{aq}}^{n}}
$$

Putting this value of $\left[\mathrm{ML}_{n}\right]_{\text {org }}$ into Equation 22-12 gives

$$
D \approx \frac{K_{\mathrm{M}} \beta K_{\mathrm{a}}^{n}[\mathrm{HL}]_{\mathrm{aq}}^{n}}{\left[\mathrm{H}^{+}\right]_{\mathrm{aq}}^{n}}
$$

Because most HL is in the organic phase, we substitute $[\mathrm{HL}]_{\mathrm{aq}}=[\mathrm{HL}]_{\text {org }} / K_{\mathrm{L}}$ to produce the most useful expression for the distribution coefficient:
$\begin{aligned} & \text { Distribution of metal-chelate } \\ & \text { complex between phases: }\end{aligned}$$\quad D \approx \frac{K_{\mathrm{M}} \beta K_{\mathrm{a}}^{n}}{K_{\mathrm{L}}^{n}} \frac{[\mathrm{HL}]_{\mathrm{org}}^{n}}{\left[\mathrm{H}^{+}\right]_{\mathrm{aq}}^{n}}$
We see that the distribution coefficient for metal ion extraction depends on pH and ligand concentration. It is often possible to select a pH where $D$ is large for one metal and small for another. For example, Figure $22-4$ shows that $\mathrm{Cu}^{2+}$ could be separated from $\mathrm{Pb}^{2+}$ and $\mathrm{Zn}^{2+}$ by extraction with dithizone at pH 5 . Demonstration 22-1 illustrates the pH dependence of an extraction. Box 22-1 describes crown ethers and phase transfer agents used to extract polar reagents into nonpolar solvents for chemical reactions.

FIGURE 22-4 Extraction of metal ions by dithizone into $\mathrm{CCl}_{4}$. At $\mathrm{pH} 5, \mathrm{Cu}^{2+}$ is completely extracted into $\mathrm{CCl}_{4}$, whereas $\mathrm{Pb}^{2+}$ and $\mathrm{Zn}^{2+}$ remain in the aqueous phase. [Adapted from G. H. Morrison and H. Freiser in C. L. Wilson and D. Wilson, eds., Comprehensive Analytical Chemistry, Vol. IA (New York: Elsevier, 1959).]
$\mathrm{M}^{n+}$ is in the aqueous phase and $\mathrm{ML}_{n}$ is in the organic phase.

FIGURE 22-3 Extraction of a metal ion with a chelator. The predominant form of metal in the aqueous phase is $\mathrm{M}^{n+}$, and the predominant form in the organic phase is $\mathrm{ML}_{n}$.

You can select a pH to bring the metal into either phase.

Crown ethers are synthetic compounds that envelop metal ions (especially alkali metal cations) in a pocket of oxygen ligands. Crown ethers are used as phase transfer catalysts because they can extract water-soluble ionic reagents into nonpolar solvents, where reaction with hydrophobic compounds can occur. In the potassium complex of dibenzo- 30 -crown- $10, \mathrm{~K}^{+}$is engulfed by 10 oxygen atoms, with $\mathrm{K}-\mathrm{O}$ distances averaging 288 pm . Only the hydrophobic outside of the complex is exposed to solvent.

Hydrophobic cations and anions can function as phase transfer agents to bring ions of the opposite charge into organic solvents. For example, Color Plate 27 shows the extraction of colored anions from the lower aqueous phase into the upper diethyl ether layer when
trioctylmethylammonium chloride is added and the mixture is stirred. For $\mathrm{KMnO}_{4}$ in the aqueous phase, the equilibrium below lies well to the right:

$$
\begin{array}{r}

\end{array}
$$

An important application of this reaction is to bring permanganate into the organic phase to oxidize an organic compound. A phase transfer, analytical separation of hafnium from tungsten is used in geochemical studies to detect debris from supernova explosions. ${ }^{5}$

(b)

(a) Molecular structure of dibenzo-30-crown-10. (b) Three-dimensional structure of its $\mathrm{K}^{+}$complex. [Adapted from M. A. Bush and M. R. Truter, "Crystal Structures of Alkali-Metal Complexes with Cyclic Polyethers," J. Chem. Soc. Chem. Commun. 1970, 1439.]

In 1903 in Warsaw, the botanist M. Tswett invented adsorption chromatography to separate plant pigments, using a hydrocarbon solvent and inulin powder (a carbohydrate) as stationary phase. The separation of colored bands led to the name chromatography, from the Greek chromatos ("color") and graphein ("to write")-"color writing." Tswett later found that $\mathrm{CaCO}_{3}$ or sucrose could also be used as stationary phases. ${ }^{6}$
Chromatography lay dormant until Tswett's methods were applied, beginning in 1931, to biochemical separations by E. Lederer and R. Kuhn in Heidelberg, P. Karrer in Zurich, and L. Zechmeister in Hungary. ${ }^{7}$ During the 1930s, adsorption chromatography became an established tool in biochemistry.

## 22-2 What Is Chromatography?

Chromatography operates on the same principle as extraction, but one phase is held in place while the other moves past it. ${ }^{8,9}$ Figure 22-5 shows a solution containing solutes A and B placed on top of a column packed with solid particles and filled with solvent. When the outlet is opened, solutes A and B flow down into the column. Fresh solvent is then applied to the top of the column and the mixture is washed down the column by continuous solvent flow. If solute A is more strongly adsorbed than solute B on the solid particles, then solute A spends a smaller fraction of the time free in solution. Solute A moves down the column more slowly than solute B and emerges at the bottom after solute B. We have just separated a mixture into its components by chromatography.

The mobile phase (the solvent moving through the column) in chromatography is either a liquid or a gas. The stationary phase (the one that stays in place inside the column) is most commonly a viscous liquid chemically bonded to the inside of a capillary tube or onto the surface of solid particles packed in the column. Alternatively, as in Figure 22-5, the solid particles themselves may be the stationary phase. In any case, the partitioning of solutes between mobile and stationary phases gives rise to separation.

Fluid entering the column is called eluent. Fluid emerging from the end of the column is called eluate:

$$
\text { eluent in } \rightarrow \text { COLUMN } \rightarrow \text { eluate out }
$$

The process of passing liquid or gas through a chromatography column is called elution.

FIGURE 22-5 The idea behind chromatography: solute $A$, with a greater affinity than solute $B$ for the stationary phase, remains on the column longer. Panel $f$ is a reconstruction of the separation of pigments from red paprika skin from the work of L. Zechmeister in the 1930s. Bands marked by horizontal lines are different pigments. The lower stationary phase is $\mathrm{Ca}(\mathrm{OH})_{2}$ and the upper stationary phase is $\mathrm{CaCO}_{3}$. [Panel $f$ from L. S. Ettre, "The Rebirth of Chromatography 75 Years Ago," LCGC 2007, 25, 640.]

Columns are either packed or open tubular. A packed column is filled with particles of stationary phase, as in Figure 22-5. An open tubular column is a narrow, hollow capillary with stationary phase coated on the inside walls.

## Types of Chromatography

Chromatography is divided into categories on the basis of the mechanism of interaction of the solute with the stationary phase, as shown in Figure 22-6.

Adsorption chromatography. A solid stationary phase and a liquid or gaseous mobile phase are used. Solute is adsorbed on the surface of the solid particles. The more strongly a solute is adsorbed, the slower it travels through the column.
Partition chromatography. A liquid stationary phase is bonded to a solid surface, which is typically the inside of the silica $\left(\mathrm{SiO}_{2}\right)$ chromatography column in gas chromatography. Solute equilibrates between the stationary liquid and the mobile phase, which is a flowing gas in gas chromatography.
Ion-exchange chromatography. Anions such as $-\mathrm{SO}_{3}^{-}$or cations such as $-\mathrm{N}\left(\mathrm{CH}_{3}\right)_{3}^{+}$ are covalently attached to the stationary solid phase, usually a resin. Solute ions of the opposite charge are attracted to the stationary phase. The mobile phase is a liquid.
Molecular exclusion chromatography. Also called size exclusion, gel filtration, or gel permeation chromatography, this technique separates molecules by size, with the larger solutes passing through most quickly. In the ideal case of molecular exclusion, there is no attractive interaction between the stationary phase and the solute. Rather, the liquid or gaseous mobile phase passes through a porous gel. The pores are small enough to exclude large solute molecules but not small ones. Large molecules stream past without entering the pores. Small molecules take longer to pass through the column because they enter the gel and therefore must flow through a larger volume before leaving the column.
Affinity chromatography. This most selective kind of chromatography employs specific interactions between one kind of solute molecule and a second molecule that is covalently attached (immobilized) to the stationary phase. For example, the immobilized molecule might be an antibody to a particular protein. When a mixture containing a thousand proteins is passed through the column, only the one protein that reacts with the antibody binds to the column. After all other solutes have been washed from the column, the desired protein is dislodged by changing the pH or ionic strength.

Volume flow rate $=$ volume of solvent per unit time traveling through column.

Linear flow rate $=$ distance per unit time traveled by solvent.

Ion-exchange chromatography

## 22-3 A Plumber's View of Chromatography

The speed of the mobile phase passing through a chromatography column is expressed either as a volume flow rate or as a linear flow rate. Consider a liquid chromatography experiment in which the column has an inner diameter of 0.60 cm (radius $\equiv r=0.30 \mathrm{~cm}$ ) and the mobile phase occupies $20 \%$ of the column volume. Each centimeter of column length has a volume of $\pi r^{2} \times$ length $=\pi(0.30 \mathrm{~cm})^{2}(1 \mathrm{~cm})=0.283 \mathrm{~mL}$, of which $20 \%(=0.0565 \mathrm{~mL})$ is mobile phase (solvent). The volume flow rate, such as $0.30 \mathrm{~mL} / \mathrm{min}$, tells how many milliliters of solvent per minute travel through the column. The linear flow rate tells how many centimeters are traveled in 1 min by the solvent. Because 1 cm of column length contains 0.0565 mL of mobile phase, 0.30 mL would occupy $(0.30 \mathrm{~mL}) /(0.0565 \mathrm{~mL} / \mathrm{cm})=5.3 \mathrm{~cm}$ of column length. The linear flow rate corresponding to $0.30 \mathrm{~mL} / \mathrm{min}$ is $5.3 \mathrm{~cm} / \mathrm{min}$.

## The Chromatogram

Solutes eluted from a chromatography column are observed with detectors described in later chapters. A chromatogram is a graph showing the detector response as a function of elution

time. Figure 22-7 shows what might be observed when a mixture of octane, nonane, and an unknown are separated by gas chromatography, which is described in Chapter 23. The retention time, $t_{\mathrm{r}}$, for each component is the time that elapses between injection of the mixture onto the column and the arrival of that component at the detector. Retention volume, $V_{\mathrm{r}}$, is the volume of mobile phase required to elute a particular solute from the column.

Mobile phase or an unretained solute travels through the column in the minimum possible time, $t_{\mathrm{m}}$. The adjusted retention time, $t_{\mathrm{r}}^{\prime}$, for a retained solute is the additional time required to travel the length of the column, beyond that required by solvent:

Adjusted retention time:

$$
\begin{equation*}
t_{\mathrm{r}}^{\prime}=t_{\mathrm{r}}-t_{\mathrm{m}} \tag{22-14}
\end{equation*}
$$

In gas chromatography, $t_{\mathrm{m}}$ is usually taken as the time needed for $\mathrm{CH}_{4}$ to travel through the column (Figure 22-7).

For two components 1 and 2, the relative retention, $\alpha$ (also called separation factor), is the ratio of their adjusted retention times:

Relative retention:

$$
\begin{equation*}
\alpha=\frac{t_{\mathrm{r} 2}^{\prime}}{t_{\mathrm{r} 1}^{\prime}} \tag{22-15}
\end{equation*}
$$

where $t_{\mathrm{r} 2}^{\prime}>t_{\mathrm{r} 1}^{\prime}$, so $\alpha>1$. The greater the relative retention, the greater the separation between two components. Relative retention is fairly independent of flow rate and can therefore be used to help identify peaks when the flow rate changes.

For component 2 eluted after component 1 , the unadjusted relative retention, $\gamma$, is the ratio of their unadjusted retention times:

$$
\begin{equation*}
\text { Unadjusted relative retention: } \quad \gamma=\frac{t_{\mathrm{r} 2}}{t_{\mathrm{r} 1}} \tag{22-16}
\end{equation*}
$$

The unadjusted relative retention is the inverse of the ratio of the speeds at which the two components travel.

For each peak in the chromatogram, the retention factor, $k$, is the time required to elute that peak minus the time $t_{\mathrm{m}}$ required for mobile phase to pass through the column, expressed in multiples of $t_{\mathrm{m}}$.

Retention factor:

$$
\begin{equation*}
k=\frac{t_{\mathrm{r}}-t_{\mathrm{m}}}{t_{\mathrm{m}}} \tag{22-17}
\end{equation*}
$$

The longer a component is retained by the column, the greater is the retention factor. It takes volume $V_{\mathrm{m}}$ to push solvent from the beginning of the column to the end of the column. If it takes an additional volume $3 V_{\mathrm{m}}$ to elute a solute, then the retention factor for that solute is 3 .

## EXAMPLE Retention Parameters

A mixture of benzene, toluene, and methane was injected into a gas chromatograph. Methane gave a sharp spike in 42 s , whereas benzene required 251 s and toluene was eluted in 333 s . Find the adjusted retention time and retention factor for each solute, the relative retention, and the unadjusted relative retention.

FIGURE 22-7 Schematic gas chromatogram showing measurement of retention times.

## Unadusted relative retention

$=\frac{\text { retention time of component } 2}{\text { retention time of component } 1}$
$=\frac{\text { speed of component } 1}{\text { speed of component } 2}$

Retention factor is also called capacity factor, capacity ratio, or partition ratio and was formerly written as $\boldsymbol{k}^{\prime}$ instead of $\boldsymbol{k}$.

Partition coefficient $=K=\frac{c_{\mathrm{s}}}{c_{\mathrm{m}}}$

## Physical basis of chromatography:

The greater the ratio of partition coefficients between mobile and stationary phases, the greater the separation between two components of a mixture.

Solution The adjusted retention times are

$$
\text { Benzene: } t_{\mathrm{r}}^{\prime}=t_{\mathrm{r}}-t_{\mathrm{m}}=251-42=209 \mathrm{~s} \quad \text { Toluene: } t_{\mathrm{r}}^{\prime}=333-42=291 \mathrm{~s}
$$

The retention factors are

$$
\text { Benezene: } k=\frac{t_{\mathrm{r}}-t_{\mathrm{m}}}{t_{\mathrm{m}}}=\frac{251-42}{42}=5.0 \quad \text { Toluene: } k=\frac{333-42}{42}=6.9
$$

The relative retention is expressed as a number greater than unity:

$$
\alpha=\frac{t_{\mathrm{r}}^{\prime}(\text { toluene })}{t_{\mathrm{r}}^{\prime}(\text { benzene })}=\frac{333-42}{251-42}=1.39
$$

The unadjusted relative retention is

$$
\gamma=\frac{t_{\mathrm{r}}(\text { toluene })}{t_{\mathrm{r}}(\text { benzene })}=\frac{333}{251}=1.33
$$

Test Yourself Ethylbenzene was eluted at 350 s . Find its retention factor and the relative retention and unadjusted relative retention for ethylbenzene and toluene. (Answer: 7.33, $1.058,1.051$ )

## Relation Between Retention Time and the Partition Coefficient

The retention factor in Equation 22-17 is equivalent to

$$
\begin{equation*}
k=\frac{\text { time solute spends in stationary phase }}{\text { time solute spends in mobile phase }} \tag{22-18a}
\end{equation*}
$$

Let's see why this is true. If the solute spends all its time in the mobile phase and none in the stationary phase, it would be eluted in time $t_{\mathrm{m}}$. Putting $t_{\mathrm{r}}=t_{\mathrm{m}}$ into Equation 22-17 gives $k=0$, because solute spends no time in the stationary phase. Suppose that solute spends equal time in the stationary and mobile phases. The retention time would then be $t_{\mathrm{r}}=2 t_{\mathrm{m}}$ and $k=$ $\left(2 t_{\mathrm{m}}-t_{\mathrm{m}}\right) / t_{\mathrm{m}}=1$. If solute spends three times as much time in the stationary phase as in the mobile phase, $t_{\mathrm{r}}=4 t_{\mathrm{m}}$ and $k=\left(4 t_{\mathrm{m}}-t_{\mathrm{m}}\right) / t_{\mathrm{m}}=3$.

If solute spends three times as much time in the stationary phase as in the mobile phase, there will be three times as many moles of solute in the stationary phase as in the mobile phase at any time. The quotient in Equation 22-18a is equivalent to

$$
\begin{align*}
\frac{\text { Time solute spends in stationary phase }}{\text { Time solute spends in mobile phase }} & =\frac{\text { moles of solute in stationary phase }}{\text { moles of solute in mobile phase }} \\
k & =\frac{c_{s} V_{s}}{c_{m} V_{\mathrm{m}}} \tag{22-18b}
\end{align*}
$$

where $c_{\mathrm{s}}$ is the concentration of solute in the stationary phase, $V_{\mathrm{s}}$ is the volume of the stationary phase, $c_{\mathrm{m}}$ is the concentration of solute in the mobile phase, and $V_{\mathrm{m}}$ is the volume of the mobile phase.

The quotient $c_{\mathrm{s}} / c_{\mathrm{m}}$ is the ratio of concentrations of solute in the stationary and mobile phases. If the column is run slowly enough to be at equilibrium, the quotient $c_{\mathrm{s}} / c_{\mathrm{m}}$ is the partition coefficient, $K$, introduced in connection with solvent extraction. Therefore, we cast Equation 22-18b in the form

## Relation of retention time to partition coefficient:

$$
\begin{equation*}
k=K \frac{V_{\mathrm{s}}}{V_{\mathrm{m}}} \stackrel{\text { Eq. } 22.17}{=} \quad \frac{t_{r}-t_{\mathrm{m}}}{t_{\mathrm{m}}}=\frac{t_{\mathrm{r}}^{\prime}}{t_{\mathrm{m}}} \tag{22-19}
\end{equation*}
$$

which relates retention time to the partition coefficient and the volumes of stationary and mobile phases. Because $t_{\mathrm{r}}^{\prime} \propto k \propto K$, relative retention can also be expressed as

Relative retention:

$$
\begin{equation*}
\alpha=\frac{t_{\mathrm{r} 2}^{\prime}}{t_{\mathrm{r} 1}^{\prime}}=\frac{k_{2}}{k_{1}}=\frac{K_{2}}{K_{1}} \tag{22-20}
\end{equation*}
$$

That is, the relative retention of two solutes is proportional to the ratio of their partition coefficients. This relation is the physical basis of chromatography.

## EXAMPLE Retention Time and Partition Coefficient

In the preceding example, methane gave a sharp spike in 42 s , whereas benzene required 251 s . The open tubular chromatography column has an inner diameter of $250 \mu \mathrm{~m}$ and is coated on the inside with a layer of stationary phase $1.0 \mu \mathrm{~m}$ thick. Estimate the partition coefficient ( $K=c_{\mathrm{s}} / c_{\mathrm{m}}$ ) for benzene between stationary and mobile phases and state what fraction of the time benzene spends in the mobile phase.

Solution We need to calculate the relative volumes of the stationary and mobile phases. The column is an open tube with a thin coating of stationary phase on the inside wall.

Radius of hollow cavity: $r_{1}=124 \mu \mathrm{~m}$
Radius to middle of stationary phase:

$$
r_{2}=124.5 \mu \mathrm{~m}
$$

The relative volumes of the phases are proportional to the relative cross-sectional areas of the phases. Therefore, $V_{\mathrm{s}} / V_{\mathrm{m}}=\left(7.8 \times 10^{2} \mu \mathrm{~m}^{2}\right) /\left(4.83 \times 10^{4} \mu \mathrm{~m}^{2}\right)=0.0161$. In the preceding example, we found that the retention factor for benzene is

$$
k=\frac{t_{\mathrm{r}}-t_{\mathrm{m}}}{t_{\mathrm{m}}}=\frac{251-42}{42}=5.0
$$

Substituting this value into Equation 22-19 gives the partition coefficient:

$$
k=K \frac{V_{\mathrm{s}}}{V_{\mathrm{m}}} \Rightarrow 5.0=K(0.0161) \Rightarrow K=310
$$

To find the fraction of time spent in the mobile phase, we use Equations 22-17 and 22-18a:

$$
k=\frac{\text { time in stationary phase }}{\text { time in mobile phase }}=\frac{t_{\mathrm{r}}-t_{\mathrm{m}}}{t_{\mathrm{m}}}=\frac{t_{\mathrm{s}}}{t_{\mathrm{m}}} \Rightarrow t_{\mathrm{s}}=k t_{\mathrm{m}}
$$

where $t_{\mathrm{s}}$ is the time in the stationary phase. The fraction of time in the mobile phase is
Fraction of time in mobile phase $=\frac{t_{\mathrm{m}}}{t_{\mathrm{s}}+t_{\mathrm{m}}}=\frac{t_{\mathrm{m}}}{k t_{\mathrm{m}}+t_{\mathrm{m}}}=\frac{1}{k+1}=\frac{1}{5.0+1}=0.17$
Test Yourself Find the partition coefficient for toluene ( $t_{\mathrm{r}}=333 \mathrm{~s}$ ) and state what fraction of the time it spends in the mobile phase. (Answer: 430, 0.13)

Retention volume, $V_{\mathrm{r}}$, is the volume of mobile phase required to elute a particular solute from the column:

Retention volume:

$$
\begin{equation*}
V_{\mathrm{r}}=t_{\mathrm{r}} \cdot u_{\mathrm{v}} \tag{22-21}
\end{equation*}
$$

where $u_{\mathrm{v}}$ is the volume flow rate (volume per unit time) of the mobile phase. The retention volume of a particular solute is constant over a range of flow rates.

## Scaling Up

We normally carry out chromatography for analytical purposes (to separate and identify or measure the components of a mixture) or for preparative purposes (to purify a significant quantity of a component of a mixture). Analytical chromatography is usually performed with thin columns that provide good separation. For preparative chromatography, we use fatter columns that can handle more load (Figure 22-8). ${ }^{10}$ Preparative chromatography is especially important in the pharmaceutical industry, which can afford the high cost of separating compounds such as optical isomers of drugs (Box 23-1).

If you have developed a procedure to separate 2 mg of a mixture on a column with a diameter of 1.0 cm , what size column should you use to separate 20 mg of the mixture? The

FIGURE 22-8 Industrial-scale preparative chromatography column can purify a kilogram of material. The column volume is 300 L . [Courtesy Prochrom, Inc., Indianapolis, IN.]

Volume is proportional to time, so any ratio of times can be written as the corresponding ratio of volumes. If $V_{m}$ is the elution volume for unretained solute,

$$
k=\frac{t_{\mathrm{r}}-t_{\mathrm{m}}}{t_{\mathrm{m}}}=\frac{V_{\mathrm{r}}-V_{\mathrm{m}}}{V_{\mathrm{m}}}
$$

where $V_{\mathrm{r}}$ is the retention volume for solute.

## Scaling rules:

- Keep column length constant
- Cross-sectional area of column $\propto$ mass of analyte:

$$
\frac{\text { Mass }_{2}}{\text { Mass }_{1}}=\left(\frac{\text { radius }_{2}}{\text { radius }_{1}}\right)^{2}
$$

(The symbol $\propto$ means "is proportional to.")

- Maintain constant linear flow rate:

$$
\frac{{\text { Volume } \text { flow }_{2}}_{\text {Volume flow }}^{1}}{}=\left(\frac{\text { radius }_{2}}{\text { radius }_{1}}\right)^{2}
$$

- Sample volume applied to column $\propto$ mass of analyte
- If you change column length, mass of sample can be increased in proportion to total length
most straightforward way to scale up is to maintain the same column length and to increase the cross-sectional area to maintain a constant ratio of sample mass to column volume. Crosssectional area is $\pi r^{2}$, where $r$ is the column radius, so the desired diameter is given by

$$
\begin{equation*}
\text { Scaling equation: } \quad \frac{\text { Large mass }}{\text { Small mass }}=\left(\frac{\text { large column radius }}{\text { small column radius }}\right)^{2} \tag{22-22}
\end{equation*}
$$

Large column radius $=1.58 \mathrm{~cm}$
A column with a diameter near 3 cm would be appropriate.
To reproduce the conditions of the smaller column in the larger column, the linear flow rate (not the volume flow rate) should be kept constant. Because the area (and hence volume) of the large column is 10 times greater than that of the small column in this example, the volume flow rate should be 10 times greater to maintain a constant linear flow rate. If the small column had a volume flow rate of $0.3 \mathrm{~mL} / \mathrm{min}$, the large column should be run at $3 \mathrm{~mL} / \mathrm{min}$.

The mass of sample (g) that can be run in preparative chromatography on a reversedphase (page 603) silica-based column is roughly

$$
\text { Column capacity }(\mathrm{g}) \approx\left(2.2 \times 10^{-7}\right) L d_{\mathrm{c}}^{2} \sigma_{\mathrm{g}}
$$

where $L$ is column length in $\mathrm{mm}, d_{\mathrm{c}}$ is column diameter in mm , and $\sigma_{\mathrm{g}}$ is the surface area $\left(\mathrm{m}^{2}\right)$ per gram of stationary phase. ${ }^{11}$ For $L=250 \mathrm{~mm}, d_{\mathrm{c}}=50 \mathrm{~mm}$, and $\sigma_{\mathrm{g}}=200 \mathrm{~m}^{2} / \mathrm{g}$, we estimate the column capacity as $\left(2.2 \times 10^{-7}\right)(250)(50)^{2}(200)=28 \mathrm{~g}$. This calculation presumes that the band will occupy the entire volume of the column, so it is surely an upper limit estimate. If you want the band to occupy just $20 \%$ of the column, so there is room for chromatography, the mass of sample would be $(0.2)(28 \mathrm{~g})=5.6 \mathrm{~g}$.

## 22-4 Efficiency of Separation

Two factors contribute to how well compounds are separated by chromatography. One is the difference in elution times between peaks: The farther apart, the better their separation. The other factor is how broad the peaks are: the wider the peaks, the poorer their separation. This section discusses how we measure the efficiency of a separation.

## Resolution

Solute moving through a chromatography column tends to spread into a Gaussian shape with standard deviation $\sigma$ (Figure 22-9). The longer a solute resides in a column, the broader the band becomes. Common measures of breadth are (1) the width $w_{1 / 2}$ measured at a height

FIGURE 22-9 Idealized Gaussian chromatogram showing how $w$ and $w_{1 / 2}$ are measured. The value of $w$ is obtained by extrapolating the tangents to the inflection points down to the baseline.

FIGURE 22-10 Resolution of Gaussian peaks of equal area and amplitude. Dashed lines show individual peaks, and solid lines are the sum of two peaks. Overlapping area is shaded.
equal to half of the peak height and (2) the width $w$ at the baseline between tangents drawn to the steepest parts of the peak. From Equation 4-3 for a Gaussian peak, it is possible to show that $w_{1 / 2}=2.35 \sigma$ and $w=4 \sigma$.

In chromatography, the resolution of two peaks from each other is defined as

Resolution:

$$
\begin{equation*}
\text { Resolution }=\frac{\Delta t_{\mathrm{r}}}{w_{\mathrm{av}}}=\frac{\Delta V_{\mathrm{r}}}{w_{\mathrm{av}}}=\frac{0.589 \Delta t_{\mathrm{r}}}{w_{1 / 2 \mathrm{av}}} \tag{22-23}
\end{equation*}
$$

where $\Delta t_{\mathrm{r}}$ or $\Delta V_{\mathrm{r}}$ is the separation between peaks (in units of time or volume) and $w_{\mathrm{av}}$ is the average width of the two peaks in corresponding units. (Peak width is measured at the base, as shown in Figure 22-9.) Alternatively, the last expression in Equation 22-23 uses $w_{1 / 2 \mathrm{av}}$, the width at half-height of Gaussian peaks. The width at half-height is usually used because it is easiest to measure. Figure 22-10 shows the overlap of two peaks with different degrees of resolution. For quantitative analysis, a resolution $>1.5$ is highly desirable.

## EXAMPLE Measuring Resolution

A peak with a retention time of 407 s has a width at half-height of 7.6 s . A neighboring peak is eluted 17 s later with $w_{1 / 2}=9.4 \mathrm{~s}$. Find the resolution for these two components.

## Solution

$$
\text { Resolution }=\frac{0.589 \Delta t_{\mathrm{r}}}{w_{1 / 2 \mathrm{av}}}=\frac{0.589(17 \mathrm{~s})}{\frac{1}{2}(7.6 \mathrm{~s}+9.4 \mathrm{~s})}=1.18
$$

Test Yourself What difference in retention times is required for an adequate resolution of 1.5? (Answer: 21.6 s )

## Diffusion

A band of solute broadens as it moves through a chromatography column (Figure 22-11). Ideally, an infinitely narrow band applied to the inlet of the column emerges with a Gaussian shape at the outlet. In less ideal circumstances, the band becomes asymmetric.

One main cause of band spreading is diffusion, which is the net transport of a solute from a region of high concentration to a region of low concentration caused by the random

Equation 22-24 is called Fick's first law of diffusion. If concentration is expressed as $\mathrm{mol} / \mathrm{m}^{3}$, the units of $D$ are $\mathrm{m}^{2} / \mathrm{s}$.

FIGURE 22-11 (a) Schematic representation of broadening of an initially sharp band of solute as it moves through a chromatography column. (b) Experimentally observed diffusional broadening of a band after 2 and 26 min in a capillary electrophoresis column. (c) Expanded view of Gaussian bandshape at 26 min. [From M. U. Musheev, S. Javaherian, V. Okhonin, and S. N. Krylov, "Diffusion as a Tool of Measuring Temperature Inside a Capillary," Anal. Chem. 2008, 80, 6752.]
movement of molecules. Figure 22-12 lets us visualize the random motion of molecules through the Brownian motion of a fluorescent bead inside a microscopic water droplet. The bead is pushed by water molecules moving with random directions and speeds. Changes in the $x$ and $y$ coordinates of the bead in successive intervals follow a Gaussian distribution.

The diffusion coefficient measures the rate at which molecules move randomly from a region of high concentration to a region of low concentration. Figure 22-13 shows motion of solute across a plane with a concentration gradient $d c / d x$. The number of moles crossing each square meter per second, called the $f l u x, J$, is proportional to the concentration gradient:
Definition of diffusion coefficient: $\quad$ Flux $\left(\frac{\mathrm{mol}}{\mathrm{m}^{2} \cdot \mathrm{~s}}\right) \equiv J=-D \frac{d c}{d x}$
The constant of proportionality, $D$, is the diffusion coefficient, and the negative sign is necessary because the net flux is from the region of high concentration to the region of low concentration.

FIGURE 22-12 Brownian motion of a 290-nm-diameter fluorescent bead in a $20-\mu \mathrm{m}$-diameter water drop at $155-\mathrm{ms}$ intervals. Histograms show $\Delta x$ and $\Delta y$ for each step in 800 photographs. Smooth curve is Gaussian fit. [From J. C. Gadd, C. L. Kuyper, B. S. Fujimoto, R. W. Allen, and D. T. Chiu, "Sizing Subcellular Organelles and Nanoparticles Confined Within Aqueous Droplets," Anal. Chem. 2008, 80, 3450.]

Table 22-1 shows that diffusion in liquids is $10^{4}$ times slower than diffusion in gases. Macromolecules such as ribonuclease and albumin diffuse 10 to 100 times slower than small molecules.

If solute begins its journey through a column in an infinitely sharp layer with $m$ moles per unit cross-sectional area of the column and spreads by diffusion as it travels, then the Gaussian profile of the band is described by

Broadening of chromatography
band by diffusion:

$$
\begin{equation*}
c=\frac{m}{\sqrt{4 \pi D t}} \mathrm{e}^{-x^{2} / 4 D t} \tag{22-25}
\end{equation*}
$$

where $c$ is concentration $\left(\mathrm{mol} / \mathrm{m}^{3}\right), t$ is time, and $x$ is the distance along the column from the current center of the band. (The band center is always $x=0$ in this equation.) Comparison of Equations 22-25 and 4-3 shows that the standard deviation of the band is

Standard deviation of band: $\quad \sigma=\sqrt{2 D t}$

## Plate Height: A Measure of Column Efficiency

Equation 22-26 tells us that the standard deviation for diffusive band spreading is $\sqrt{2 D t}$. If solute has traveled a distance $x$ at the linear flow rate $u_{\mathrm{x}}(\mathrm{m} / \mathrm{s})$, then the time it has been on the column is $t=x / u_{\mathrm{x}}$. Therefore,

Plate height:

$$
\begin{gather*}
\sigma^{2}=2 D t=2 D \frac{x}{u_{x}}=\underbrace{\left(\frac{2 D}{u_{x}}\right)}_{\text {Plate height }=H} x=H x \\
H=\sigma^{2} / x
\end{gather*}
$$

Plate height, $H$, is the constant of proportionality between the variance, $\sigma^{2}$, of the band and the distance it has traveled, $x$. The name came from the theory of distillation in which separation could be performed in discrete stages called plates. Plate height is also called the height equivalent to a theoretical plate. It is approximately the length of column required for one equilibration of solute between mobile and stationary phases. We explore this concept later in Box 22-2. The smaller the plate height, the narrower the bandwidth.

The ability of a column to separate components of a mixture is improved by decreasing plate height. An efficient column has more theoretical plates than an inefficient column.

FIGURE 22-13 The flux of molecules diffusing across a plane of unit area is proportional to the concentration gradient and to the diffusion coefficient: $J=-D(d c / d x)$.

Bandwidth $\propto \sqrt{t}$. If elution time increases by a factor of 4 , diffusion will broaden the band by a factor of 2 .
$u_{\mathrm{x}}=$ linear flow rate (distance/time)
$u_{v}=$ volume flow rate (volume/time)

As a teenager, A. J. P. Martin, coinventor of partition chromatography, built distillation columns in discrete sections from coffee cans. (We don't know what he was distilling!) When he formulated the theory of partition chromatography, he adopted terms from distillation theory.

Small plate height $\Rightarrow$ narrow peaks $\Rightarrow$ better separations

Choose a peak with a retention factor greater than 5 when you measure plate height for a column.

Challenge If $N$ is constant, show that the width of a chromatographic peak increases in proportion to retention time. That is, successive peaks in a chromatogram should be increasingly broad.

All quantities must be measured in the same units, such as time or length.

FIGURE 22-14 Asymmetric peak showing parameters used to estimate the number of theoretical plates.

Different solutes passing through the same column have different plate heights because they have different diffusion coefficients. Plate heights are $\sim 0.1$ to 1 mm in gas chromatography, $\sim 10 \mu \mathrm{~m}$ in high-performance liquid chromatography, and $<1 \mu \mathrm{~m}$ in capillary electrophoresis.

Plate height is the length $\sigma^{2} / x$, where $\sigma$ is the standard deviation of the Gaussian band in Figure 22-9 and $x$ is the distance traveled. For solute emerging from a column of length $L$, the number of plates, $N$, in the entire column is the length $L$ divided by the plate height:

$$
N=\frac{L}{H}=\frac{L x}{\sigma^{2}}=\frac{L^{2}}{\sigma^{2}}=\frac{16 L^{2}}{w^{2}}
$$

because $x=L$ and $\sigma=w / 4$. In this expression, $w$ has units of length and the number of plates is dimensionless. If we express $L$ and $w($ or $\sigma$ ) in units of time instead of length, $N$ is still dimensionless. We obtain a useful expression for $N$ by writing

Number of plates on column:

$$
\begin{equation*}
N=\frac{16 t_{\mathrm{r}}^{2}}{\mathrm{w}^{2}}=\frac{t_{\mathrm{r}}^{2}}{\sigma^{2}} \tag{22-28a}
\end{equation*}
$$

where $t_{\mathrm{r}}$ is the retention time of the peak and $w$ is the width at the base in Figure 22-9 in units of time. If we use the width at half-height, also called the half-width, instead of the width at the base, we get
Number of plates on column: $\quad N=\frac{5.55 t_{\mathrm{r}}^{2}}{w_{1 / 2}^{2}}$

## EXAMPLE Measuring Plates

A solute with a retention time of 407 s has a width at the base of 13.0 s on a column 12.2 m long. Find the number of plates and plate height.

## Solution

$$
\begin{aligned}
& N=\frac{16 t_{r}^{2}}{w^{2}}=\frac{16 \cdot 407^{2}}{13.0^{2}}=1.57 \times 10^{4} \\
& H=\frac{L}{N}=\frac{12.2 \mathrm{~m}}{1.57 \times 10^{4}}=0.78 \mathrm{~mm}
\end{aligned}
$$

Test Yourself The half-width of the same peak is 7.6 s . Find the plate height. (Answer: 0.77 mm )

To estimate the number of theoretical plates for the asymmetric peak in Figure 22-14, draw a horizontal line across the band at $1 / 10$ of the maximum height. The quantities $A$ and $B$ can then be measured, and the number of plates is ${ }^{12}$

$$
\begin{equation*}
N \approx \frac{41.7\left(t_{r} / w_{0.1}\right)^{2}}{A / B+1.25} \tag{22-29}
\end{equation*}
$$

where $w_{0.1}$ is the width $(=A+B)$ at $1 / 10$ height.

## Factors Affecting Resolution

For two closely spaced, symmetric peaks, the relation between plates and resolution is ${ }^{13}$

$$
\begin{equation*}
\text { Resolution }=\frac{\sqrt{N}}{4}(\gamma-1) \tag{22-30}
\end{equation*}
$$

where $N$ is the number of theoretical plates and $\gamma$ is the unadjusted relative retention in Equation 22-16. For retention times $t_{A}=341 \mathrm{~s}$ and $t_{B}=348 \mathrm{~s}, \gamma=348 / 341=1.021$.

One important feature of Equation 22-30 is that resolution is proportional to $\sqrt{N}$. Therefore, doubling the column length increases resolution by $\sqrt{2}$. Figure 22-15 shows the effect of column length on the separation of L-phenylalanine from L-phenylalanine- $\mathrm{D}_{5}$, in which the phenyl ring bears five deuterium atoms. The mixture was cycled repeatedly through a pair of chromatography columns by an ingenious valving system. After 1 pass in Figure 22-15, the peaks are barely resolved. By 15 passes, baseline separation has been achieved. The inset shows that the square of resolution is proportional to the number of passes, as predicted by Equation 22-30.

FIGURE 22-15 Separation of 0.5 mM L-phenylalanine and 0.5 mM L-phenylalanine- $\mathrm{D}_{5}$ by repeated passes through a pair of Hypersil C8 liquid chromatography columns ( $25 \mathrm{~cm} \times 4.6 \mathrm{~mm}$ ) eluted with $10: 90$ acetonitrile:water containing $25 \mathrm{mM} \mathrm{Na}_{2} \mathrm{SO}_{4}$ and $0.1 \%$ trifluoroacetic acid in the water. The relative retention on the first pass is $\boldsymbol{\alpha}=1.03$. [From K. Lan and J. W. Jorgensen, "Pressure-Induced Retention Variations in Reversed-Phase Alternate-Pumping Recycle Chromatography," Anal. Chem. 1998, 70, 2773.]

Equation 22-30 also tells us that resolution increases as the unadjusted relative retention $\gamma$ increases. The unadjusted relative retention is the relative velocity of the two components through the column. The way to change relative velocity is to change the stationary phase in gas chromatography or either the stationary or the mobile phase in liquid chromatography. Important equations from chromatography are summarized in Table 22-2.

## EXAMPLE Plates Needed for Desired Resolution

Two solutes have an unadjusted relative retention of $\gamma=1.06$. How many plates are required to give a resolution of 1.5 ? Of 3.0 ? If the plate height is 0.5 mm in gas chromatography, how long must the column be for a resolution of 1.5 ?

Solution We use Equation 22-30:

$$
\text { Resolution }=1.5=\frac{\sqrt{N}}{4}(\gamma-1) \Rightarrow N=\left(\frac{4(1.5)}{1.06-1}\right)^{2}=1.0 \times 10^{4} \text { plates }
$$

To double the resolution to 3.0 requires four times as many plates $=4.0 \times 10^{4}$ plates. For resolution $=1.5$, the required length is $(0.5 \mathrm{~mm} /$ plate $)\left(1.0 \times 10^{4}\right.$ plates $)=5 \mathrm{~m}$.

Test Yourself If $\gamma=1.06$ and $H=3 \mu \mathrm{~m}$ in liquid chromatography, what length of column in cm gives a resolution of 1.5 ? (Answer: 3.0 cm )

Unadjusted relative retention: $\gamma=\frac{u_{A}}{u_{B}}=\frac{t_{B}}{t_{A}}$
$u_{A}, u_{B}=$ linear velocities of components $A$ and $B$
$t_{A}, t_{B}=$ retention times of components $A$ and $B$

Resolution $\propto \sqrt{N} \propto \sqrt{L}$

TABLE 22-2 Summary of chromatography equations

| Quantity | Equation | Parameters |
| :---: | :---: | :---: |
| Partition coefficient | $K=c_{\mathrm{s}} / c_{\mathrm{m}}$ | $c_{\mathrm{s}}=$ concentration of solute in stationary phase <br> $c_{\mathrm{m}}=$ concentration of solute in mobile phase |

Variance is additive, but standard deviation is not.

## 22-5 Why Bands Spread ${ }^{14}$

A band of solute invariably spreads as it travels through a chromatography column (Figure 22-11) and emerges at the detector with a standard deviation $\sigma$. Each individual mechanism contributing to broadening produces a standard deviation $\sigma_{i}$. The observed variance ( $\sigma_{\mathrm{obs}}^{2}$ ) is the sum of variances from all contributing mechanisms:

Variance is additive:

$$
\begin{equation*}
\sigma_{\mathrm{obs}}^{2}=\sigma_{1}^{2}+\sigma_{2}^{2}+\sigma_{3}^{2}+\cdots=\sum \sigma_{i}^{2} \tag{22-31}
\end{equation*}
$$

## Broadening Outside the Column

Solute cannot be applied to the column in an infinitesimally thin zone, so the band has a finite width even before it enters the column. If the band is applied as a plug of width $\Delta t$ (measured in units of time), the contribution to the variance of the final bandwidth is

Variance due to

$$
\begin{equation*}
\sigma_{\text {injection }}^{2}=\sigma_{\text {detector }}^{2}=\frac{(\Delta t)^{2}}{12} \tag{22-32}
\end{equation*}
$$

The same relation holds for broadening in a detector that requires a time $\Delta t$ for the sample to pass through. Sometimes on-column detection is possible, thereby eliminating the problem of band spreading in a detector.

## EXAMPLE Band Spreading Before and After the Column

A band from a column eluted at a rate of $1.35 \mathrm{~mL} / \mathrm{min}$ has a width at half-height of 16.3 s . The sample was applied as a sharp plug with a volume of 0.30 mL , and the detector volume is 0.20 mL . Find the variances introduced by injection and detection. What would $w_{1 / 2}$ be if broadening occurred only on the column?

Solution Figure 22-9 tells us that the width at half-height is $w_{1 / 2}=2.35 \sigma$. Therefore, the observed total variance is

$$
\sigma_{\mathrm{obs}}^{2}=\left(\frac{w_{1 / 2}}{2.35}\right)^{2}=\left(\frac{16.3}{2.35}\right)^{2}=48.11 \mathrm{~s}^{2}
$$

Injection time is $\Delta t_{\text {injection }}=(0.30 \mathrm{~mL}) /(1.35 \mathrm{~mL} / \mathrm{min})=0.222 \mathrm{~min}=13.3 \mathrm{~s}$. Therefore,

$$
\sigma_{\text {injection }}^{2}=\frac{\Delta t_{\text {injection }}^{2}}{12}=\frac{13.3^{2}}{12}=14.81 \mathrm{~s}^{2}
$$

The time spent in the detector is $\Delta t_{\text {detector }}=(0.20 \mathrm{~mL}) /(1.35 \mathrm{~mL} / \mathrm{min})=8.89 \mathrm{~s}$, so $\sigma_{\text {detector }}^{2}=\Delta t_{\text {detector }}^{2} / 12=6.58 \mathrm{~s}^{2}$. The observed variance is

$$
\begin{gathered}
\sigma_{\text {obs }}^{2}=\sigma_{\text {column }}^{2}+\sigma_{\text {injection }}^{2}+\sigma_{\text {detector }}^{2} \\
48.11=\sigma_{\text {column }}^{2}+14.81+6.58 \Rightarrow \sigma_{\text {column }}=5.17 \mathrm{~s}
\end{gathered}
$$

The width due to column broadening alone is $w_{1 / 2}=2.35 \sigma_{\text {column }}=12.1 \mathrm{~s}$, which is about three-fourths of the observed width.

Test Yourself Predict $w_{1 / 2}$ if the injected volume were decreased to 0.15 mL ? (Answer: 14.3 s )

The worst possible band spreading occurs in the large dead space beneath some rudimentary benchtop chromatography columns where each new drop exiting the column mixes with a significant volume of eluate already in the dead space. To minimize band spreading, dead spaces and tubing lengths should be minimized. Sample should be applied uniformly in a narrow zone and allowed to enter the column before mixing with eluent.

## Plate Height Equation

Plate height, $H$, is proportional to the variance of a chromatographic band (Equation 22-27): the smaller the plate height, the narrower the band. The van Deemter equation tells us how the column and flow rate affect plate height:
van Deemter equation
for plate height:

where $u_{\mathrm{x}}$ is the linear flow rate and $A, B$, and $C$ are constants for a given column and stationary phase. Changing the column and stationary phase changes $A, B$, and $C$. The van Deemter equation says there are band-broadening mechanisms that are proportional to flow rate, inversely proportional to flow rate, and independent of flow rate (Figure 22-16).

In packed columns, all three terms contribute to band broadening. For open tubular columns, the multiple path term, $A$, is 0 , so bandwidth decreases and resolution increases. In capillary electrophoresis (Chapter 25), both $A$ and $C$ go to 0 , thereby reducing plate height to submicron values and providing extraordinary separation powers.

## Longitudinal Diffusion

If you could apply a thin, disk-shaped band of solute to the center of a column, the band would slowly broaden as molecules diffuse from the high concentration within the band to regions of lower concentration on the edges of the band. Diffusional broadening of a band, called longitudinal diffusion because it takes place along the axis of the column, occurs while the band is transported along the column by the flow of solvent (Figure 22-17).

The term $B / u_{\mathrm{x}}$ in Equation 22-33 arises from longitudinal diffusion. The faster the linear flow, the less time is spent in the column and the less diffusional broadening occurs. Equation 22-26 told us that the variance resulting from diffusion is

Plate height due to longitudinal diffusion:

$$
\begin{align*}
\sigma^{2} & =2 D_{\mathrm{m}} t=\frac{2 D_{\mathrm{m}} L}{u_{\mathrm{x}}} \\
H_{\mathrm{D}} & =\frac{\sigma^{2}}{L}=\frac{2 D_{\mathrm{m}}}{u_{\mathrm{x}}} \equiv \frac{B}{u_{\mathrm{x}}} \tag{22-34}
\end{align*}
$$

FIGURE 22-16 Application of van Deemter equation to gas chromatography: $A=1.65 \mathrm{~mm}$, $B=25.8 \mathrm{~mm} \cdot \mathrm{~mL} / \mathrm{min}$, and $C=0.0236 \mathrm{~mm} \cdot$ $\mathrm{min} / \mathrm{mL}$. [Experimental points from H. W. Moody,
"The Evaluation of the Parameters in the van Deemter Equation," J. Chem. Ed. 1982, 59, 290.]

Packed columns: $A, B, C \neq 0$
Open tubular columns: $A=0$
Capillary electrophoresis: $A=C=0$

FIGURE 22-17 Longitudinal diffusion gives rise to $B / u_{\mathrm{x}}$ in the van Deemter equation. Solute continuously diffuses away from the concentrated center of its zone. The faster the flow, the less time is spent on the column and the less longitudinal diffusion occurs.

Longitudinal diffusion in a gas is much faster than diffusion in a liquid, so the optimum linear flow rate in gas chromatography is higher than in liquid chromatography.

FIGURE 22-18 The finite time required for solute to equilibrate between mobile and stationary phases gives rise to $C u_{x}$ in the van Deemter equation. The slower the linear flow, the more complete equilibration is and the less zone broadening occurs.

The term $A$ was formerly called the eddy diffusion term.
where $D_{\mathrm{m}}$ is the diffusion coefficient of solute in the mobile phase, $t$ is time, and $H_{\mathrm{D}}$ is the plate height due to longitudinal diffusion. The time needed to travel the length of the column is $L / u_{\mathrm{x}}$, where $L$ is the column length and $u_{\mathrm{x}}$ is the linear flow rate.

## Finite Equilibration Time Between Phases

The term $C u_{\mathrm{x}}$ in Equation 22-33 comes from the finite time required for solute to equilibrate between mobile and stationary phases. ${ }^{15}$ Although some solute is stuck in the stationary phase, the remainder in the mobile phase moves forward, spreading the overall zone of solute (Figure 22-18).

Plate height from finite equilibration time, also called the mass transfer term, is
Plate height due to
finite equilibration time: $\quad H_{\text {mass transfer }}=C u_{\mathrm{x}}=\left(C_{\mathrm{s}}+C_{\mathrm{m}}\right) u_{\mathrm{x}}$
where $C_{\mathrm{s}}$ describes the rate of mass transfer through the stationary phase and $C_{\mathrm{m}}$ describes mass transfer through the mobile phase. Specific equations for $C_{\mathrm{s}}$ and $C_{\mathrm{m}}$ depend on the type of chromatography.

For gas chromatography in an open tubular column, the terms are
Mass transfer in stationary phase:

Mass transfer in mobile phase:

$$
\begin{gather*}
C_{\mathrm{s}}=\frac{2 k}{3(k+1)^{2}} \frac{d^{2}}{D_{\mathrm{s}}}  \tag{22-35a}\\
C_{\mathrm{m}}=\frac{1+6 k+11 k^{2}}{24(k+1)^{2}} \frac{r^{2}}{D_{\mathrm{m}}} \tag{22-35b}
\end{gather*}
$$

where $k$ is the retention factor, $d$ is the thickness of stationary phase, $D_{\mathrm{s}}$ is the diffusion coefficient of solute in the stationary phase, $r$ is the column radius, and $D_{\mathrm{m}}$ is the diffusion coefficient of solute in the mobile phase. Decreasing stationary phase thickness, $d$, reduces plate height and increases efficiency because solute can diffuse faster from the farthest depths of the stationary phase into the mobile phase. Decreasing column radius, $r$, reduces plate height by decreasing the distance through which solute must diffuse to reach the stationary phase.

Mass transfer plate height is also decreased by increasing temperature, which increases the diffusion coefficient of solute in the stationary phase. In Figure 22-19, raising the temperature allows the linear flow rate to be increased by a factor of 5 while maintaining acceptable resolution. Resolution is maintained because of the increased rate of mass transfer between phases at elevated temperature. Many common silica-based stationary phases for liquid chromatography are not stable at elevated temperature. The zirconia $\left(\mathrm{ZrO}_{2}\right)$-based material in Figure 22-19 is used because it is stable.

## Multiple Flow Paths

The term $A$ in the van Deemter equation (22-33) arises from multiple effects for which the theory is murky. Figure 22-20 is a pictorial explanation of one effect. Because some flow paths are longer than others, molecules entering the column at the same time on the left are

FIGURE 22-19 Liquid chromatography showing decreased analysis time when temperature is raised from $30^{\circ}$ to $100^{\circ} \mathrm{C}$. 1, uracil; $2, p$-nitroaniline; 3 , methyl benzoate; 4 , phenetole; 5 , toluene. The 4.6 - mm -diameter $\times$ $100-\mathrm{cm}$-long column was packed with $4.5-\mu \mathrm{m}$ diameter zirconia $\left(\mathrm{ZrO}_{2}\right)$ coated with $2.1 \mathrm{wt} \%$ polybutadiene and eluted with 20 vol\% acetonitrile in water. [From J. Li, Y. Hu, and P. W. Carr, "Fast Separations at Elevated Temperatures on Polybutadiene-Coated Zirconia Reversed-Phase Material," Anal. Chem. 1997, 69, 3884.] For a silica-based stationary phase, temperature is usually kept below $60^{\circ} \mathrm{C}$ to prevent hydrolysis of the silica.

eluted at different times on the right. For simplicity, we approximate many different effects by the constant $A$ in Equation 22-33.

## Advantages of Open Tubular Columns

In gas chromatography, we have a choice of using open tubular columns or packed columns. For similar analysis times, open tubular columns provide higher resolution and increased sensitivity to small quantities of analyte. Open tubular columns have small sample capacity, so they are not useful for preparative separations.

Particles in a packed column resist flow of the mobile phase, so the linear flow rate cannot be very fast. For the same length of column and applied pressure, the linear flow rate in an open tubular column is much higher than that of a packed column. Therefore, the open tubular column can be made 100 times longer than the packed column and still achieve a similar pressure drop and linear flow rate. If plate height is the same, the longer column provides 100 times more theoretical plates, yielding $\sqrt{100}=10$ times more resolution.

Plate height is reduced in an open tubular column because band spreading by multiple flow paths (Figure 22-20) cannot occur. In the van Deemter curve for the packed column in Figure 22-16, the $A$ term accounts for half of the plate height at the most efficient flow rate (minimum $H$ ) near $30 \mathrm{~mL} / \mathrm{min}$. If $A$ were deleted, the number of plates on the column would be doubled. To obtain high performance from an open tubular column, the radius of the column must be small and the stationary phase must be as thin as possible to ensure rapid exchange of solute between mobile and stationary phases.

Table 22-3 compares the performances of packed and open tubular gas chromatography columns with the same stationary phase. For similar analysis times, the open tubular column gives resolution seven times better ( 10.6 versus 1.5) than that of the packed column. Alternatively, speed could be traded for resolution. If the open tubular column were reduced to 5 m in length, the same solutes could be separated with a resolution of 1.5 , but the time would be reduced from 38.5 to 0.83 min .

## A Touch of Reality: Asymmetric Bandshapes

A Gaussian bandshape results when the partition coefficient, $K\left(=c_{\mathrm{s}} / c_{\mathrm{m}}\right)$, is independent of the concentration of solute on the column. In real columns, $K$ changes as the concentration of solute increases, and bandshapes are skewed. ${ }^{16}$ A graph of $c_{\mathrm{s}}$ versus $c_{\mathrm{m}}$ (at a given temperature) is called an isotherm. Three common isotherms and their resulting bandshapes are shown in Figure 22-21. The ideal center isotherm gives a symmetric peak.

The upper isotherm in Figure 22-21 arises from an overloaded column in which too much solute has been applied to the column. As the concentration of solute increases, the solute becomes more and more soluble in the stationary phase. There is so much solute in the stationary phase that the stationary phase begins to resemble solute. (There is a rule of thumb in chemistry that "like dissolves like.") The front of an overloaded peak has gradually increasing concentration.

TABLE 22-3 Comparison of packed and wall-coated open tubular column performance ${ }^{\text {a }}$

| Property | Packed | Open tubular |
| :--- | :--- | :--- |
| Column length, $L$ | 2.4 m | 100 m |
| Linear gas velocity | $8 \mathrm{~cm} / \mathrm{s}$ | $16 \mathrm{~cm} / \mathrm{s}$ |
| Plate height for methyl oleate | 0.73 mm | 0.34 mm |
| Retention factor, $k$, for methyl oleate | 58.6 | 2.7 |
| Theoretical plates, $N$ | 3290 | 294000 |
| Resolution of methyl stearate and methyl oleate | 1.5 | 10.6 |
| Retention time of methyl oleate | 29.8 min | 38.5 min |

[^14]FIGURE 22-20 Band spreading from multiple flow paths. The smaller the stationary phase particles, the less serious this problem is. This process is absent in an open tubular column. [Adapted from H. M. McNair and E. J. Bonelli, Basic Gas Chromatography (Palo Alto, CA: Varian Instrument Division, 1968).]

Compared with packed columns, open tubular columns can provide

- higher resolution
- shorter analysis time
- increased sensitivity
- lower sample capacity

For a given pressure, linear flow rate is proportional to cross-sectional area of the column and inversely proportional to column length:

$$
u_{\mathrm{x}} \propto \frac{\text { area }}{\text { length }}
$$

Compared with packed columns, open tubular columns allow

- increased linear flow rate or a longer column or both
- decreased plate height, which means higher resolution
$c_{\mathrm{s}}=$ concentration of solute in stationary phase $c_{m}=$ concentration of solute in mobile phase

Overloading produces a gradual rise and an abrupt fall of the chromatographic peak.

A long tail occurs when some sites retain solute more strongly than other sites.

As the concentration increases, the band becomes overloaded. The solute is so soluble in the overloaded zone that little solute trails behind the peak. The band emerges gradually from the column but ends abruptly.

The lower isotherm in Figure 22-21 arises when small quantities of solute are retained more strongly than large quantities. It leads to a long "tail" of gradually decreasing concentration after the peak.

Sites that bind solute strongly cause tailing. Silica surfaces of columns and stationary phase particles have hydroxyl groups that form hydrogen bonds with polar solutes, thereby leading to serious tailing. Silanization reduces tailing by blocking the hydroxyl groups with nonpolar trimethylsilyl groups:

Glass and silica columns used for gas and liquid chromatography can also be silanized to minimize interaction of the solute with active sites on the walls.

Now that you have been exposed to many concepts, you might want to read about a microscopic model of chromatography in Box 22-2.

## BOX 22-2 Microscopic Description of Chromatography

A stochastic theory provides a model for chromatography. ${ }^{17}$ The term "stochastic" implies the presence of a random variable. The model supposes that as a molecule travels through a column, it spends an average time $\tau_{\mathrm{m}}$ in the mobile phase between adsorption events. The time between desorption and the next adsorption is random, but the average time is $\tau_{\mathrm{m}}$. The average time spent adsorbed to the stationary phase between one adsorption and one desorption is $\tau_{\mathrm{s}}$. While the molecule is adsorbed on the stationary phase, it does not move. When the molecule is in the mobile phase, it moves with the speed $u_{\mathrm{x}}$ of the mobile phase. The probability that an adsorption or desorption occurs in a given time follows the Poisson distribution, which was described briefly in Problem 18-23.

We assume that all molecules spend total time $t_{\mathrm{m}}$ in the mobile phase. This is the retention time of unretained solute. Important results of the stochastic model are

- A solute molecule is adsorbed and desorbed an average of $n$ times as it flows through the column, where $n=t_{\mathrm{m}} / \tau_{\mathrm{m}}$.
- The adjusted retention time for a solute is

$$
\begin{equation*}
t_{\mathrm{r}}^{\prime}=n \tau_{\mathrm{s}} \tag{A}
\end{equation*}
$$

This is the average time that the solute is bound to the stationary phase during its transit through the column.

- The width (standard deviation) of a peak due to effects of the stationary phase is

$$
\begin{equation*}
\sigma=\tau_{\mathrm{s}} \sqrt{2 n} \tag{B}
\end{equation*}
$$

Consider the idealized chromatogram in the illustration, with one unretained component and two retained substances, A and B. The chromatographic parameters are representative of a high-performance liquid chromatography separation on a $15-\mathrm{cm}$-long $\times$ 0.39 -cm-diameter column packed with 5 - $\mu \mathrm{m}$-diameter spherical particles of $\mathrm{C}_{18}$-silica (Section 24-1). With a volume flow rate of $1.0 \mathrm{~mL} / \mathrm{min}$, the linear velocity is $u_{\mathrm{x}}=2.4 \mathrm{~mm} / \mathrm{s}$. From the measured width at half-height $\left(w_{1 / 2}\right)$, the standard deviation $(\sigma)$ of a Gaussian
peak is computed from $w_{1 / 2}=2.35 \sigma$ (Figure 22-9). The plate number for components A and B , computed with Equation 22-28, is $N=\left(t_{\mathrm{r}} / \sigma\right)^{2}=1.00 \times 10^{4}$.

The stochastic model applies to processes involving the stationary phase. To analyze the chromatogram, we need to subtract contributions to peak broadening from dispersion in the mobile phase and extra-column effects such as finite injection width and finite detector volume. These effects account for the width of the unretained peak. To subtract the unwanted effects, we write

$$
\begin{aligned}
& \sigma_{\text {observed }}^{2}=\sigma_{\text {stationary phase }}^{2}+\sigma_{\text {unretained peak }}^{2} \\
& \sigma_{\text {stationary phase }}^{2}=\sigma_{\text {observed }}^{2}-\sigma_{\text {unretained peak }}^{2}
\end{aligned}
$$

For component $\mathrm{A}, \sigma_{\text {stationary phase }}^{2}=\sigma_{\text {observed }}^{2}-\sigma_{\text {unretained peak }}^{2}=$ $(3.6 \mathrm{~s})^{2}-(1.5 \mathrm{~s})^{2} \Rightarrow \sigma_{\text {stationary phase }}=3.27 \mathrm{~s}$. For component $B$, we find $\sigma_{\text {stationary phase }}=5.81 \mathrm{~s}$. The adjusted retention time for component A is $t_{\mathrm{r}}^{\prime}=t_{\mathrm{r}}-t_{\mathrm{m}}=360-60=300 \mathrm{~s}$. For component B , $t_{\mathrm{r}}^{\prime}=600-60=540 \mathrm{~s}$.

Now we use $t_{\mathrm{r}}^{\prime}$ and $\sigma\left(=\sigma_{\text {stationary phase }}\right)$ for each component to find physically meaningful parameters. Combining Equations A and $B$ above, we find

$$
n=2\left(\frac{t_{\mathrm{r}}^{\prime}}{\sigma}\right)^{2} \quad \tau_{\mathrm{s}}=\frac{\sigma^{2}}{2 t_{\mathrm{r}}^{\prime}}
$$

and we already knew that $\tau_{\mathrm{m}}=t_{\mathrm{m}} / n$. From the parameters in the illustration, we compute the results in the table below.

|  | Component A | Component B |
| :--- | :---: | :---: |
| $n$ | 16800 | 17300 |
| $\tau_{\mathrm{s}}$ | 17.8 ms | 31.2 ms |
| $\tau_{\mathrm{m}}$ | 3.6 ms | 3.5 ms |
| Distance between adsorptions |  |  |
| $\quad\left(=u_{\mathrm{x}} \tau_{\mathrm{m}}\right)$ | $8.6 \mu \mathrm{~m}$ | $8.4 \mu \mathrm{~m}$ |

FIGURE 22-21 Common isotherms and their resulting chromatographic bandshapes.

Both components spend nearly the same time ( $\sim 3.5 \mathrm{~ms}$ ) in the mobile phase between adsorption events. Component A spends an average of 17.8 ms bound to the stationary phase each time it is adsorbed and component B spends an average of 31.2 ms . This difference in $\tau_{\mathrm{s}}$ is the reason why A and B are separated from each other.

During its transit through the column, each substance becomes adsorbed $n \approx 17000$ times. The distance traveled between adsorptions is $\sim 8.6 \mu \mathrm{~m}$. The chromatogram was simulated for a column with $N=$ 10000 theoretical plates. The plate height is $15 \mathrm{~cm} /(10000$ plates $)=$ $15 \mu \mathrm{~m}$. In Section 22-4, we stated that plate height is approximately the length of column required for one equilibration of solute between mobile and stationary phases. From the stochastic theory in this example, we find that there are approximately two equilibrations with the stationary phase in each length corresponding to the plate height.

The time required for a solute to flow past a stationary-phase particle whose diameter is $d=5 \mu \mathrm{~m}$ is $t=(5 \mu \mathrm{~m}) /(2.4 \mathrm{~mm} / \mathrm{s})=$
2.1 ms . The stochastic theory predicts that the fraction of time that a molecule in the mobile phase will travel less than distance $d$ is $1-\mathrm{e}^{-t / \tau_{\mathrm{m}}}=1-\mathrm{e}^{-(2.1 \mathrm{~ms}) /(3.5 \mathrm{~ms})}=0.55$. That is, approximately half of the time, a solute molecule does not travel as far as the next particle of stationary phase before becoming adsorbed again to the same particle from which it just desorbed. If we lined up spherical particles of stationary phase, it would take 30000 particles to cover the $15-\mathrm{cm}$ length of the column. Each solute molecule binds $\sim 17000$ times as it transits the column, and half of those binding steps are to the same particle from which it just desorbed.

The model provides insight into microscopic events that occur during chromatography. The model omits some phenomena that occur in real columns. For example, in a porous stationary phase, the mobile phase could be stagnant inside the pores. When a molecule enters such a pore, it will adsorb and desorb many times from the same particle before escaping from the pore.

Idealized liquid chromatographic separation of 3 components.

## Summary

A solute can be extracted from one phase into another in which it is more soluble. The ratio of solute concentrations in each phase at equilibrium is called the partition coefficient. If more than one form of the solute exists, we use a distribution coefficient instead of a partition coefficient. We derived equations relating the fraction of solute extracted to the partition or distribution coefficient, volumes, and pH . Many small extractions are more effective than a few large extractions. A metal chelator, soluble only in organic solvents, can extract metal ions from aqueous solutions, with selectivity achieved by adjusting pH . Crown ethers and salts containing a hydrophobic ion act as phase transfer agents to bring a hydrophilic ion from an aqueous phase into an organic phase.

In adsorption and partition chromatography, a continuous equilibration of solute between mobile and stationary phases occurs. Eluent goes into a column and eluate comes out. Columns may be packed with stationary phase or may be open tubular, with stationary phase bonded to the inner wall. In ion-exchange chromatography, the solute is attracted to the stationary phase by coulombic forces. In molecular exclusion chromatography, the fraction of stationary phase volume available to solute decreases as the size of the solute molecules increases. Affinity chromatography relies on specific, noncovalent interactions between the stationary phase and one solute in a complex mixture.

The relative retention of two components is the quotient of their adjusted retention times. The retention factor for a single component is the adjusted retention time divided by the elution time for solvent. Retention factor gives the ratio of time spent by solute in the stationary phase to time spent in the mobile phase. When a separation is scaled up from a small load to a large load, linear flow rate is held constant and the cross-sectional area of the column should be increased in proportion to the loading.

Plate height $\left(H=\sigma^{2} / x\right)$ is related to the breadth of a band emerging from the column. The smaller the plate height, the sharper the band. The number of plates for a Gaussian peak is $N=5.55 t_{\mathrm{r}}^{2} / w_{1 / 2}^{2}$. Plate height is approximately the length of column required for one equilibration of solute between mobile and stationary phases. Resolution of neighboring peaks is the difference in retention time divided by the average width (measured at the baseline, $w=4 \sigma$ ). Resolution is proportional to $\sqrt{N}$ and increases with the unadjusted relative retention, $\gamma$, which is the quotient of linear velocities of two components. Doubling the length of a column increases resolution by $\sqrt{2}$.

The standard deviation of a diffusing band of solute is $\sigma=\sqrt{2 D t}$, where $D$ is the diffusion coefficient and $t$ is time. The van Deemter equation describes band broadening on the chromatographic column: $H \approx A+B / u_{\mathrm{x}}+C u_{\mathrm{x}}$, where $H$ is plate height, $u_{\mathrm{x}}$ is linear flow rate, and $A, B$, and $C$ are constants. The first term represents irregular flow paths, the second, longitudinal diffusion, and the third, the finite rate of transfer of solute between mobile and stationary phases. The optimum flow rate, which minimizes plate height, is faster for gas chromatography than for liquid chromatography. The number of plates and the optimal flow rate increase as the stationary phase particle size decreases. In gas chromatography, open tubular columns can provide higher resolution or shorter analysis times than packed columns. Bands spread during injection and detection, as well as during passage through the column. The observed variance of the band is the sum of the variances for all mechanisms of spreading. Overloading and tailing can be corrected by using smaller samples and by masking strong adsorption sites on the stationary phase.

## Exercises

22-A. Consider a chromatography experiment in which two components with retention factors $k_{1}=4.00$ and $k_{2}=5.00$ are injected into a column with $N=1.00 \times 10^{3}$ theoretical plates. The retention time for the less-retained component is $t_{\mathrm{r} 1}=10.0 \mathrm{~min}$.
(a) Calculate $t_{\mathrm{m}}$ and $t_{\mathrm{r} 2}$. Find $w_{1 / 2}$ (width at half-height) and $w$ (width at the base) for each peak
(b) Using graph paper, sketch the chromatogram analogous to Figure 22-7, supposing that the two peaks have the same amplitude (height). Draw the half-widths accurately.
(c) Calculate the resolution of the two peaks and compare this value with those drawn in Figure 22-10.

22-B. A solute with a partition coefficient of 4.0 is extracted from 10 mL of phase 1 into phase 2 .
(a) What volume of phase 2 is needed to extract $99 \%$ of the solute in one extraction?
(b) What is the total volume of solvent 2 needed to remove $99 \%$ of the solute in three equal extractions instead?

22-C. (a) Find the retention factors for octane and nonane in Figure 22-7.
(b) Find the ratio
$\frac{\text { Time octane spends in stationary phase }}{\text { Total time octane spends on column }}$
(c) Find the relative retention for octane and nonane.
(d) Find the partition coefficient for octane by assuming that the volume of the stationary phase equals half the volume of the mobile phase.

22-D. A gas chromatogram of a mixture of toluene and ethyl acetate is shown here.

(a) Use the width of each peak (measured at the base) to calculate the number of theoretical plates in the column. Estimate all lengths to the nearest 0.1 mm .
(b) Using the width of the toluene peak at its base, calculate the width expected at half-height. Compare the measured and calculated values. When the thickness of the pen line is significant relative to the length being measured, it is important to take the pen line width into account. You can measure from the edge of one line to the corresponding edge of the other line, as shown here.

$22-\mathrm{E}$. The three chromatograms shown below were obtained with $2.5,1.0$, and $0.4 \mu \mathrm{~L}$ of ethyl acetate injected on the same column under the same conditions. Explain why the peak becomes less symmetric with increasing sample size.

22-F. The relative retention for two compounds in gas chromatography is 1.068 on a column with a plate height of 0.520 mm . The retention factor for compound 1 is 5.16.
(a) Find the unadjusted relative retention $(\gamma)$ for the two compounds.
(b) What length of column will separate the compounds with a resolution of 1.00 ?
(c) The retention time for air $\left(t_{\mathrm{m}}\right)$ is 2.00 min . If the number of plates is the same for both compounds, find $t_{\mathrm{r}}$ and $w_{1 / 2}$ for each peak.
(d) If the ratio of stationary phase to mobile phase is 0.30 , find the partition coefficient for compound 1 .

## Problems

## Solvent Extraction

22-1. If you are extracting a substance from water into ether, is it more effective to do one extraction with 300 mL of ether or three extractions with 100 mL ?

22-2. If you wish to extract aqueous acetic acid into hexane, is it more effective to adjust the aqueous phase to pH 3 or pH 8 ?
22-3. (a) Why is it difficult to extract the EDTA complex of aluminum into an organic solvent but easy to extract the 8 -hydroxyquinoline complex?
(b) If you need to bring the EDTA complex into the organic solvent, should you add a phase transfer agent with a hydrophobic cation or a hydrophobic anion?

22-4. Why is the extraction of a metal ion into an organic solvent with 8-hydroxyquinoline more complete at higher pH ?

22-5. The distribution coefficient for extraction of a metal complex from aqueous to organic solvents is $D=[\text { total metal }]_{\text {org }} /[\text { total metal }]_{\text {aq- }}$. Give physical reasons why $\beta$ and $K_{\mathrm{a}}$ appear in the numerator of Equation 22-13, but $K_{\mathrm{L}}$ and $\left[\mathrm{H}^{+}\right]_{\mathrm{aq}}$ appear in the denominator.
22-6. Give a physical interpretation of Equations 22-6 and 22-7 in terms of the fractional composition equations for a monoprotic acid discussed in Section 9-5.

22-7. Solute $S$ has a partition coefficient of 4.0 between water (phase 1 ) and chloroform (phase 2) in Equation 22-1.
(a) Calculate the concentration of S in chloroform if $[\mathrm{S}(a q)]$ is 0.020 M . (b) If the volume of water is 80.0 mL and the volume of chloroform is 10.0 mL , find the quotient ( mol S in chloroform)/( mol S in water).
22-8. The solute in Problem 22-7 is initially dissolved in 80.0 mL of water. It is then extracted six times with $10.0-\mathrm{mL}$ portions of chloroform. Find the fraction of solute remaining in the aqueous phase.

22-9. The weak base B $\left(K_{\mathrm{b}}=1.0 \times 10^{-5}\right)$ equilibrates between water (phase 1) and benzene (phase 2).
(a) Define the distribution coefficient, $D$, for this system.
(b) Explain the difference between $D$ and $K$, the partition coefficient.
(c) Calculate $D$ at pH 8.00 if $K=50.0$.
(d) Will $D$ be greater or less at pH 10 than at pH 8 ? Explain why.

22-10. Consider the extraction of $\mathrm{M}^{n+}$ from aqueous solution into organic solution by reaction with protonated ligand, HL:

$$
\begin{gathered}
\mathrm{M}^{n+}(a q)+n \mathrm{HL}(\text { org }) \rightleftharpoons \mathrm{ML}_{n}(\text { org })+n \mathrm{H}^{+}(a q) \\
K_{\text {extraction }}=\frac{\left[\mathrm{ML}_{n}\right]_{\text {org }}\left[\mathrm{H}^{+}\right]_{\mathrm{aq}}^{n}}{\left[\mathrm{M}^{n+}\right]_{\mathrm{aq}}[\mathrm{HL}]_{\mathrm{org}}^{n}}
\end{gathered}
$$

Rewrite Equation 22-13 in terms of $K_{\text {extraction }}$ and express $K_{\text {extraction }}$ in terms of the constants in Equation 22-13. Give a physical reason why each constant increases or decreases $K_{\text {extraction }}$.
22-11. Butanoic acid has a partition coefficient of 3.0 (favoring benzene) when distributed between water and benzene. Find the formal concentration of butanoic acid in each phase when 100 mL of 0.10 M aqueous butanoic acid is extracted with 25 mL of benzene (a) at pH 4.00 and (b) at pH 10.00 .

22-12. For a given value of $[\mathrm{HL}]_{\text {org }}$ in Equation 22-13, over what pH range (how many pH units) will $D$ change from 0.01 to 100 if $n=2$ ?

22-13. For the extraction of $\mathrm{Cu}^{2+}$ by dithizone in $\mathrm{CCl}_{4}, K_{\mathrm{L}}=1.1 \times 10^{4}$, $K_{\mathrm{M}}=7 \times 10^{4}, K_{\mathrm{a}}=3 \times 10^{-5}, \beta=5 \times 10^{22}$, and $n=2$.
(a) Calculate the distribution coefficient for extraction of $0.1 \mu \mathrm{M}$ $\mathrm{Cu}^{2+}$ into $\mathrm{CCl}_{4}$ by 0.1 mM dithizone at pH 1.0 and at pH 4.0 .
(b) If 100 mL of $0.1 \mu \mathrm{M}$ aqueous $\mathrm{Cu}^{2+}$ are extracted once with 10 mL of 0.1 mM dithizone at pH 1.0 , what fraction of $\mathrm{Cu}^{2+}$ remains in the aqueous phase?
22-14. Consider the extraction of 100.0 mL of $\mathrm{M}^{2+}(a q)$ by 2.0 mL of $1 \times 10^{-5} \mathrm{M}$ dithizone in $\mathrm{CHCl}_{3}$, for which $K_{\mathrm{L}}=1.1 \times 10^{4}$, $K_{\mathrm{M}}=7 \times 10^{4}, K_{\mathrm{a}}=3 \times 10^{-5}, \beta=5 \times 10^{18}$, and $n=2$.
(a) Derive an expression for the fraction of metal ion extracted into the organic phase, in terms of the distribution coefficient and volumes of the two phases.
(b) Prepare a graph of the percentage of metal ion extracted over the pH range 0 to 5 .
22-15. 扉閏 The theoretical limit for extracting solute $S$ from phase 1 (volume $V_{1}$ ) into phase 2 (volume $V_{2}$ ) is attained by dividing $V_{2}$ into an infinite number of infinitesimally small portions and conducting an infinite number of extractions. With a partition coefficient $K=[\mathrm{S}]_{2} /[\mathrm{S}]_{1}$, the limiting fraction of solute remaining in phase 1 is $^{2} q_{\text {limit }}=\mathrm{e}^{-\left(V_{2} / V_{1}\right) K}$. Let $V_{1}=V_{2}=50 \mathrm{~mL}$ and let $K=2$. Let volume $V_{2}$ be divided into $n$ equal portions to conduct $n$ extractions. Find the fraction of $S$ extracted into phase 2 for $n=1,2,10$ extractions. How many portions are required to attain $95 \%$ of the theoretical limit?

## A Plumber's View of Chromatography

22-16. Match the terms in the first list with the characteristics in the second list.

1. adsorption chromatography
2. partition chromatography
3. ion-exchange chromatography
4. molecular exclusion chromatography
5. affinity chromatography
A. Ions in mobile phase are attracted to counterions covalently attached to stationary phase.
B. Solute in mobile phase is attracted to specific groups covalently attached to stationary phase.
C. Solute equilibrates between mobile phase and surface of stationary phase.
D. Solute equilibrates between mobile phase and film of liquid attached to stationary phase.
E. Different-sized solutes penetrate voids in stationary phase to different extents. Largest solutes are eluted first.
22-17. The partition coefficient for a solute in chromatography is $K=c_{\mathrm{s}} / c_{\mathrm{m}}$, where $c_{\mathrm{s}}$ is the concentration in the stationary phase and $c_{\mathrm{m}}$ is the concentration in the mobile phase. The larger the partition coefficient, the longer it takes a solute to be eluted. Explain why.
22-18. (a) Write the meaning of the retention factor, $k$, in terms of time spent by solute in each phase.
(b) Write an expression in terms of $k$ for the fraction of time spent by a solute molecule in the mobile phase.
(c) The retention ratio in chromatography is defined as

$$
R=\frac{\text { time for solvent to pass through column }}{\text { time for solute to pass through column }}=\frac{t_{\mathrm{m}}}{t_{\mathrm{r}}}
$$

Show that $R$ is related to the retention factor by the equation $R=1 /(k+1)$.
22-19. (a) A chromatography column with a length of 10.3 cm and inner diameter of 4.61 mm is packed with a stationary phase that occupies $61.0 \%$ of the volume. If the volume flow rate is $1.13 \mathrm{~mL} / \mathrm{min}$, find the linear flow rate in $\mathrm{cm} / \mathrm{min}$.
(b) How long does it take for solvent (which is the same as unretained solute) to pass through the column?
(c) Find the retention time for a solute with a retention factor of 10.0.

22-20. An open tubular column is 30.1 m long and has an inner diameter of 0.530 mm . It is coated on the inside wall with a layer of stationary phase that is $3.1 \mu \mathrm{~m}$ thick. Unretained solute passes through in 2.16 min , whereas a particular solute has a retention time of 17.32 min .
(a) Find the linear and volume flow rates.
(b) Find the retention factor for the solute and the fraction of time spent in the stationary phase.
(c) Find the partition coefficient, $c_{\mathrm{s}} / c_{\mathrm{m}}$, for this solute.

22-21. A chromatographic procedure separates 4.0 mg of unknown mixture on a column with a length of 40 cm and a diameter of 0.85 cm .
(a) What size column would you use to separate 100 mg of the same mixture?
(b) If the flow is $0.22 \mathrm{~mL} / \mathrm{min}$ on the small column, what volume flow rate should be used on the large column?
(c) If mobile phase occupies $35 \%$ of the column volume, calculate the linear flow rate for the small column and the large column.
22-22. Solvent passes through a column in 3.0 min but solute requires 9.0 min .
(a) Calculate the retention factor, $k$.
(b) What fraction of time is the solute in the mobile phase in the column?
(c) The volume of stationary phase is $1 / 10$ of the volume of the mobile phase in the column $\left(V_{\mathrm{s}}=0.10 V_{\mathrm{m}}\right)$. Find the partition coefficient, $K$, for this system.

22-23. Solvent occupies $15 \%$ of the volume of a chromatography column whose inner diameter is 3.0 mm . If the volume flow rate is $0.2 \mathrm{~mL} / \mathrm{min}$, find the linear flow rate.

22-24. Consider a chromatography column in which $V_{\mathrm{s}}=V_{\mathrm{m}} / 5$. Find the retention factor if $K=3$ and if $K=30$.
$\mathbf{2 2 - 2 5}$. The retention volume of a solute is 76.2 mL for a column with $V_{\mathrm{m}}=16.6 \mathrm{~mL}$ and $V_{\mathrm{s}}=12.7 \mathrm{~mL}$. Calculate the retention factor and the partition coefficient for this solute.

22-26. An open tubular column has an inner diameter of $207 \mu \mathrm{~m}$ and the thickness of the stationary phase on the inner wall is $0.50 \mu \mathrm{~m}$. Unretained solute passes through in 63 s and a particular solute emerges in 433 s . Find the partition coefficient for this solute and find the fraction of time spent in the stationary phase.
22-27. Isotopic compounds are separated in Figure 22-15 by repeated passage through a pair of columns. Each cycle in the figure represents one pass through length $L=50 \mathrm{~cm}$ containing $N$ theoretical plates. The unadjusted relative retention is $\gamma=1.018$.
(a) The observed resolution after 10 cycles is 1.60 . Calculate the number of theoretical plates, $N$, in column length $L$. The mixture has passed through length $10 L$ in 10 cycles.
(b) Find the plate height in $\mu \mathrm{m}$.
(c) Predict the resolution expected from two cycles. The observed value is 0.71 .

## Efficiency and Band Spreading

22-28. Chromatograms of compounds A and B were obtained at the same flow rate with two columns of equal length.

(a) Which column has more theoretical plates?
(b) Which column has a larger plate height?
(c) Which column gives higher resolution?
(d) Which column gives a greater relative retention?
(e) Which compound has a higher retention factor?
(f) Which compound has a greater partition coefficient?
(g) What is the numerical value of the unadjusted relative retention?

22-29. Why does plate height depend on linear flow rate, not volume flow rate?

22-30. Which column is more efficient: plate height $=$ (a) 0.1 mm or (b) 1 mm ?

22-31. Why is longitudinal diffusion a more serious problem in gas chromatography than in liquid chromatography?

22-32. In chromatography, why is the optimal flow rate greater if the stationary phase particle size is smaller?

22-33. What is the optimal flow rate in Figure 22-16 for best separation of solutes?

22-34. Explain how silanization reduces tailing of chromatographic peaks.

22-35. Describe how nonlinear partition isotherms lead to nonGaussian bandshapes. Draw the bandshape produced by an overloaded column and a column with tailing.

22-36. A separation of 2.5 mg of an unknown mixture has been optimized on a column of length $L$ and diameter $d$. Explain why you might not achieve the same resolution for 5.0 mg on a column of length $2 L$ and diameter $d$.

22-37. An infinitely sharp zone of solute is placed at the center of a column at time $t=0$. After diffusion for time $t_{1}$, the standard deviation of the Gaussian band is 1.0 mm . After 20 min more, at time $t_{2}$, the standard deviation is 2.0 mm . What will be the width after another 20 min, at time $t_{3}$ ?

22-38. A chromatogram with ideal Gaussian bands has $t_{\mathrm{r}}=9.0 \mathrm{~min}$ and $w_{1 / 2}=2.0 \mathrm{~min}$.
(a) How many theoretical plates are present?
(b) Find the plate height if the column is 10 cm long.

22-39. (a) The asymmetric chromatogram in Figure 22-14 has a retention time equal to 15 min , and the values of A and B are 33 and 11 s , respectively. Find the number of theoretical plates.
(b) The width of the Gaussian peak in Figure 22-9 at a height equal to $1 / 10$ of the peak height is $4.297 \sigma$. Suppose that the peak in part (a) is symmetric with $A=B=22 \mathrm{~s}$. Use Equations 22-28 and 22-29 to find the plate number.

22-40. Two chromatographic peaks with widths, $w$, of 6 min are eluted at 24 and 29 min . Which diagram in Figure 22-10 will most closely resemble the chromatogram?

22-41. A chromatographic band has a width, $w$, of 4.0 mL and a retention volume of 49 mL . What width is expected for a band with a retention volume of 127 mL ? Assume that the only band spreading occurs on the column itself.

22-42. A band from a column eluted at $0.66 \mathrm{~mL} / \mathrm{min}$ has a width at half-height, $w_{1 / 2}$, of 39.6 s . The sample was applied as a sharp plug with a volume of 0.40 mL , and the detector volume is 0.25 mL . Find the variances introduced by injection and detection. What would $w_{1 / 2}$ be if the only broadening occurred on the column?

22-43. Two compounds with partition coefficients of 15 and 18 are to be separated on a column with $V_{\mathrm{m}} / V_{\mathrm{s}}=3.0$ and $t_{\mathrm{m}}=1.0 \mathrm{~min}$. Calculate the number of theoretical plates needed to produce a resolution of 1.5 .

22-44. (a) Calculate the number of theoretical plates needed to achieve a resolution of 2.0 for compounds with unadjusted relative retention times of $t_{2} / t_{1}=1.01,1.05$, or 1.10.
(b) How can you increase $N$ and $\gamma=t_{2} / t_{1}$ in a chromatography experiment?

22-45. Consider the peaks for pentafluorobenzene and benzene in the chromatogram below. The elution time for unretained solute is 1.06 min . The open tubular column is 30.0 m in length and 0.530 mm in diameter, with a layer of stationary phase $3.0 \mu \mathrm{~m}$ thick on the inner wall.

## WHAT DID THEY EAT IN THE YEAR $1000 ?$

Gas chromatogram of cholesterol and other lipids extracted from bones and derivatized with trimethylsilyl $\left(\left(\mathrm{CH}_{3}\right)_{3} \mathrm{Si}-\right)$ groups to increase volatility for chromatography. Bone contains 2 to $50 \mu \mathrm{~g}$ cholesterol/gram of dry bone. [From A. W. Stott and R. P. Evershed, " $\delta^{13} \mathrm{C}$ Analysis of Cholesterol Preserved in Archaeological Bones and Teeth," Anal. Chem. 1996, 68, 4402. Excellent questions for student interpretation of this article can be found in L. Roecker, "Introducing Students to the Scientific Literature," J. Chem. Ed. 2007, 84, 1380.]
${ }^{13} \mathrm{C}$ content of cholesterol from bones of 50 people who lived on British coast in the years A.D. $500-1800 . \delta^{13} \mathrm{C}$ is the deviation of the atomic ratio ${ }^{13} \mathrm{C} /{ }^{12} \mathrm{C}$ from that of a standard material, measured in parts per thousand. [Data from A. W. Stott and R. P. Evershed, " $\delta{ }^{13} \mathrm{C}$ Analysis of Cholesterol Preserved in Archaeological Bones and Teeth," Anal. Chem. 1996, 68, 4402.]

The ${ }^{13} \mathrm{C}$ content of cholesterol preserved in ancient bones provides information on the diets of people who lived long ago. Approximately $1.1 \%$ of natural carbon is ${ }^{13} \mathrm{C}$ and $98.9 \%$ is ${ }^{12} \mathrm{C}$. Different types of plants and animals have consistent, slightly different ratios of ${ }^{13} \mathrm{C} /{ }^{12} \mathrm{C}$, which reflect their biosynthetic pathways.

To learn whether people from the ancient British coastal town of Barton-on-Humber ate mainly plants or fish, cholesterol from the bones of 50 people was extracted with organic solvent, isolated by gas chromatography, combusted to convert it into $\mathrm{CO}_{2}$, and its ${ }^{13} \mathrm{C} /{ }^{12} \mathrm{C}$ ratio measured by mass spectrometry. Observed ${ }^{13} \mathrm{C} /{ }^{12} \mathrm{C}$ ratios differ from that of a standard material by about -21 to -24 parts per thousand. A diet of local plants yields a $\delta^{13} \mathrm{C}$ value (defined in Box 21-3) in cholesterol of -28 parts per thousand. Values more positive than -28 parts per thousand are indicative of a marine diet. It appears that the population got much of its food from the sea.

## Gas chromatography:

mobile phase: gas
stationary phase: usually a nonvolatile liquid, but sometimes a solid
analyte: gas or volatile liquid

Chapter 22 gave a foundation for understanding chromatographic separations. Chapters 23 through 25 discuss specific methods and instrumentation. The goal is for you to understand how chromatographic methods work and what parameters you can control for best results. ${ }^{1}$

## 23-1 The Separation Process in Gas Chromatography

In gas chromatography, ${ }^{2,3,4}$ gaseous analyte is transported through the column by a gaseous mobile phase, called the carrier gas. In gas-liquid partition chromatography, the stationary phase is a nonvolatile liquid bonded to the inside of the column or to a fine solid support

The choice of carrier gas depends on the detector and the desired separation efficiency and speed.

Compared with packed columns, open tubular columns offer

- higher resolution
- shorter analysis time
- greater sensitivity
- lower sample capacity

Wall-coated open tubular column (WCOT): liquid stationary phase on inside wall of column Support-coated open tubular column (SCOT): liquid stationary phase coated on solid support attached to inside wall of column
Porous-layer open tubular column (PLOT): solid stationary phase on inside wall of column

FIGURE 23-1 Schematic diagram of a gas chromatograph.
(Figure 22-6, upper right). In gas-solid adsorption chromatography, analyte is adsorbed directly on solid particles of stationary phase (Figure 22-6, upper left).

In the schematic gas chromatograph in Figure 23-1, volatile liquid or gaseous sample is injected through a septum (a rubber disk) into a heated port, in which it rapidly evaporates. Vapor is swept through the column by $\mathrm{He}, \mathrm{N}_{2}$, or $\mathrm{H}_{2}$ carrier gas, and separated analytes flow through a detector, whose response is displayed on a computer. The column must be hot enough to provide sufficient vapor pressure for analytes to be eluted in a reasonable time. The detector is maintained at a higher temperature than the column so analytes will be gaseous.

## Open Tubular Columns

The vast majority of analyses use long, narrow open tubular columns (Figure 23-2) made of fused silica $\left(\mathrm{SiO}_{2}\right)$ and coated with polyimide (a plastic capable of withstanding $350^{\circ} \mathrm{C}$ ) for support and protection from atmospheric moisture. ${ }^{5}$ As discussed in Section 22-5, open tubular columns offer higher resolution, shorter analysis time, and greater sensitivity than packed columns, but they have less sample capacity.

The wall-coated column in Figure 23-2c features a 0.1 - to $5-\mu \mathrm{m}$-thick film of stationary liquid phase on the inner wall of the column. A support-coated column has solid particles coated with stationary liquid phase and attached to the inner wall. In the porous-layer column in Figure 23-3, solid particles are the active stationary phase. With their high surface area, support-coated columns can handle larger samples than can wall-coated columns. The performance of support-coated columns is intermediate between those of wall-coated columns and packed columns.

(b) Chromatogram of vapors from the headspace of a beer can, obtained with 0.25 -mm-diameter $\times 30$-m-long porous carbon column operated at $30^{\circ} \mathrm{C}$ for 2 min and then ramped up to $160^{\circ} \mathrm{C}$ at $20^{\circ} / \mathrm{min}$. [Courtesy Alltech Associates, State College, PA.]

Column inner diameters are typically 0.10 to 0.53 mm and lengths are 15 to 100 m , with 30 m being common. Narrow columns provide higher resolution than wider columns (Figure 23-4 and Equation 22-35b) but require higher operating pressure and have less sample capacity. Diameters $\geq 0.32 \mathrm{~mm}$ tend to overload the vacuum system of a mass spectrometer, so the gas stream must be split and only a fraction sent to the spectrometer. The number of theoretical plates, $N$, on a column is proportional to length. In Equation 22-30, resolution is proportional to $\sqrt{N}$ and, therefore, to the square root of column length (Figure 23-5).

At the constant linear velocity in Figure 23-6, increasing the thickness of the stationary phase increases retention time and sample capacity and increases resolution of earlyeluting peaks with a retention factor (Equation 22-17) of $k \lesssim 5$. Thick films of stationary phase can shield analytes from the silica surface and reduce tailing (Figure 22-21), but

FIGURE 23-4 Effect of open tubular column inner diameter on resolution. Narrower columns provide higher resolution. Notice the increased resolution of peaks 1 and 2 in the narrow column. Conditions: DB-1 stationary phase ( $0.25 \mu \mathrm{~m}$ thick) in $15-\mathrm{m}$ wall-coated column operated at $95^{\circ} \mathrm{C}$ with He linear velocity of $34 \mathrm{~cm} / \mathrm{s}$. Arylene polysiloxane

FIGURE 23-6 Effect of stationary phase thickness on open tubular column performance. Increasing thickness increases retention time and increases resolution of early-eluting peaks. Conditions: DB-1 stationary phase in 15 -m-long $\times 0.32$-mm-diameter wall-coated column operated at $40^{\circ} \mathrm{C}$ with He linear velocity of $38 \mathrm{~cm} / \mathrm{s}$. [Courtesy J\&W Scientific, Folsom, CA.]

they can also increase bleed (decomposition and evaporation) of the stationary phase at elevated temperature. A thickness of $0.25 \mu \mathrm{~m}$ is standard, but thicker films are used for volatile analytes.

The choice of liquid stationary phase (Table 23-1) is based on the rule "like dissolves like." Nonpolar columns are best for nonpolar solutes (Table 23-2). Columns of intermediate polarity are best for intermediate polarity solutes, and strongly polar columns are best for strongly polar solutes. Box 23-1 describes chiral (optically active) bonded phases for separating optical isomers.

As a column ages, stationary phase can be lost, surface silanol groups $(\mathrm{Si}-\mathrm{O}-\mathrm{H})$ are exposed, and tailing increases. To reduce the tendency of stationary phase to bleed from the column at high temperature, it is usually bonded (covalently attached) to the silica surface and covalently cross-linked to itself. To monitor column performance, it is good practice to periodically measure the retention factor of a standard (Equation 22-17), the number of plates (Equation 22-28), and peak asymmetry (Figure 22-14). Changes in these parameters indicate degradation of the column.

At upper operating temperatures, stationary phases decompose, giving a slow "bleed" of decomposition products from the column. These products produce elevated background signal in most detectors, reducing the signal-to-noise for analyte and potentially contaminating the detector. Arylene stationary phases have increased thermal stability, bleed less at high temperature, and are especially suitable for gas chromatography-mass spectrometry. Compared with (diphenyl)(dimethyl)polysiloxanes, arylene phases produce some differences in relative retention of different compounds.

Optical isomers-also called enantiomers-are mirror image compounds that cannot be superimposed. For example, the natural amino acid building blocks of proteins are L-amino acids.

Enantiomers of an amino acid

Chromatography with a chiral (optically active) stationary phase is one of the few ways to separate enantiomers. We can estimate ages of fossils up to 500 million years old by measuring the fraction of amino acid that has transformed into the D enantiomer in a fossil. ${ }^{6,7}$ Amino acids do not have enough vapor pressure for gas chromatography. A volatile derivative suitable for gas chromatography is shown in the figure above. ${ }^{8}$

Common chiral stationary phases for gas chromatography have $c y$ clodextrins bonded to a conventional polysiloxane stationary phase., ${ }^{9,10}$ Cyclodextrins are naturally occurring cyclic sugars. $\beta$-Cyclodextrin has a 0.78 -nm-diameter opening into a chiral, hydrophobic cavity. The hydroxyls are capped with alkyl groups to decrease the polarity of the faces.

(a) Structure of $\beta$-cyclodextrin, a cyclic sugar made of seven glucose molecules. ( $\alpha$-Cyclodextrin contains six monomers and $\gamma$-cyclodextrin contains eight.) (b) Primary hydroxyl groups lie on one face and the secondary hydroxyl groups lie on the other face.

Enantiomers have different affinities for the cyclodextrin cavity, so they separate as they travel through the chromatography column. The chromatogram shows a chiral separation of a by-product found in pesticides.

Programmed temperature $\left(120^{\circ}-200^{\circ} \mathrm{C}\right)$ chiral separation on a $0.25-\mathrm{mm} \times 25-\mathrm{m}$ open tubular column with a $0.25-\mu \mathrm{m}$-thick stationary phase containing $10 \mathrm{wt} \%$ fully methylated $\beta$-cyclodextrin chemically bonded to poly(dimethylsiloxane). [From W. Vetter and W. Jun, "Elucidation of a Polychlorinated Bipyrrole Structure Using Enantioselective GC," Anal. Chem. 2002, 74, 4287.]

Chlorinated pesticide impurity. The two rings are perpendicular to each other. The mirror images are not superimposable, because there is no free rotation about the $\mathrm{C}-\mathrm{N}$ bond between the rings.

To reduce interference from column bleeding, use the thinnest possible stationary phase and the narrowest and shortest column that provides adequate separation. Oxidation of the stationary phase by $\mathrm{O}_{2}$ is also a major source of bleed. High-purity carrier gas should be used, and it should be passed through an $\mathrm{O}_{2}$ scrubber before the column. Even 1 ppb of $\mathrm{O}_{2}$ slowly degrades the column. To a lesser extent, $\mathrm{H}_{2} \mathrm{O}$ can break down the stationary phase by hydrolysis. To minimize bleed, manufacturers modify the silica surface of the capillary to eliminate exposed silanol groups ( $\mathrm{Si}-\mathrm{OH}$ ), which can initiate breakdown of the stationary phase.

Ionic liquids are the newest type of stationary phase for gas chromatography. They melt below room temperature and have a wide liquid range with low volatility at elevated temperature. Ionic liquids have the potential to offer novel selectivities for polar analytes and increased operating temperature with low bleed.

1,9-Di(3-vinylimidazolium)nonane bis(trifluoromethyl)sulfonylimidate (Supelco SP-IL 100 stationary phase)

Among the solids used for porous-layer open tubular columns, porous polymers, high-surface-area carbon (Figure 23-3), and alumina $\left(\mathrm{Al}_{2} \mathrm{O}_{3}\right)$ can separate hydrocarbons in gas-solid adsorption chromatography. Molecular sieves (Figure 23-7) are inorganic or organic materials with cavities into which small molecules enter and are partially retained. ${ }^{11}$ Molecules such as $\mathrm{H}_{2}, \mathrm{O}_{2}, \mathrm{~N}_{2}, \mathrm{CO}_{2}$, and $\mathrm{CH}_{4}$ can be separated from one another. Gases can be dried by passage through traps containing molecular sieves because water is strongly retained. Inorganic sieves can be regenerated (dried) by heating to $300^{\circ} \mathrm{C}$ in vacuum or under flowing $\mathrm{N}_{2}$.

FIGURE 23-7 Structure of the molecular sieve $\mathrm{Na}_{12}\left(\mathrm{Al}_{12} \mathrm{Si}_{12} \mathrm{O}_{48}\right) \cdot 27 \mathrm{H}_{2} \mathrm{O}$. (a) Aluminosilicate framework of one cubo-octahedron of a mineral class called zeolites. (b) Interconnection of eight cubo-octahedra to produce a cavity into which small molecules can enter.

## Packed Columns

Packed columns contain fine particles of solid support coated with nonvolatile liquid stationary phase, or the solid itself may be the stationary phase. Compared with open tubular columns, packed columns provide greater sample capacity but give broader peaks, longer retention times, and less resolution. (Compare Figure 23-8 with Figure 23-3.) Despite their inferior resolution, packed columns are used for preparative separations, which require a great deal of stationary phase, or to separate gases that are poorly retained. Packed columns are usually made of stainless steel or glass and are typically $3-6 \mathrm{~mm}$ in diameter and $1-5 \mathrm{~m}$ in length. The solid support is often silica that is silanized (Reaction 22-36) to reduce hydrogen bonding to polar solutes. For tenaciously binding solutes, Teflon is a useful support, but it is limited to $<200^{\circ} \mathrm{C}$.

In a packed column, uniform particle size decreases the multiple path term in the van Deemter equation (22-33), thereby reducing plate height and increasing resolution. Small particle

FIGURE 23-8 Chromatogram of alcohol mixture at $40^{\circ} \mathrm{C}$ using packed column ( 2 mm inner diameter $\times 76 \mathrm{~cm}$ long) containing 20\% Carbowax 20M on Gas-Chrom R support and flame ionization detector. [Courtesy Norman Pearson.]

size decreases the time required for solute equilibration, thereby improving column efficiency. However, the smaller the particle size, the less space between particles and the more pressure required to force mobile phase through the column. Particle size is expressed in micrometers or as a mesh size, which refers to the size of screens through which the particles are passed or retained (Table 27-2). A 100/200 mesh particle passes through a 100 mesh screen, but not through a 200 mesh screen. The mesh number equals the number of openings per linear inch of screen.

## Retention Index

Figure 23-9 illustrates how the relative retention times of polar and nonpolar solutes change as the polarity of the stationary phase changes. In Figure 23-9a, 10 compounds are eluted nearly in order of increasing boiling point from a nonpolar stationary phase. The principal determinant of retention on this column is the volatility of the solutes. In Figure 23-9b, the strongly polar stationary phase retains the strongly polar solutes. The three alcohols are the last to be eluted, following the three ketones, which follow four alkanes. Hydrogen bonding

FIGURE 23-9 Separation of 10 compounds on (a) nonpolar poly(dimethylsiloxane) and (b) strongly polar poly(ethylene glycol) 1- $\mu \mathrm{m}$-thick stationary phases in 0.32 -mm-diameter $\times 30$-m-long open tubular columns at $70^{\circ} \mathrm{C}$. [Courtesy Restek Co., Bellefonte, PA.]
to the stationary phase is probably the strongest force leading to retention. Dipole interactions of the ketones are the second strongest force.

The Kovats retention index, $I$, for a linear alkane equals 100 times the number of carbon atoms. For octane, $I=800$; and for nonane, $I=900$. A compound eluted between octane and nonane (Figure 22-7) has a retention index between 800 and 900 computed by the formula

Retention index: $\quad I=100\left[n+(N-n) \frac{\log t_{\mathrm{r}}^{\prime}(\text { unknown })-\log t_{\mathrm{r}}^{\prime}(n)}{\log t_{\mathrm{r}}^{\prime}(N)-\log t_{\mathrm{r}}^{\prime}(n)}\right]$
where $n$ is the number of carbon atoms in the smaller alkane; $N$ is the number of carbon atoms in the larger alkane; $t_{\mathrm{r}}^{\prime}(n)$ is the adjusted retention time of the smaller alkane; and $t_{\mathrm{r}}^{\prime}(N)$ is the adjusted retention time of the larger alkane.

## EXAMPLE Retention Index

If the retention times in Figure 22-7 are $t_{\mathrm{r}}\left(\mathrm{CH}_{4}\right)=0.5 \mathrm{~min}, t_{\mathrm{r}}($ octane $)=14.3 \mathrm{~min}$, $t_{\mathrm{r}}($ unknown $)=15.7 \mathrm{~min}$, and $t_{\mathrm{r}}($ nonane $)=18.5 \mathrm{~min}$, find the retention index for the unknown.

Solution The index is computed with Equation 23-1:

$$
I=100\left[8+(9-8) \frac{\log 15.2-\log 13.8}{\log 18.0-\log 13.8}\right]=836
$$

Test Yourself Where would an unknown with a retention index of 936 be eluted in Figure 22-7? (Answer: after nonane)

The retention index of 657 for benzene on poly(dimethylsiloxane) in Table 23-3 means that benzene is eluted between hexane $(I \equiv 600)$ and heptane ( $I \equiv 700$ ) from this nonpolar stationary phase. Nitropropane is eluted just after heptane on the same column. As we go down the table, the stationary phases become more polar. For (biscyanopropyl) $0_{0.9^{-}}$ (cyanopropylphenyl $)_{0.1}$ polysiloxane at the bottom of the table, benzene is eluted after decane, and nitropropane is eluted after $n-\mathrm{C}_{14} \mathrm{H}_{30}$.

Retention index relates the retention time of a

When identifying an eluted compound by comparing its mass spectrum with a mass spectral library, false matches are frequent. If retention index is used as a second characteristic, false matches are reduced.

Raising column temperature:

- decreases retention time
- sharpens peaks
solute to the retention times of linear alkanes.

Adjusted retention time $=t_{\mathrm{r}}^{\prime}=t_{\mathrm{r}}-t_{\mathrm{m}}$ $t_{\mathrm{r}}=$ retention time for solute $t_{\mathrm{m}}=$ time for unretained solute $\left(\mathrm{CH}_{4}\right)$ to pass through column

## Temperature and Pressure Programming

A large fraction of all gas chromatography is run with temperature programming, in which the temperature of the column is raised during the separation to increase analyte vapor pressure

TABLE 23-3 Retention indexes for several compounds on common stationary phases

| Phase | Retention index ${ }^{a}$ |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  |  <br> Benzene $\text { b.p. } 80^{\circ} \mathrm{C}$ |  |  | $\mathrm{NO}_{2}$ |  <br> Pyridine <br> b.p. $116^{\circ} \mathrm{C}$ |
| Poly(dimethylsiloxane) | 657 | 648 | 670 | 708 | 737 |
| (Diphenyl) $)_{0.05}(\text { dimethyl })_{0.95^{-}}$ polysiloxane | 672 | 664 | 691 | 745 | 761 |
| (Diphenyl) $0_{0.35}(\text { dimethyl })_{0.65^{-}}$ polysiloxane | 754 | 717 | 777 | 871 | 879 |
| (Cyanopropylphenyl) $)_{0.14^{-}}$ (dimethyl) ${ }_{0.86}$ polysiloxane | 726 | 773 | 784 | 880 | 852 |
| (Diphenyl) $)_{0.65}(\text { dimethyl })_{0.35^{-}}$ polysiloxane | 797 | 779 | 824 | 941 | 943 |
| Poly(ethylene glycol) | 956 | 1142 | 987 | 1217 | 1185 |
| (Biscyanopropyl) $0_{0.9^{-}}$ (cyanopropylphenyl) $0_{0.1^{-}}$ polysiloxane | 1061 | 1232 | 1174 | 1409 | 1331 |

a. For reference, boiling points (b.p.) for various alkanes are hexane, $69^{\circ} \mathrm{C}$; heptane, $98^{\circ} \mathrm{C}$; octane, $126^{\circ} \mathrm{C}$; nonane, $151^{\circ} \mathrm{C}$; decane, $174^{\circ} \mathrm{C}$; undecane, $196^{\circ} \mathrm{C}$. Retention indexes for the straight-chain alkanes are fixed values and do not vary with the stationary phase: hexane, 600 ; heptane, 700; octane, 800; nonane, 900; decane, 1 000; undecane, 1100.

FIGURE 23-11 van Deemter curves for gas chromatography of $n-\mathrm{C}_{17} \mathrm{H}_{36}$ at $175^{\circ} \mathrm{C}$, using $\mathrm{N}_{2}$, He , or $\mathrm{H}_{2}$ in a $0.25-\mathrm{mm}$-diameter $\times 25$-m-long wall-coated column with OV-101 stationary phase. [From R. R. Freeman, ed., High Resolution Gas Chromatography (Palo Alto, CA: Hewlett Packard Co., 1981).]

and decrease retention times of late-eluting components. Figure 23-10 shows the elution of $\mathrm{C}_{5}$ to $\mathrm{C}_{15}$ linear alkanes from a 3-m-long column etched in a silicon chip described in Box 23-2. At a constant temperature of $30^{\circ} \mathrm{C}$ (not shown), heavier alkanes take so long to be eluted and emerge over such a long time that they would not be detected. The three traces in Figure 23-10 show what happens when column temperature is raised from $30^{\circ}$ to $150^{\circ} \mathrm{C}$ at rates of (a) $20^{\circ} \mathrm{C} / \mathrm{min}$, (b) $40^{\circ} \mathrm{C} / \mathrm{min}$, and (c) $60^{\circ} \mathrm{C} / \mathrm{min}$. Broad, late-eluting peaks can be sharpened and eluted in less time with temperature programming. To maintain adequate resolution of earlier eluting peaks, programs often include a period of time at constant, low temperature prior to raising the temperature.

Most gas chromatography columns come with a label showing two temperatures limits. The lower one is the isothermal temperature limit at which the column can be kept for a long time. The upper one is the programmed temperature limit to which the column should only be exposed for a few minutes at a time at the end of a programmed temperature run. High temperatures decompose the stationary phase and cause column "bleeding." An increase in baseline signal at low temperature is an indicator of column degradation. Other signs of column degradation are peak broadening, tailing, and changing retention times.

Many chromatographs are equipped with electronic pressure control of the carrier gas. Increasing the inlet pressure increases the flow of mobile phase and decreases retention time. In some cases, programmed pressure can be used instead of programmed temperature to reduce retention times of late-eluting components. At the end of a run, the pressure can be rapidly reduced to its initial value for the next run. Time is not wasted waiting for a hot column to cool before the next injection. Programmed pressure is useful for analytes that cannot tolerate high temperature.

## Carrier Gas

Helium is the most common carrier gas and is compatible with most detectors. For a flame ionization detector, $\mathrm{N}_{2}$ gives a lower detection limit than He . Figure 23-11 shows that $\mathrm{H}_{2}, \mathrm{He}$, and $\mathrm{N}_{2}$ give essentially the same optimal plate height $(0.3 \mathrm{~mm})$ at significantly different flow rates. Optimal flow rate increases in the order $\mathrm{N}_{2}<\mathrm{He}<\mathrm{H}_{2}$. Fastest separations can be achieved with $\mathrm{H}_{2}$ as carrier gas, and $\mathrm{H}_{2}$ can be run much faster than its optimal velocity with little penalty in resolution. ${ }^{12}$ Figure 23-12 shows the effect of carrier gas on the separation of two compounds on the same column with the same temperature program.

The main reason $\mathrm{H}_{2}$ was not used more often in the past is that concentrations $>4 \mathrm{vol} \%$ in air are explosive. Flow rates in capillary chromatography are unlikely to create a dangerous concentration of $\mathrm{H}_{2}$. Electrolytic generators produce high-purity $\mathrm{H}_{2}$ and eliminate the need for tanks of compressed $\mathrm{H}_{2}$. For gas chromatography-mass spectrometry, $\mathrm{H}_{2}$ reduces the

FIGURE 23-12 Separation of two polyaromatic hydrocarbons on a wall-coated open tubular column with different carrier gases. Resolution, $R$, increases and analysis time decreases as we change from $\mathrm{N}_{2}$ to He to $\mathrm{H}_{2}$ carrier gas. [Courtesy J\&W Scientific, Folsom, CA.]
efficiency of a turbomolecular vacuum pump but has little effect on a diffusion pump. ${ }^{13}$ It is possible for $\mathrm{H}_{2}$ to react with unsaturated compounds on metal surfaces.
$\mathrm{H}_{2}$ and He give better resolution (smaller plate height) than $\mathrm{N}_{2}$ at high flow rate because solutes diffuse more rapidly through $\mathrm{H}_{2}$ and He than through $\mathrm{N}_{2}$. The more rapidly a solute diffuses between phases, the smaller is the mass transfer $\left(C u_{\mathrm{x}}\right)$ term in the van Deemter equation (22-33). Equations 22-35a and 22-35b describe the effects of the finite rate of mass transfer in an open tubular column. If the stationary phase is thin enough ( $\lesssim 0.5 \mu \mathrm{~m}$ ), mass transfer is dominated by slow diffusion through the mobile phase rather than through the stationary phase. That is, $C_{\mathrm{s}} \ll C_{\mathrm{m}}$ in Equations 22-35a and 22-35b. For a column of a given radius, $r$, and a solute of a given retention factor, $k$, the only variable affecting the rate of mass transfer in the mobile phase (Equation 22-35b) is the diffusion coefficient of solute through the mobile phase. Diffusion coefficients follow the order $\mathrm{H}_{2}>\mathrm{He}>\mathrm{N}_{2}$.

Most analyses are run at carrier gas velocities that are 1.5 to 2 times greater than the optimum velocity at the minimum of the van Deemter curve. The higher velocity is chosen to give maximum efficiency (most theoretical plates) per unit time. A decrease in resolution is tolerated in return for faster analyses.

Gas flow through a narrow column may be too low for best detector performance, so extra makeup gas is sometimes added between the column and the detector. Makeup gas that is optimum for detection can be a different gas from that used in the column.

Impurities in carrier gas degrade the stationary phase. High-quality gas should be used, and it should be passed through purifiers to remove traces of $\mathrm{O}_{2}, \mathrm{H}_{2} \mathrm{O}$, and organic compounds. An oxygen indicator trap should be in line after the main purifier. Steel or copper tubing, rather than plastic or rubber, should be used for gas lines because metals are less permeable to air and do not release volatile contaminants into the gas stream. As with thermal degradation, symptoms of oxidative degradation of the stationary phase include increased baseline signal at low temperature, peak broadening and tailing, and altered retention times.

## Guard Columns and Retention Gaps

In gas chromatography, a guard column and a retention gap are both typically a $3-$ to $10-\mathrm{m}$ length of empty capillary in front of the capillary chromatography column. The capillary is silanized so that solutes are not retained by the bare silica wall. Physically, the guard column and the retention gap are identical, but they are employed for different purposes.

The purpose of a guard column is to accumulate nonvolatile substances that would otherwise contaminate the chromatography column and degrade its performance. Periodically,
van Deemter equation:

$$
\begin{aligned}
& H \approx A+\frac{B}{U_{\mathrm{x}}}+C{u_{\mathrm{x}}}_{\substack{\text { Multiple } \\
\text { paths }}}^{\text {Longitudinal }} \begin{array}{c}
\text { Equilibration } \\
\text { difusion }
\end{array}
\end{aligned}
$$

Guard column: accumulates nonvolatile substances that would contaminate chromatography column

The column for Figure 23-10 is part of a microfabricated instrument being developed for environmental monitoring, medical diagnosis, and forensic science. A 3-m-long square spiral channel was etched into silicon, whose edge dimension is 3.2 cm . In panel $a$, gas flows into the white spiral and out from the colored spiral. The connection between the two paths at the center of the structure is shown in panel $b$. A glass plate bonded to the top of the silicon creates a gas-tight channel, which is coated with a $\sim 0.15-\mu \mathrm{m}$-thick layer of cross-linked poly(dimethylsiloxane) (Table 23-1). The carrier gas for a chip designed for field deployment is air that is filtered to remove water and organic vapors.

Efficiency of the column (plate number) increases as the channels are made narrower. Panel $c$ shows the measured effect of channel width on optimum plate height. The smaller the plate height, the greater the plate number. The narrower the channels,
the less time is needed for solute to diffuse from the gas phase to the mobile phase and the more rapidly equilibration occurs between phases.

In addition to band broadening by longitudinal diffusion and finite equilibration time (the terms $B / u_{\mathrm{x}}$ and $C u_{\mathrm{x}}$ in the van Deemter equation 22-33), broadening is created by right-angle corners where gas at the outside of the corner travels farther than gas at the inside of the corner. This problem was reduced in later designs by making curved bends instead of right-angle bends. Parts of the system outside the column create band broadening that is proportional to the square of the linear velocity-giving an additional term $D u_{\mathrm{x}}^{2}$ in the van Deemter equation. Major challenges in creating a small, autonomous chromatograph include making low-power miniature pumps, injectors, detectors, and a gas sampling system to run on battery power.
 Performance, Static-Coated Silicon Microfabricated Columns for Gas Chromatography," Anal. Chem. 2006, 78, 2623.]

Retention gap: improves peak shape by separating volatile solvent from less volatile solutes prior to chromatography
the beginning of the guard column should be cut off to eliminate nonvolatile residues. Trim the guard column when you observe irregular peak shapes from a column that had been producing symmetric peaks. It is a good idea to trim $10-20 \mathrm{~cm}$ off the guard column every time the injection inlet liner is changed. With electronic pneumatically controlled chromatographs, be sure to enter the new length of the guard column in the control software.

A retention gap is used to improve peak shapes under certain conditions. If you introduce a large volume of sample ( $>2 \mu \mathrm{~L}$ ) by splitless or on-column injection (described in the next section), microdroplets of liquid solvent can persist inside the column for the first few meters. Solutes dissolved in the droplets are carried along with them and give rise to a series of ragged bands. The retention gap allows solvent to evaporate prior to entering the chromatography column. Use at least 1 m of retention gap per microliter of solvent. Even small volumes of solvent with very different polarity from the stationary phase can cause irregular peak shapes. The retention gap helps separate solvent from solute to improve peak shapes.

We calculate plate number, $N$, with Equation 22-28 by using retention time and peak width. Plate height, $H$, is the length of the column, $L$, divided by $N$. Do not include the retention gap or guard column as part of $L$ for calculating $H .{ }^{14}$ For peaks with a retention factor $k<5$, plate height might not be meaningful when a guard column or retention gap is used.

FIGURE 23-13 "Sandwich" injection technique. [Adapted from J. T. Watson, Introduction to Mass Spectrometry, 3rd ed. (Philadelphia: Lippincott-Raven, 1997).]

## 23-2 Sample Injection ${ }^{15}$

Figure 23-13 shows a good technique for using a syringe to inject liquid sample into a gas chromatograph. After cleaning the syringe several times with solvent, take up air, then solvent, then air, then sample, and then more air. When the needle is inserted through the rubber septum into the heated injection port of the chromatograph, sample does not immediately evaporate because there is no sample in the needle. If there were sample in the needle, the most volatile components would begin to evaporate and would be depleted before the sample is injected. The air bubble behind the sample plug prevents sample and solvent from mixing. The solvent plug washes sample out of the needle, and the final air plug expels solvent from the needle. Many autosamplers are capable of this "sandwich" injection.

An injection port with a silanized glass liner is shown in Figure 23-14. Carrier gas sweeps vaporized sample from the port into the chromatography column. For analytical chromatography, the injected volume is typically $0.1-2 \mu \mathrm{~L}$ of liquid sample. Gases are injected by a gastight syringe into the same kind of sample loop used in liquid chromatography (Figure 24-18). Decomposed sample, nonvolatile components, and septum debris accumulate in the glass liner, which is periodically replaced. Glass wool is used near the bottom of some liners to trap particles and pyrolysis products to prevent them from reaching the column. The liner must seal properly or carrier gas will bypass the liner. The lifetime of the rubber septum could be as little as 20 manual injections or $\sim 100$ autosampler injections.

## Split Injection

If analytes of interest constitute $>0.1 \%$ of the sample, split injection is usually preferred. For high-resolution work, best results are obtained with the smallest amount of sample $(\leq 1 \mu \mathrm{~L})$ that can be adequately detected-preferably containing $\leq 1 \mathrm{ng}$ of each component. A complete injection contains too much material for a $0.32-\mathrm{mm}$-diameter or smaller column. A split injection delivers only $0.2-2 \%$ of the sample to the column. In Figure $23-14$, sample is injected rapidly ( $<1 \mathrm{~s}$ ) through the septum into the evaporation zone. The injector temperature is kept high (for example, $350^{\circ} \mathrm{C}$ ) to promote fast evaporation. A brisk flow of carrier gas sweeps the sample through the mixing chamber, where complete vaporization and good mixing occur. At the split point, a small fraction of vapor enters the chromatography column, but most passes through needle valve 2 to a waste vent. The pressure regulator leading to needle valve 2 controls the fraction of sample discarded. The proportion of sample that does not reach the column is called the split ratio and typically ranges from 50:1 to 600:1. After sample has been flushed from the injection port ( $\sim 30 \mathrm{~s}$ ), needle valve 2 is closed and carrier gas

Different injection port liners are designed for split, splitless, and on-column injection and for use with solid-phase microextraction.

Injection into open tubular columns: split: routine for introducing small sample volume into open tubular column splitless: best for trace levels of high-boiling solutes in low-boiling solvents on-column: best for thermally unstable solutes and high-boiling solvents; best for quantitative analysis

FIGURE 23-14 Injection port for split injection into an open tubular column. The glass liner is slowly contaminated by nonvolatile and decomposed samples and must be replaced periodically. For splitless injection, the glass liner is a straight tube with no mixing chamber. For dirty samples, split injection is used and a packing material can be placed inside the liner to adsorb undesirable components of the sample. Glass wool might be placed at the near end of the liner so that liquid on the outside of the syringe needle gets wiped off by the wool before the needle is withdrawn.

For solvent trapping, sample should contain $10^{4}$ times as much solvent as analyte and column temperature should be $40^{\circ} \mathrm{C}$ below the solvent's boiling point.

For cold trapping, stationary phase film thickness must be $\geq 2 \mu \mathrm{~m}$.
flow is correspondingly reduced. Quantitative analysis with split injection can be inaccurate because the split ratio is not reproducible from run to run.

A $1-\mu \mathrm{L}$ liquid injection creates roughly 0.5 mL of gas volume, which can fill the glass liner in Figure 23-14. Some vapor can escape backward toward the septum. Lower boiling components evaporate first and are more likely to escape than components with higher boiling points. The injection port temperature should be high enough to minimize this fractionation of the sample. However, if the injector temperature is too high, decomposition can occur. During injection and chromatography, septum purge gas flow through needle valve 1 in Figure 23-14 is run at $\sim 1 \mathrm{~mL} / \mathrm{min}$ to remove excess sample vapor and gas that bleeds from the hot rubber septum.

## Splitless Injection

For trace analysis ${ }^{16}$ of analytes that are less than $0.01 \%$ of the sample, splitless injection is appropriate. The same port shown for split injection in Figure 23-14 is used. However, the glass liner is a straight, empty tube with no mixing chamber, as shown in Figure 23-15. A large volume $(\sim 2 \mu \mathrm{~L})$ of dilute solution in a low-boiling solvent is injected slowly ( $\sim 2$ s) into the liner, with the split vent closed. Slow flow through the septum purge is maintained during injection and chromatography to remove any vapors that escape from the injection liner. Injector temperature for splitless injection is lower $\left(\sim 220^{\circ} \mathrm{C}\right)$ than that for split injection, because the sample spends more time in the port and we do not want it to decompose. The residence time of the sample in the glass liner is $\sim 1 \mathrm{~min}$, because carrier gas flows through the liner at the column flow rate, which is $\sim 1 \mathrm{~mL} / \mathrm{min}$. In splitless injection, $\sim 80 \%$ of the sample is applied to the column, and little fractionation occurs during injection.

The initial column temperature is set $40^{\circ} \mathrm{C}$ below the boiling point of the solvent, which therefore condenses at the beginning of the column. As solutes catch up with the condensed plug of solvent, they are trapped in the solvent in a narrow band at the beginning of the column. This solvent trapping leads to sharp chromatographic peaks. Without solvent trapping, the bands could not be sharper than the 1-min injection time. Chromatography is initiated by raising the column temperature to vaporize the solvent trapped at the head of the column.

An alternative means of condensing solutes in a narrow band at the beginning of the column is called cold trapping. The initial column temperature is $150^{\circ} \mathrm{C}$ lower than the boiling points of the solutes of interest. Solvent and low-boiling components are eluted rapidly, but high-boiling solutes remain in a narrow band at the beginning of the column. The column is then rapidly warmed to initiate chromatography of the high-boiling solutes. For low-boiling solutes, cryogenic focusing is required, with an initial column temperature below room temperature.

Figure 23-16 shows effects of operating parameters in split and splitless injections. Experiment A is a standard split injection with brisk flow through the split vent in Figure 23-15. The column was kept at $75^{\circ} \mathrm{C}$. The injection liner was purged rapidly by carrier gas, and peaks are quite sharp. Experiment B shows the same sample injected in the same way, except the split vent was closed. Then the injection liner was purged slowly, and sample was applied to the column over a long time. Peaks are broad, and they tail badly because fresh carrier gas continuously mixes with vapor in the injector, making it more and more dilute but never completely flushing the

FIGURE 23-15 Representative injection conditions for split, splitless, and on-column injection into an open tubular column.

FIGURE 23-16 Split and splitless injections of a solution containing 1 vol\% methyl isobutyl ketone (b.p. $118^{\circ} \mathrm{C}$ ) and 1 vol $\%$ p-xylene (b.p. $138^{\circ} \mathrm{C}$ ) in dichloromethane (b.p. $40^{\circ} \mathrm{C}$ ) on a BP- 10 moderately polar cyanopropylphenyl methyl silicone open tubular column ( 0.22 mm diameter $\times 10 \mathrm{~m}$ long, film thickness $=0.25 \mu \mathrm{~m}$, column temperature $=75^{\circ} \mathrm{C}$ ). Vertical scale is the same for $A-C$. In $D$, signal heights should be multiplied by 2.33 to be on the same scale as A-C. [From P. J. Marriott and P. D. Carpenter, "Capillary Gas Chromatography Injection," J. Chem. Ed. 1996, 73, 96.]
sample from the injector. Peak areas in B are much greater than those in A because the entire sample reaches the column in B, whereas only a small fraction of sample reaches the column in A.

Experiment C is the same as B , but the split vent was opened after 30 s to rapidly purge all vapors from the injection liner. The bands in chromatogram C would be similar to those in B, but the bands are truncated after 30 s . Experiment D was the same as C, except that the column was initially cooled to $25^{\circ} \mathrm{C}$ to trap solvent and solutes at the beginning of the column. This is the correct condition for splitless injection. Solute peaks are sharp because the solutes were applied to the column in a narrow band of trapped solvent. Detector response in D is different from A-C. Actual peak areas in D are greater than those in A because most of the sample is applied to the column in D , but only a small fraction is applied in A. To make experiment D a proper splitless injection, the sample would need to be much more dilute.

## On-Column Injection

On-column injection is used for samples that decompose above their boiling points and is preferred for quantitative analysis. Solution is injected directly into the column, without going through a hot injector (Figure 23-15). The initial column temperature is low enough to condense solutes in a narrow zone. Warming the column initiates chromatography. Samples are subjected to the lowest possible temperature in this procedure, and little loss of any solute occurs. The needle of a standard microliter syringe fits inside a $0.53-\mathrm{mm}$-diameter column, but this column does not give the best resolution. For 0.20 - to $0.32-\mathrm{mm}$-diameter columns, which give better resolution, special syringes with thin silica needles are required.

## 23-3 Detectors

For qualitative analysis, a mass spectrometer (Chapter 21) can identify a chromatographic peak by comparing its spectrum with a library of spectra. For mass spectral identification, sometimes two prominent mass spectral peaks are selected in the electron ionization spectrum. The quantitation ion is used for quantitative analysis. The confirmation ion is used for qualitative identification. For example, the confirmation ion might be expected to be $65 \%$ as abundant as the quantitation ion. If the observed abundance is not close to $65 \%$, then we suspect that the compound is misidentified.

Another method to identify a peak is to compare its retention time with that of an authentic sample of the suspected compound. The most reliable way to compare retention times is by spiking, also called co-chromatography, in which an authentic compound is added to the unknown. If the added compound is identical with a component of the unknown, then the relative area of that one peak will increase. Identification is tentative when carried out with one column but it is firmer when carried out on several columns with different stationary phases.

TABLE 23-4 Detection limits and linear ranges of gas chromatography detectors

| Detector | Approximate detection limit | Linear range |
| :--- | :--- | :--- |
| Thermal conductivity | $400 \mathrm{pg} / \mathrm{mL}$ (propane) | $>10^{5}$ |
| Flame ionization | $2 \mathrm{pg} / \mathrm{s}$ | $>10^{7}$ |
| Electron capture | As low as $5 \mathrm{fg} / \mathrm{s}$ | $10^{4}$ |
| Flame photometric | $<1 \mathrm{pg} / \mathrm{s}$ (phosphorus) | $>10^{4}$ |
|  | $<10 \mathrm{pg} / \mathrm{s}$ (sulfur) | $>10^{3}$ |
| Nitrogen-phosphorus | $100 \mathrm{fg} / \mathrm{s}$ | $10^{5}$ |
| Sulfur chemiluminescence | $100 \mathrm{fg} / \mathrm{s}$ (sulfur) | $10^{5}$ |
| Photoionization | 25 pg to 50 pg (aromatics) | $>10^{5}$ |
| Fourier transform infrared | 200 pg to 40 ng | $10^{4}$ |
| Mass spectrometric | 25 fg to 100 pg | $10^{5}$ |

Source: Most data are from D. G. Westmoreland and G. R. Rhodes, "Detectors for Gas Chromatography," Pure Appl. Chem. 1989, 61, 1147.

Quantitative analysis is based on the area of a chromatographic peak. In the linear response concentration range, the area of a peak is proportional to the quantity of that component. In most instruments, peak area is reported by a computer. Judgment is required to draw baselines beneath peaks and to decide on the boundaries of the area to be measured. ${ }^{17}$ If area must be measured by hand, and if the peak is Gaussian, then the area is

$$
\begin{equation*}
\text { Area of Gaussian peak }=1.064 \times \text { peak height } \times w_{1 / 2} \tag{23-2}
\end{equation*}
$$

where $w_{1 / 2}$ is the width at half-height (Figure 22-9). Quantitative analysis is almost always performed by adding a known quantity of internal standard to the unknown (Section 5-4). After measurement of the response factor with standard mixtures, the equation in the margin is used to measure the quantity of unknown.

## Thermal Conductivity Detector

In the past, thermal conductivity detectors were common in gas chromatography because they are simple and universal-responding to all analytes. Thermal conductivity is useful for packed columns. It is less sensitive than other detectors used with open tubular columns (Table 23-4).

Thermal conductivity measures the ability of a substance to transport heat from a hot region to a cold region (Table 23-5). Helium is the carrier gas commonly used with a thermal conductivity detector. Helium has the second highest thermal conductivity (after $\mathrm{H}_{2}$ ), so any analyte mixed with helium lowers the conductivity of the gas stream. In Figure 23-17, eluate from the chromatography column flows over a hot tungsten-rhenium filament. When analyte emerges from the column, the conductivity of the gas stream decreases, the filament gets hotter, its electrical resistance increases, and the voltage across the filament changes. The detector measures the change in voltage.

FIGURE 23-17 Thermal conductivity detectors. [Adapted from J. V. Hinshaw, "The Thermal Conductivity Detector," LCGC 2006, 24, 38.]

It is common to split the carrier gas into two streams, sending part through the analytical column and part through a matched reference column. Each stream is passed over a different filament or alternated over a single filament. Resistance of the sample filament is measured with respect to that of the reference filament. The reference column minimizes flow differences when temperature is changed. Sensitivity increases with the square of the filament current. However, to avoid burning out the filament, the maximum recommended current should not be exceeded. The filament should be off when carrier gas is not flowing.

The sensitivity of a thermal conductivity detector (but not that of the flame ionization detector described next) is inversely proportional to flow rate: It is more sensitive at a lower flow rate. Sensitivity also increases with increasing temperature differences between the filament and the surrounding block in Figure 23-17. The block should therefore be maintained at the lowest temperature that allows all solutes to remain gaseous.

## Flame Ionization Detector

In the flame ionization detector in Figure 23-18, eluate is burned in a mixture of $\mathrm{H}_{2}$ and air. ${ }^{18}$ Carbon atoms (except carbonyl and carboxyl carbons) produce CH radicals, which are thought to produce $\mathrm{CHO}^{+}$ions and electrons in the flame.

$$
\mathrm{CH}+\mathrm{O} \rightarrow \mathrm{CHO}^{+}+\mathrm{e}^{-}
$$

Only about 1 in $10^{5}$ carbon atoms produces an ion, but ion production is proportional to the number of susceptible carbon atoms entering the flame. In the absence of analyte, $\sim 10^{-14} \mathrm{~A}$ flows between the flame tip and the collector, which is held at +200 to 300 V with respect to the flame tip. Eluted analytes produce a current of $\sim 10^{-12} \mathrm{~A}$, which is converted to voltage, amplified, filtered to remove high-frequency noise, and finally converted to a digital signal.

Response to organic compounds is proportional to solute mass over seven orders of magnitude. The detection limit is $\sim 100$ times smaller than that of the thermal conductivity detector (Table 23-4) and is reduced by $50 \%$ when $\mathrm{N}_{2}$ carrier gas is used instead of He . For open tubular columns, $\mathrm{N}_{2}$ makeup gas is added to the $\mathrm{H}_{2}$ or He eluate before it enters the detector. The flame ionization detector is sensitive enough for narrow-bore open tubular columns. It responds to most hydrocarbons and is insensitive to nonhydrocarbons such as $\mathrm{H}_{2}$, $\mathrm{He}, \mathrm{N}_{2}, \mathrm{O}_{2}, \mathrm{CO}, \mathrm{CO}_{2}, \mathrm{H}_{2} \mathrm{O}, \mathrm{NH}_{3}, \mathrm{NO}, \mathrm{H}_{2} \mathrm{~S}$, and $\mathrm{SiF}_{4}$.

## Electron Capture Detector

Most detectors other than flame ionization and thermal conductivity respond to limited classes of analytes. The electron capture detector (Figure 23-19) is particularly sensitive to halogencontaining molecules, conjugated carbonyls, nitriles, nitro compounds, and organometallic compounds but relatively insensitive to hydrocarbons, alcohols, and ketones. The carrier or makeup gas must be either $\mathrm{N}_{2}$ or $5 \%$ methane in Ar. Moisture decreases the sensitivity. Gas entering the detector is ionized by high-energy electrons (" $\beta$-rays") emitted from a foil containing radioactive ${ }^{63} \mathrm{Ni}$. Electrons in the plasma thus formed are attracted to an anode, producing a small current that is maintained at a constant level by variable frequency pulses applied between the cathode and anode. When analytes with a high electron affinity enter the detector, they capture some electrons and decrease the conductivity of the plasma. The detector responds by varying the frequency of voltage pulses to maintain a constant current. The frequency of the pulses is the detector signal. The electron capture detector is extremely sensitive (Table 23-4), with a detection limit comparable to that of mass spectrometric selected ion monitoring.

## Other Detectors

The nitrogen-phosphorus detector, also called an alkali flame detector, is a modified flame ionization detector that is especially sensitive to compounds containing N and $\mathrm{P}^{19}$ Its response to N and P is $10^{4}-10^{6}$ times greater than the response to carbon. It is particularly important for drug, pesticide, and herbicide analyses. The detector features a $\mathrm{Rb}_{2} \mathrm{SO}_{4}$-containing glass bead at the burner tip. Ions such as $\mathrm{NO}_{2}^{-}, \mathrm{CN}^{-}$, and $\mathrm{PO}_{2}^{-}$produced by these elements when they contact the bead carry the current that is measured. $\mathrm{N}_{2}$ from air is inert to this detector and does not interfere. The bead must be replaced periodically because $\mathrm{Rb}_{2} \mathrm{SO}_{4}$ is consumed. Figure 23-26 (in the next section) shows a chromatogram from a nitrogenphosphorus detector.

A flame photometric detector measures optical emission from phosphorus, sulfur, lead, tin, or other selected elements. When eluate passes through a $\mathrm{H}_{2}$-air flame, as in the flame

- $10^{5}$ linear response range
- $\mathrm{H}_{2}$ and He give lowest detection limit
- sensitivity increases with increasing filament current decreasing flow rate lower detector block temperature

## Flame ionization detector:

- $\mathrm{N}_{2}$ gives best detection limit
- signal proportional to number of susceptible carbon atoms
- 100 -fold better detection than thermal conductivity
- $10^{7}$ linear response range

FIGURE 23-18 Flame ionization detector. [Courtesy Varian Associates, Palo Alto, CA.]

FIGURE 23-19 Electron capture detector.

FIGURE 23-20 Gas chromatograms showing sulfur compounds in natural gas: (a) flame ionization detector response and (b) sulfur chemiluminescence detector response. The organosulfur compounds are too dilute to be seen in flame ionization, and the sulfur chemiluminescence is insensitive to hydrocarbons. [From N. G. Johansen and J. W. Birks, "Determination of Sulfur Compounds in Difficult Matrices," Am. Lab., February 1991, p. 112.]

Other gas chromatography detectors:
electron capture: halogens, conjugated
$\mathrm{C}=\mathrm{O},-\mathrm{C} \equiv \mathrm{N},-\mathrm{NO}_{2}$
nitrogen-phosphorus: highlights $\mathrm{P}, \mathrm{N}$
flame photometer: individual selected
elements, such as $\mathrm{P}, \mathrm{S}, \mathrm{Sn}, \mathrm{Pb}$
photoionization: aromatics, unsaturated compounds
sulfur chemiluminescence: S nitrogen chemiluminescence: $N$ atomic emission: most elements (selected individually)
mass spectrometer: most analytes
infrared spectrometer: most analytes

Reactions thought to give sulfur chemiluminescence:
sulfur compound $\xrightarrow{\mathrm{H}_{2}-\mathrm{O}_{2} \text { flame }} \mathrm{SO}+$ products
$\mathrm{SO}+\mathrm{O}_{3} \rightarrow \mathrm{SO}_{2}{ }^{*}+\mathrm{O}_{2} \quad\left(\mathrm{SO}_{2}{ }^{*}=\right.$ excited state $)$
$\mathrm{SO}_{2}{ }^{*} \rightarrow \mathrm{SO}_{2}+h \nu$
ionization detector, excited atoms emit characteristic light. Phosphorus emission at 536 nm or sulfur emission at 394 nm can be isolated by a narrow-band interference filter and detected with a photomultiplier tube.

A photoionization detector uses a vacuum ultraviolet source to ionize aromatic and unsaturated compounds; it has little response to saturated hydrocarbons or halocarbons. Electrons produced by the ionization are collected and measured.

A sulfur chemiluminescence detector takes exhaust from a flame ionization detector, in which sulfur has been oxidized to SO , and mixes it with ozone $\left(\mathrm{O}_{3}\right)$ to form an excited state of $\mathrm{SO}_{2}$ that emits blue light and ultraviolet radiation. Emission intensity is proportional to the mass of sulfur eluted, regardless of the source, and the response to S is $10^{7}$ times greater than the response to C (Figure 23-20). A nitrogen chemiluminescence detector is analogous. Combustion of eluate at $1800^{\circ} \mathrm{C}$ converts nitrogen into NO, which reacts with $\mathrm{O}_{3}$ to create a chemiluminescent product. The response to N is $10^{7}$ times greater than the response to C .

## Gas Chromatography-Mass Spectrometry

Mass spectrometry is a sensitive detector that provides both qualitative and quantitative information. With selected ion monitoring or selected reaction monitoring (Section 21-4), we can measure one component in a complex chromatogram of poorly separated compounds. Selected ion monitoring lowers the detection limit by a factor of $10^{2}-10^{3}$ compared with $\mathrm{m} / \mathrm{z}$ scanning, because more time is spent just collecting ions of interest in selected ion monitoring.

Figure 23-21 illustrates selected ion monitoring. The reconstructed total ion chromatogram in trace $a$ was obtained from a portable gas chromatograph-mass spectrometer designed for identification of spills at accident sites. A total of 1072 spectra of eluate were recorded at equal time intervals between 1 and 10 min . The ordinate in the reconstructed total ion chromatogram is the sum of detector signal for all $\mathrm{m} / \mathrm{z}$ above a selected cutoff. It measures everything eluted from the column. The selected ion chromatogram in trace $b$ is obtained by parking the detector at $m / z 78$ and only measuring this one mass. By spending all the time measuring just one ion, the signal-to-noise ratio increases and the

chromatogram is simplified. A peak is observed for benzene (nominal mass 78 Da ) and minor peaks are observed for benzene derivatives at $7-9 \mathrm{~min}$. For quantitative analysis, an internal standard with a signal at $m / z 69$ is added to the mixture. Even though this internal standard overlaps the congested part of the chromatogram near a retention time of 2 min , the selected ion chromatogram for $m / z 69$ has a single peak in trace $c$. To measure benzene, the area of the $m / z 78$ peak in trace $d$ is compared with the area of $m / z 69$ in trace $c$.

Selected reaction monitoring is illustrated in Figure 23-22. Trace $a$ is the reconstructed total ion chromatogram of extract from an orange peel. To make the analysis selective for the pesticide fensulfothion, the precursor ion $m / z 293$ selected by mass filter Q1 in Figure 21-26 was passed to collision cell Q2, in which it broke into fragments with a prominent ion at $\mathrm{m} / \mathrm{z}$ 264. Trace $b$ in Figure 23-22 shows the detector signal at $m / z 264$ from mass filter Q3. Only

FIGURE 23-22 Selected reaction monitoring in gas chromatography-mass spectrometry. (a) Reconstructed total ion chromatogram of extract from orange peel with electron ionization. (b) Selected reaction monitoring with the precursor ion $m / z 293$ selected by mass filter Q1 in Figure 21-26 and product ion $m / z 264$ selected by mass filter Q3. The chromatogram is a graph of intensity at $m / z 264$ from Q3 versus time. [Courtesy Thermo Finnigan GC and GC/MS Division, San Jose, CA.]

FIGURE 23-23 Extracted element chromatograms produced by gas chromatography-inductively coupled plasma-mass spectrometry. Each trace responds to just one element. [From D. Profrock, P. Leonhard, S. Wilbur, and A. Prange, "Sensitive, Simultaneous Determination of $\mathrm{P}, \mathrm{S}, \mathrm{Cl}$, Br , and I Containing Pesticides in Environmental Samples by GC Hyphenated with Collision-Cell ICP-MS," J. Anal. Atom. Spectros. 2004, 19, 1.]

one peak is observed because few compounds other than fensulfothion give rise to an ion at $\mathrm{m} / \mathrm{z} 293$ that produces a fragment at $\mathrm{m} / \mathrm{z} 264$. Selected reaction monitoring increases the signal-to-noise ratio in chromatographic analysis and eliminates much interference.

## Element-Specific Plasma Detectors

Eluate from a chromatography column can be passed through a plasma to atomize and ionize its components and measure selected elements by atomic emission spectroscopy or mass spectrometry. An atomic emission detector directs eluate through a helium plasma in a microwave cavity. Every element of the periodic table produces characteristic emission that can be detected by a photodiode array polychromator (Figure 19-16). Sensitivity for sulfur can be 10 times better than the sensitivity of a flame photometric detector.

The extremely sensitive inductively coupled plasma-mass spectrometer was described in Section 20-6. Figure 23-23 shows 15 pesticides measured by gas chromatography-inductively coupled plasma-mass spectrometry. Eluate was atomized and ionized in the plasma. Ions were measured by a mass spectrometer that could monitor any set of $\mathrm{m} / \mathrm{z}$ values. The figure shows traces for $\mathrm{P}, \mathrm{S}, \mathrm{I}, \mathrm{Cl}$, and Br .

## 23-4 Sample Preparation

Sample preparation is the process of transforming a sample into a form that is suitable for analysis. This process might entail extracting analyte from a complex matrix, preconcentrating very dilute analytes to get a concentration high enough to measure, removing or masking interfering species, or chemically transforming (derivatizing) analyte into a more convenient or more easily detected form. Chapter 27 addresses sample preparation, so we now describe only techniques that are especially applicable to gas chromatography.

Solid-phase microextraction extracts compounds from liquids, air, or even sludge without using any solvent. ${ }^{20}$ The key component is a fused silica fiber coated with a 10 to $100-\mu \mathrm{m}$-thick film of stationary phase similar to those used in gas chromatography.

Figure 23-24 shows the fiber attached to the base of a syringe with a fixed metal needle. The fiber can be extended from the needle or retracted inside the needle. Figure 23-25 demonstrates the procedure of exposing the fiber to a sample solution (or the gaseous headspace above the liquid) for a fixed time while stirring and, perhaps, heating. It is best to determine by experiment how much time is required for the fiber to become saturated with analyte and to allow this much time for extraction. If you use shorter times, the concentration of analyte in the fiber is likely to vary from sample to sample. Only a fraction of the analyte in the sample is extracted into the fiber. When you extract the headspace, liquid sample should occupy about two-thirds of the vial. Too much headspace volume reduces extraction efficiency.

After sample collection, retract the fiber and insert the syringe into a gas chromatograph equipped with a $0.7-\mathrm{mm}$-inner diameter injection port liner. Extend the fiber into the hot injection liner, where analyte is thermally desorbed from the fiber in splitless mode for a fixed time. The narrow port maintains desorbed analyte in a narrow band. Collect desorbed analyte by cold trapping (page 578) at the head of the column prior to chromatography. If there will be a long time between sampling and injection, insert the needle into a septum to seal the fiber from the atmosphere. Figure 23-26 shows a chromatogram of chemical warfare nerve agents isolated from seawater by solid-phase microextraction and detected with a nitrogen-phosphorus detector. The chromatogram is deceptively simple because the detector responds only to compounds containing N and P .

In solid-phase microextraction, the mass of analyte $(m, \mu \mathrm{~g})$ absorbed in the coated fiber is
Mass of analyte extracted: $\quad m=\frac{K V_{\mathrm{f}} c_{0} V_{\mathrm{s}}}{K V_{\mathrm{f}}+V_{\mathrm{s}}}$
where $V_{\mathrm{f}}$ is the volume of film on the fiber, $V_{\mathrm{s}}$ is the volume of solution being extracted, and $c_{0}$ is the initial concentration $(\mu \mathrm{g} / \mathrm{mL})$ of analyte in the solution being extracted. $K$ is the partition coefficient for solute between the film and the solution: $K=c_{\mathrm{f}} / c_{\mathrm{s}}$, where $c_{\mathrm{f}}$ is the concentration of analyte in the film and $c_{\mathrm{s}}$ is the concentration of analyte in the solution. If you extract a large volume of solution such that $V_{\mathrm{s}} \gg K V_{\mathrm{f}}$, then Equation 23-3 reduces to $m=K V_{\mathrm{f}} c_{0}$. That is, the mass extracted is proportional to the concentration of analyte in solution. For quantitative analysis, you can construct a calibration curve by extracting known solutions. Alternatively, internal standards and standard additions are both useful for solid-phase microextraction.

Tenax

You need to establish the time and temperature required to purge $100 \%$ of the analyte from the sample in separate control experiments.

FIGURE 23-26 Gas chromatogram of nerve agents sampled by solid-phase microextraction for 30 min from seawater spiked with 60 nL of each agent per liter ( 60 ppb by volume). The fiber had a $65-\mu \mathrm{m}$-thick coating of copoly(dimethylsiloxane/divinylbenzene). The nitrogenphosphorus detector had a detection limit of 0.05 ppb . Analytes were desorbed from the fiber for 2 min at $250^{\circ} \mathrm{C}$ in splitless mode in the injection port. The column temperature was $30^{\circ} \mathrm{C}$ during desorption, and then it was ramped up at $10^{\circ} \mathrm{C} / \mathrm{min}$ during chromatography. The column was $0.32 \mathrm{~mm} \times 30 \mathrm{~m}$ with a $1-\mu \mathrm{m}$ coating of (phenyl) $)_{0.05}$ (methyl) $)_{0.95}$ polysiloxane. Soman appears as a split peak because it has two isomers. [From H.- $\AA$. Lakso and W. F. Ng, "Determination of Chemical Warfare Agents in Natural Water Samples by Solid-Phase Microextraction," Anal. Chem. 1997, 69, 1866.]

Stir-bar sorptive extraction is closely related to solid-phase microextraction, but it is $\sim 100$ times more sensitive for trace analysis. ${ }^{21}$ A magnetic stirring bar enclosed in a thin glass jacket is coated with a 0.5 - to $1-\mathrm{mm}$-thick layer of sorbent such as poly(dimethylsiloxane)-the same as the stationary phase in nonpolar gas chromatography columns. The stirring bar is placed in an aqueous liquid sample such as fruit juice, wine, urine, or blood plasma and stirred for $0.5-4 \mathrm{~h}$ to absorb hydrophobic analytes. The mass of analyte extracted is given by Equation 23-3, but the volume of sorbent $\left(V_{\mathrm{f}}\right)$ is increased from $\sim 0.5 \mu \mathrm{~L}$ in solid-phase microextraction to $25-125 \mu \mathrm{~L}$ in stir-bar sorptive extraction. Therefore, 50 to 250 times more analyte is extracted with the stir bar. After extraction, the stir bar is touched to a tissue to remove water droplets, possibly rinsed with a few milliliters of water, and then placed in a thermal desorption tube. Desorption is typically conducted by heating the tube to $250^{\circ} \mathrm{C}$ for 5 min in flowing carrier gas. Volatile analytes are collected by cold trapping and then separated by gas chromatography. Analytes at part per billion or lower concentration can be measured by using standard addition, isotopic internal standards, or a calibration curve constructed with the same matrix.

Purge and trap is a method for removing volatile analytes from liquids or solids (such as groundwater or soil), concentrating the analytes, and introducing them into a gas chromatograph. In contrast with solid-phase microextraction, which removes only a portion of analyte from the sample, the goal in purge and trap is to remove $100 \%$ of analyte from the sample. Quantitative removal of polar analytes from polar matrices can be difficult.

Figure 23-27 shows apparatus for measuring volatile flavor components in carbonated beverages. Helium purge gas from a stainless steel needle is bubbled through the cola in the sample vial, which is heated to $50^{\circ} \mathrm{C}$ to aid evaporation of analytes. Purge gas exiting the sample vial passes through an adsorption tube containing three layers of adsorbent compounds with increasing adsorbent strength. For example, the moderate adsorbent could be a nonpolar phenylmethylpolysiloxane, the stronger adsorbent could be the polymer Tenax, and the strongest adsorbent could be carbon molecular sieves. ${ }^{22}$

During the purge and trap process, gas flows through the adsorbent tube from end A to end B in Figure 23-27. After purging all analyte from the sample into the adsorption tube, reverse the gas flow to go from B to A and purge the trap at $25^{\circ} \mathrm{C}$ to remove as much water or other solvent as possible from the adsorbents. Then connect outlet A of the adsorption tube to the injection port of a gas chromatograph operating in splitless mode and heat the trap to $\sim 200^{\circ} \mathrm{C}$. Desorbed analytes flow into the chromatography column where they are concentrated by cold trapping. After complete desorption from the trap, warm the chromatography column to initiate the separation.

Thermal desorption is a method for releasing volatile compounds from solid samples. A weighed sample is placed in a steel or glass tube and held in place with glass wool. The sample is purged with carrier gas to remove $\mathrm{O}_{2}$, which is vented to the air, not into the chromatography column. The desorption tube is then connected to the chromatography column and heated to release volatile substances, which are collected by cold trapping at the beginning of the column. The column is then heated rapidly to initiate chromatography.

## 23-5 Method Development in Gas Chromatography

With the bewildering choice of parameters in gas chromatography, is there a rational way to choose a procedure for a particular problem? In general, there are many satisfactory solutions. As a broad guide to method selection, consider the following topics in this order: (1) the goal of the analysis, (2) sample preparation, (3) detector, (4) column, and (5) injection. ${ }^{23}$

## Goal of the Analysis

What is required from the analysis? Is it qualitative identification of components in a mixture? Will you require high-resolution separation of everything or do you just need good resolution in a portion of the chromatogram? Can you sacrifice resolution to shorten the analysis time? Do you need quantitative analysis of one or many components? Do you need high precision? Will analytes be present in adequate concentration or do you need preconcentration or a very sensitive detector for ultratrace analysis? How much can the analysis cost? Each of these factors creates trade-offs in selecting techniques.

## Sample Preparation

The key to successful chromatography of a complex sample is to clean it up before it ever sees the column. In Section 23-4, we described solid-phase microextraction, stir-bar sorptive extraction, purge and trap, and thermal desorption to isolate volatile components from complex matrices. Other methods include liquid extraction, supercritical fluid extraction, and solid-phase extraction, most of which are described in Chapter 27. These techniques isolate desired analytes from interfering substances, and they can concentrate dilute analytes up to detectable levels. If you do not clean up your samples, chromatograms could contain a broad "forest" of unresolved peaks, and nonvolatile substances will ruin the expensive chromatography column.

## Choosing the Detector

The next step is to choose a detector. Do you need information about everything in the sample or do you want to detect a particular element or class of compounds?

The most general purpose detector for open tubular chromatography is a mass spectrometer. Flame ionization is probably the most popular detector, but it mainly responds to hydrocarbons; and Table 23-4 shows that it is not as sensitive as electron capture, nitrogen-phosphorus, or chemiluminescence detectors. The flame ionization detector requires the sample to contain $\geq 10 \mathrm{ppm}$ of each analyte for split injection. The thermal conductivity detector responds to all classes of compounds, but it is not very sensitive.

Sensitive detectors for ultratrace analysis each respond to a limited class of analytes. The electron capture detector is specific for halogen-containing molecules, nitriles, nitro compounds, and conjugated carbonyls. For split injection, the sample should contain $\geq 100 \mathrm{ppb}$ of each analyte if an electron capture detector is to be used. A photoionization detector can be specific for aromatic and unsaturated compounds. The nitrogen-phosphorus detector has enhanced response to compounds containing either of these two elements, but it also responds to hydrocarbons. Sulfur and nitrogen chemiluminescence detectors each respond to just one element. Flame photometric detectors are specific for selected elements, such as $\mathrm{S}, \mathrm{P}, \mathrm{Pb}$, or Sn . A selective detector might be chosen to simplify the chromatogram by not responding to everything that is eluted (as in Figure 23-23). Mass spectrometry with selected reaction monitoring (Figure 23-22) is an excellent way to monitor one analyte of interest in a complex sample.

If qualitative information is required to identify eluates, then mass spectral or infrared detectors are good choices. The infrared detector, like the thermal conductivity detector, is not sensitive enough for high-resolution, narrow-bore, open tubular columns.

## Selecting the Column

The basic choices are stationary phase, column diameter and length, and thickness of the stationary phase. A nonpolar stationary phase from Table 23-1 is most useful. An intermediate polarity stationary phase will handle most separations that the nonpolar column cannot. For highly polar compounds, a strongly polar column might be necessary. Optical isomers and closely related geometric isomers require special stationary phases for separation.

Table 23-6 shows that there are only a few sensible combinations of column diameter and film thickness. Highest resolution is afforded by the narrowest columns. Thin-film, narrowbore columns are especially good for separating mixtures of high-boiling-point compounds that are retained too strongly on thick-film columns. Short retention times provide high-speed analyses. However, thin-film, narrow-bore columns have very low sample capacity, require

## Order of decisions:

1. goal of analysis
2. sample preparation
3. detector
4. column
5. injection

## Garbage in-garbage out!

FIGURE 23-27 Purge and trap apparatus for extracting volatile substances from a liquid or solid by flowing gas.

TABLE 23-6 Gas chromatography column comparisons ${ }^{23}$

| Description |  |  | Thick-film narrow-bore |
| :--- | :--- | :--- | :--- |

To improve resolution, use a

- longer column
- narrower column
- different stationary phase
high-sensitivity detectors (flame ionization might not be adequate), do not retain low-boilingpoint compounds well, and could suffer from exposure of active sites on the silica.

Thick-film, narrow-bore columns in Table 23-6 provide a good compromise between resolution and sample capacity. They can be used with most detectors (but usually not thermal conductivity detectors) and with compounds of high volatility. Retention times are longer than those of thin-film columns. Thick-film, wide-bore columns are required for use with thermal conductivity and infrared detectors. They have high sample capacity and can handle highly volatile compounds, but they give low resolution and have long retention times.

If a particular column meets most of your requirements but does not provide sufficient resolution, then a narrower column of the same type could be used (Equation 22-35b). To obtain similar retention times for the same length of column, the thickness of the stationary phase should be decreased in proportion to the diameter. A column diameter of 0.15 mm is sensible for maximizing resolution without requiring a different gas chromatograph designed for narrower columns. ${ }^{24}$

Doubling the length of a column doubles the number of plates and, according to Equation 22-30, increases resolution by $\sqrt{2}$. Doubling the column length is not the best way to increase resolution because it doubles retention time. A narrower column increases resolution with no penalty in retention time. Selecting another stationary phase changes the unadjusted relative retention ( $\gamma$ in Equation 22-30) and might resolve components of interest.

To increase the speed of analysis without decreasing resolution, a shorter, narrower column can be chosen. Another way to decrease retention time without sacrificing resolution is to switch carrier gas from He to $\mathrm{H}_{2}$ and increase flow rate by a factor of 1.5 to 2 (Figure 23-11).

If you have measured resolution of a few key components of a mixture under a small number of conditions, commercial software is available to optimize conditions (such as temperature and pressure programming) for the best separation. ${ }^{25}$

Figure 23-28 suggests approximate upper and lower analyte mass limits for different columns and detectors. The abscissa shows the mass of a given analyte that reaches the column or detector. A typical volume of injected liquid is $1 \mu \mathrm{~L}$, with a mass of 1 mg . If analyte concentration is 1 ppm , the mass of analyte in $1 \mu \mathrm{~L}$ is $10^{-9} \mathrm{~g}=1 \mathrm{ng}$. A vertical line at $10^{-9} \mathrm{~g}$ falls in the operating range of all columns and four of the detectors. The sample mass is too small for thermal conductivity, too great for electron capture, and near the upper limit for selected ion monitoring. For a 100:1 split injection, the mass of analyte introduced onto the column would be 100 times smaller, or $10^{-11} \mathrm{~g}$. This mass is in range for all but the thermal conductivity detector. For columns, the region to the left of $10^{-11} \mathrm{~g}$ is shaded because chromatography becomes progressively more problematic as the

mass gets smaller. Analyte masses less than $10^{-11} \mathrm{~g}$ could be lost to adsorption or decomposition in the injector and column. Polar solutes might be lost to adsorption at even higher levels. At the upper end of the column scale, a dividing line recommends where to change from a thin-film stationary phase to a thick film to have adequate sample capacity.

## Choosing the Injection Method

The last major decision is how to inject the sample. Split injection is best for high concentrations of analyte or gas analysis. Quantitative analysis is very poor. Less volatile components can be lost during injection. Split injection offers high resolution and can handle dirty samples if an adsorbent packing is added to the injection liner. Thermally unstable compounds can decompose during the high-temperature injection.

Splitless injection is required for very dilute solutions. It offers high resolution but is poor for quantitative analysis because less volatile compounds can be lost during injection. It is better than split injection for compounds of moderate thermal stability because the injection temperature is lower. Splitless injection introduces sample onto the column slowly, so solvent trapping or cold trapping is required. Therefore, splitless injection cannot be used for isothermal chromatography. Samples containing less than 100 ppm of each analyte can be analyzed with a column film thickness of $<1 \mu \mathrm{~m}$ and splitless injection. Samples containing $100-1000 \mathrm{ppm}$ of each analyte require a column film thickness $\geq 1 \mu \mathrm{~m}$.

On-column injection is best for quantitative analysis and for thermally sensitive compounds. It is strictly a low-resolution technique and cannot be used with columns whose inner diameter is less than 0.2 mm . It can handle dilute or concentrated solutions and relatively large or small volumes. Other column requirements are the same as in splitless injection.

FIGURE 23-28 Approximate injected analyte mass limits for wall-coated open tubular gas chromatography columns and detectors. [Adapted from J. V. Hinshaw, "Setting Realistic Expectations for GC Optimization," LCGC 2006, 24, 1194.]

## Split injection:

- concentrated sample
- high resolution
- dirty samples (use packed liner)
- could cause thermal decomposition

Splitless injection:

- dilute sample
- high resolution
- requires solvent trapping or cold trapping

On-column injection:

- best for quantitative analysis
- thermally sensitive compounds
- low resolution

selected ion monitoring selected reaction monitoring septum solid-phase microextraction solvent trapping spiking split injection
splitless injection stir-bar sorptive extraction temperature programming thermal conductivity detector thermal desorption

## Summary

In gas chromatography, a volatile liquid or gaseous solute is carried by a gaseous mobile phase over a stationary phase on the inside of an open tubular column or on a solid support. Long, narrow, fused-silica open tubular columns have low capacity but give excellent separa-
tion. They can be wall coated, support coated, or porous layer. Packed columns provide high capacity but poor resolution. Each liquid stationary phase most strongly retains solutes in its own polarity class ("like dissolves like"). Solid stationary phases include porous carbon,
alumina, and molecular sieves. The retention index measures elution times in relation to those of linear alkanes. Temperature or pressure programming reduce elution times of strongly retained components. Without compromising separation efficiency, the linear flow rate may be increased when $\mathrm{H}_{2}$ or He , instead of $\mathrm{N}_{2}$, is used as carrier gas. Split injection provides high-resolution separations of relatively concentrated samples. Splitless injection of very dilute samples requires solvent trapping or cold trapping to concentrate solutes at the start of the column (to give sharp bands). On-column injection is best for quantitative analysis and for thermally unstable solutes.

Quantitative analysis is usually done with internal standards in gas chromatography. Co-elution of an unknown peak with a spike of a known compound on several different columns is useful for qualitative identification of the unknown peak. Mass spectral and infrared detectors provide qualitative information to help identify unknowns.

The mass spectrometer is more sensitive and less subject to interference when selected ion monitoring or selected reaction monitoring are employed. Thermal conductivity detection has universal response but is not very sensitive. Flame ionization detection is sensitive enough for most columns and responds to most organic compounds. Electron capture, nitrogen-phosphorus, flame photometry, photoionization, chemiluminescence, and atomic emission detectors are specific for certain classes of compounds or individual elements.

You need to define the goal of an analysis before developing a chromatographic method. The key to successful chromatography is a clean sample. Solid-phase microextraction, stir-bar sorptive extraction, purge and trap, and thermal desorption can isolate volatile components from complex matrices. After sample preparation, the remaining decisions for method development are to select a detector, a column, and the injection method, in that order.

## Exercises

23-A. (a) When a solution containing 234 mg of butanol (FM 74.12) and 312 mg of hexanol (FM 102.17) in 10.0 mL was separated by gas chromatography, the relative peak areas were butanol:hexanol = 1.00:1.45. Considering butanol to be the internal standard, find the response factor for hexanol.
(b) Use Equation 23-2 to estimate the areas of the peaks for butanol and hexanol in Figure 23-8.
(c) The solution from which the chromatogram was generated contained 112 mg of butanol. What mass of hexanol was in the solution?
(d) What is the largest source in uncertainty in this problem? How great is this uncertainty?
$23-B$. When 1.06 mmol of 1-pentanol and 1.53 mmol of 1-hexanol were separated by gas chromatography, they gave relative peak areas of 922 and 1570 units, respectively. When 0.57 mmol of pentanol was added to an unknown containing hexanol, the relative chromatographic peak areas were 843:816 (pentanol:hexanol). How much hexanol did the unknown contain?

23-C. (a) In Table 23-3, 2-pentanone has a retention index of 987 on a poly(ethylene glycol) column (also called Carbowax). Between which two straight-chain hydrocarbons is 2-pentanone eluted?
(b) An unretained solute is eluted from a certain column in 1.80 min. Decane $\left(\mathrm{C}_{10} \mathrm{H}_{22}\right)$ is eluted in 15.63 min and undecane $\left(\mathrm{C}_{11} \mathrm{H}_{24}\right)$ is eluted in 17.22 min . What is the retention time of a compound whose retention index is 1050 ?

23-D. For isothermal elution of a homologous series of compounds (those with similar structures, but differing by the number of $\mathrm{CH}_{2}$
groups in a chain), $\log t_{\mathrm{r}}^{\prime}$ is usually a linear function of the number of carbon atoms. A compound was known to be a member of the family

$$
\left(\mathrm{CH}_{3}\right)_{2} \mathrm{CH}\left(\mathrm{CH}_{2}\right)_{n} \mathrm{CH}_{2} \mathrm{OSi}\left(\mathrm{CH}_{3}\right)_{3}
$$

(a) From the gas chromatographic retention times given here, prepare a graph of $\log t_{\mathrm{r}}^{\prime}$ versus $n$ and estimate the value of $n$ in the chemical formula.

| $n=7$ | 4.0 min | $\mathrm{CH}_{4}$ | 1.1 min |
| :--- | ---: | :--- | ---: |
| $n=8$ | 6.5 min | unknown | 42.5 min |
| $n=14$ | 86.9 min |  |  |

(b) Calculate the retention factor for the unknown.

23-E. Resolution of two peaks (Equation 22-30) depends on the column plate number, $N$, and the unadjusted relative retention, $\gamma$. Suppose you have two peaks with a resolution of 1.0 and you want to increase the resolution to 1.5 for a baseline separation for quantitative analysis (Figure 22-10).
(a) You can increase the resolution to 1.5 by increasing column length. By what factor must the column length be increased? If flow rate is constant, how much more time will the separation require when the length is increased?
(b) You might change relative retention by choosing a different stationary phase. If $\gamma$ was 1.013 , to what value must it be increased to obtain a resolution of 1.5 ? If you were separating two alcohols with a (diphenyl) $)_{0.05}(\text { dimethyl })_{0.95}$ polysiloxane stationary phase (Table 23-1), what stationary phase would you choose to increase $\gamma$ ? Will this change affect the time required for chromatography?

## Problems

23-1. (a) What is the advantage of temperature programming in gas chromatography?
(b) What is the advantage of pressure programming?

23-2. (a) What are the relative advantages and disadvantages of packed and open tubular columns in gas chromatography?
(b) Explain the difference between wall-coated, support-coated, and porous-layer open tubular columns.
(c) What is the advantage of bonding (covalently attaching) the stationary phase to the column wall or cross-linking the stationary phase to itself?

23-3. (a) Why do open tubular columns provide greater resolution than packed columns in gas chromatography?
(b) Why do $\mathrm{H}_{2}$ and He allow more rapid linear flow rates in gas chromatography than $\mathrm{N}_{2}$ does, without loss of column efficiency (Figure 23-12)?

23-4. (a) When would you use split, splitless, or on-column injection in gas chromatography?
(b) Explain how solvent trapping and cold trapping work in splitless injection.

23-5. To which kinds of analytes do the following gas chromatography detectors respond?
(a thermal conductivity
(b) flame ionization
(f) photoionization
(g) sulfur chemiluminescence
(c) electron capture
(h) atomic emission
(d) flame photometric
(i) mass spectrometer
(e) nitrogen-phosphorus

23-6. Why does a thermal conductivity detector respond to all analytes except the carrier gas? Why isn't the flame ionization detector universal?
23-7. Explain what is displayed in a reconstructed total ion chromatogram, selected ion monitoring, and selected reaction monitoring. Which technique is most selective and which is least selective and why?
23-8. Use Table 23-3 to predict the elution order of the following compounds from columns containing (a) poly(dimethylsiloxane), (b) (diphenyl) $)_{0.35}$ (dimethyl) $)_{0.65}$ polysiloxane, and (c) poly(ethylene glycol): hexane, heptane, octane, benzene, butanol, 2-pentanone.
23-9. Use Table 23-3 to predict the elution order of the following compounds from columns containing (a) poly(dimethylsiloxane), (b) (diphenyl) $)_{0.35}$ (dimethyl) $)_{0.65}$ polysiloxane, and (c) poly(ethylene glycol):

1. 1-pentanol ( $n-\mathrm{C}_{5} \mathrm{H}_{11} \mathrm{OH}$, b.p. $138^{\circ} \mathrm{C}$ )
2. 2-hexanone $\left(\mathrm{CH}_{3} \mathrm{C}(=\mathrm{O}) \mathrm{C}_{4} \mathrm{H}_{9}\right.$, b.p. $\left.128^{\circ} \mathrm{C}\right)$
3. heptane $\left(n-\mathrm{C}_{7} \mathrm{H}_{16}\right.$, b.p. $\left.98^{\circ} \mathrm{C}\right)$
4. octane ( $n-\mathrm{C}_{8} \mathrm{H}_{18}$, b.p. $126^{\circ} \mathrm{C}$ )
5. nonane ( $n-\mathrm{C}_{9} \mathrm{H}_{20}$, b.p. $151^{\circ} \mathrm{C}$ )
6. decane ( $n-\mathrm{C}_{10} \mathrm{H}_{22}$, b.p. $174^{\circ} \mathrm{C}$ )

23-10. This problem reviews concepts from Chapter 22. An unretained solute passes through a chromatography column in 3.7 min and analyte requires 8.4 min .
(a) Find the adjusted retention time and retention factor for the analyte.
(b) The volume of the mobile phase is 1.4 times the volume of the stationary phase. Find the partition coefficient for the analyte.
23-11. If retention times in Figure 22-7 are 1.0 min for $\mathrm{CH}_{4}, 12.0 \mathrm{~min}$ for octane, 13.0 min for unknown, and 15.0 min for nonane, find the Kovats retention index for the unknown.

23-12. Retention time depends on temperature, $T$, according to the equation $\log t_{\mathrm{r}}^{\prime}=(a / T)+b$, where $a$ and $b$ are constants for a specific compound on a specific column. A compound is eluted from a gas chromatography column at an adjusted retention time $t_{\mathrm{r}}^{\prime}=15.0 \mathrm{~min}$ when the column temperature is 373 K . At $363 \mathrm{~K}, t_{\mathrm{r}}^{\prime}=20.0 \mathrm{~min}$. Find the parameters $a$ and $b$ and predict $t_{\mathrm{r}}^{\prime}$ at 353 K .

23-13. What is the purpose of derivatization in chromatography? Give an example.

23-14. (a) Explain how solid-phase microextraction works. Why is cold trapping necessary during injection with this technique? Is all the analyte in an unknown extracted into the fiber in solid-phase microextraction?
(b) Explain the differences between stir-bar sorptive extraction and solid-phase microextraction. Which is more sensitive and why?
23-15. Why is splitless injection used with purge and trap sample preparation?
23-16. State the order of decisions in method development for gas chromatography.
23-17. (a) Why is it illogical to use a thin stationary phase $(0.2 \mu \mathrm{~m})$ in a wide-bore $(0.53-\mathrm{mm})$ open tubular column?
(b) Consider a narrow-bore ( 0.25 mm diameter), thin-film ( $0.10 \mu \mathrm{~m}$ ) column with 5000 plates per meter. Consider also a wide-bore ( 0.53 mm diameter), thick-film ( $5.0 \mu \mathrm{~m}$ ) column with 1500 plates per meter. The density of stationary phase is approximately $1.0 \mathrm{~g} / \mathrm{mL}$. What mass of stationary phase is in each column in a length equivalent to one theoretical plate? How many nanograms of analyte can be injected into each column if the mass of analyte is not to exceed $1.0 \%$ of the mass of stationary phase in one theoretical plate?

23-18. How can you improve the resolution between two closely spaced peaks in gas chromatography?
23-19. The graph shows van Deemter curves for $n$-nonane at $70^{\circ} \mathrm{C}$ in the $3.0-\mathrm{m}-$ long microfabricated column in Box $23-2$ with a 1 - to $2-\mu \mathrm{m}$-thick stationary phase.

van Deemter curves. [From G. Lambertus, A. Elstro, K. Sensenig, J. Potkay, M. Agah, S. Scheuering, K. Wise, F. Dorman, and R. Sacks, "Design, Fabrication, and Evaluation of Microfabricated Columns for Gas Chromatography," Anal. Chem. 2004, 76, 2629.]
(a) Why would air be chosen as the carrier gas? What is the danger of using air as carrier gas?
(b) Measure the optimum velocity and plate height for air and for $\mathrm{H}_{2}$ carriers.
(c) How many plates are there in the 3-m-long column for each carrier at optimum flow rate?
(d) How long does unretained gas take to travel through the column at optimum velocity for each gas?
(e) If stationary phase is sufficiently thin with respect to column diameter, which of the two mass transfer terms (22-35a and 22-35b) becomes negligible? Why?
(f) Why is the loss of column efficiency at high flow rates less severe for $\mathrm{H}_{2}$ than for air carrier gas?
23-20. (a) When a solution containing 234 mg of pentanol (FM 88.15) and 237 mg of 2,3-dimethyl-2-butanol (FM 102.17) in 10.0 mL was separated, the relative peak areas were pentanol:2,3-dimethyl-2-butanol $=0.913: 1.00$. Considering pentanol to be the internal standard, find the response factor for 2,3-dimethyl-2-butanol.
(b) Use Equation 23-2 to find the areas for pentanol and 2,3-dimethyl-2-butanol in Figure 23-8.
(c) The concentration of pentanol internal standard in the unknown solution was 93.7 mM . What was the concentration of 2,3-dimethyl-2-butanol?
23-21. A standard solution containing $6.3 \times 10^{-8} \mathrm{M}$ iodoacetone and $2.0 \times 10^{-7} \mathrm{M} p$-dichlorobenzene (an internal standard) gave peak areas of 395 and 787 , respectively, in a gas chromatogram. A $3.00-\mathrm{mL}$ unknown solution of iodoacetone was treated with 0.100 mL of $1.6 \times$ $10^{-5} \mathrm{M} p$-dichlorobenzene and the mixture was diluted to 10.00 mL . Gas chromatography gave peak areas of 633 and 520 for iodoacetone and $p$-dichlorobenzene, respectively. Find the concentration of iodoacetone in the 3.00 mL of original unknown.

23-22. Heptane, decane, and an unknown had adjusted retention times of 12.6 min (heptane), 22.9 min (decane), and 20.0 min (unknown). The retention indexes for heptane and decane are 700 and 1000 , respectively. Find the retention index for the unknown.
23-23. The gasoline additive methyl $t$-butyl ether (MTBE) has been leaking into groundwater ever since its introduction in the 1990s. MTBE can be measured at parts per billion levels by solid-phase microextraction from groundwater to which $25 \%$ (wt/vol) NaCl has been added (salting out, Problem 7-8). After microextraction, analytes are thermally desorbed from the fiber in the port of a gas chromatograph. The figure below shows a reconstructed total ion chromatogram and selected ion monitoring of substances desorbed from the extraction fiber.

(a) What is the purpose of adding NaCl prior to extraction?
(b) What nominal mass is being observed in selected ion monitoring? Why are only three peaks observed?
(c) Here is a list of major ions above $m / z 50$ in the mass spectra. The base (tallest) peak is marked by an asterisk. Given that MTBE and TAME have an intense peak at $m / z 73$ and there is no significant peak at $m / z 73$ for ETBE, suggest a structure for $m / z 73$. Suggest structures for all ions listed in the table.

Reconstructed total ion chromatogram and selected ion monitoring of solidphase microextract of groundwater. Chromatography conditions: $0.32-\mathrm{mm} \times$ $30-\mathrm{m}$ column with $5-\mu \mathrm{m}$ film of poly(dimethylsiloxane). Temperature $=50^{\circ} \mathrm{C}$ for 4 min , then raised $20^{\circ} \mathrm{C} / \mathrm{min}$ to $90^{\circ} \mathrm{C}$, held for 3 min , and then raised $40^{\circ} \mathrm{C} / \mathrm{min}$ to $200^{\circ} \mathrm{C}$. [From D. A. Cassada, Y. Zhang, D. D. Snow, and R. F. Spalding, "Trace Analysis of Ethanol, MTBE, and Related Oxygenate Compounds in Water Using Solid-Phase Microextraction and Gas Chromatography/Mass Spectrometry," Anal. Chem. 2000, 72, 4654.]

23-24. Here is a student procedure to measure nicotine in urine. A $1.00-\mathrm{mL}$ sample of biological fluid was placed in a $12-\mathrm{mL}$ vial containing $0.7 \mathrm{~g} \mathrm{Na}_{2} \mathrm{CO}_{3}$ powder. After $5.00 \mu \mathrm{~g}$ of the internal standard 5 -aminoquinoline were injected, the vial was capped with a Teflon-coated silicone rubber septum. The vial was heated to $80^{\circ} \mathrm{C}$ for 20 min and then a solid-phase microextraction needle was passed through the septum and left in the headspace for 5.00 min . The fiber was retracted and inserted into a gas chromatograph. Volatile substances were desorbed from the fiber at $250^{\circ} \mathrm{C}$ for 9.5 min in the injection port while the column was at $60^{\circ} \mathrm{C}$. The column temperature was then raised to $260^{\circ} \mathrm{C}$ at $25^{\circ} \mathrm{C} / \mathrm{min}$ and eluate was monitored by electron ionization mass spectrometry with selected ion monitoring at $m / z 84$ for nicotine and $m / z 144$ for internal standard. Calibration data from replicate standard mixtures taken through the same procedure are given in the table.

| Nicotine in urine $(\mu \mathrm{g} / \mathrm{L})$ | Area ratio $\mathrm{m} / \mathrm{z} 84 / 144$ |
| :--- | :--- |
| 12 | $0.05_{6}, 0.05_{9}$ |
| 51 | $0.40_{2}, 0.39_{1}$ |
| 102 | $0.68_{4}, 0.66_{9}$ |
| 157 | $1.01_{1}, 1.06_{3}$ |
| 205 | $1.27_{8}, 1.35_{5}$ |

Source: A. E. Wittner, D. M. Klinger, X. Fan, M. Lam, D. T. Mathers, and S. A. Mabury, "Quantitative Determination of Nicotine and Cotinine in Urine and Sputum Using a Combined SPME-GC/MS Method," J. Chem. Ed. 2002, 79, 1257.
(a) Why was the vial heated to $80^{\circ} \mathrm{C}$ before and during extraction?
(b) Why was the chromatography column kept at $60^{\circ} \mathrm{C}$ during thermal desorption of the extraction fiber?
(c) Suggest a structure for $m / z 84$ from nicotine. What is the $m / z 144$ ion from the internal standard, 5 -aminoquinoline?

Nicotine
$\mathrm{C}_{10} \mathrm{H}_{14} \mathrm{~N}_{2}$

5-Aminoquinoline
$\mathrm{C}_{9} \mathrm{H}_{8} \mathrm{~N}_{2}$
(d) Urine from an adult female nonsmoker had an area ratio $\mathrm{m} / \mathrm{z} 84 / 144=0.51$ and 0.53 in replicate determinations. Urine from a nonsmoking girl whose parents are heavy smokers had an area ratio 1.18 and 1.32. Find the nicotine concentration ( $\mu \mathrm{g} / \mathrm{L}$ ) and its uncertainty in the urine of each person.
23-25. Nitric oxide (NO) is a cell-signaling agent in physiologic processes including vasodilation, inhibition of clotting, and inflammation. A sensitive chromatography-mass spectrometry method was developed to measure two of its metabolites, nitrite $\left(\mathrm{NO}_{2}^{-}\right)$and nitrate $\left(\mathrm{NO}_{3}^{-}\right)$, in biological fluids. Internal standards, ${ }^{15} \mathrm{NO}_{2}^{-}$and ${ }^{15} \mathrm{NO}_{3}^{-}$, were added to the fluid at concentrations of 80.0 and $800.0 \mu \mathrm{M}$, respectively. Natural ${ }^{14} \mathrm{NO}_{2}^{-}$and ${ }^{14} \mathrm{NO}_{3}^{-}$plus the internal standards were then converted to volatile derivatives:

CHAPTER 23 Gas Chromatography

Because biological fluids are so complex, the derivatives were first isolated by high-performance liquid chromatography. For quantitative analysis, liquid chromatography peaks corresponding to the two products were injected into a gas chromatograph, ionized by negative ion chemical ionization (giving major peaks for $\mathrm{NO}_{2}^{-}$and $\mathrm{NO}_{3}^{-}$) and the products measured by selected ion monitoring. Results are shown in the figure. If the ${ }^{15} \mathrm{~N}$ internal standards undergo the same reactions and same separations at the same rate as the ${ }^{14} \mathrm{~N}$ analytes, then the concentrations of analytes are simply

$$
\left[{ }^{14} \mathrm{NO}_{x}^{-}\right]=\left[{ }^{15} \mathrm{NO}_{x}^{-}\right]\left(R-R_{\text {blank }}\right)
$$

where $R$ is the measured peak area ratio $(\mathrm{m} / \mathrm{z} 46 / 47$ for nitrite and $\mathrm{m} / z 62 / 63$ for nitrate) and $R_{\text {blank }}$ is the measured ratio of peak areas in a blank prepared from the same buffers and reagents with no added nitrate or nitrite. The ratios of peak areas are $m / z 46 / 47=$ 0.062 and $\mathrm{m} / \mathrm{z} 62 / 63=0.538$. The ratios for the blank were $\mathrm{m} / \mathrm{z} 46 / 47$ $=0.040$ and $\mathrm{m} / \mathrm{z} 62 / 63=0.058$. Find the concentrations of nitrite and nitrate in the urine.

Selected ion chromatogram showing negative ions at $m / z 46,47,62$, and 63 obtained by derivatizing nitrite and nitrate plus internal standards $\left({ }^{15} \mathrm{NO}_{2}^{-}\right.$ and ${ }^{15} \mathrm{NO}_{3}^{-}$) in urine. [From D. Tsikas, "Derivatization and Quantification of Nitrite and Nitrate in Biological Fluids by Gas Chromatography/Mass Spectrometry," Anal. Chem. 2000, 72, 4064.]

23-26. van Deemter equation for open tubular column. Equation 22-33 contains terms ( $A, B$, and $C$ ) describing three band-broadening mechanisms.
(a) Which term is 0 for an open tubular column? Why?
(b) Express the value of $B$ in terms of measurable physical properties.
(c) Express the value of $C$ in terms of measurable physical quantities.
(d) The linear flow rate that produces minimum plate height is found by setting the derivative $d H / d u_{\mathrm{x}}=0$. Find an expression of the minimum plate height in terms of the measurable physical quantities used to answer parts (b) and (c).

23-27. Theoretical performance in gas chromatography. As the inside radius of an open tubular column is decreased, the maximum possible column efficiency increases and sample capacity decreases. For a thin stationary phase that equilibrates rapidly with analyte, the minimum theoretical plate height is given by

$$
\frac{H_{\min }}{r}=\sqrt{\frac{1+6 k+11 k^{2}}{3(1+k)^{2}}}
$$

where $r$ is the inside radius of the column and $k$ is the retention factor.
(a) Find the limit of the square-root term as $k \rightarrow 0$ (unretained solute) and as $k \rightarrow \infty$ (infinitely retained solute).
(b) If the column radius is 0.10 mm , find $H_{\text {min }}$ for the two cases in (a).
(c) What is the maximum number of theoretical plates in a $50-\mathrm{m}$-long column with a $0.10-\mathrm{mm}$ radius if $k=5.0$ ?
(d) The relation between retention factor $k$ and partition coefficient $K$ (Equation 22-19) can also be written $k=2 t K / r$, where $t$ is the thickness of the stationary phase in a wall-coated column and $r$ is the inside radius of the column. Derive the equation $k=2 t K / r$ and find $k$ if $K=1000, t=0.20 \mu \mathrm{~m}$, and $r=0.10 \mathrm{~mm}$.

23-28. Consider the chromatography of $n-\mathrm{C}_{12} \mathrm{H}_{26}$ on a 25 -m-long $\times$ $0.53-\mathrm{mm}$-diameter open tubular column of $5 \%$ phenyl- $95 \%$ methyl polysiloxane with a stationary-phase thickness of $3.0 \mu \mathrm{~m}$ and He carrier gas at $125^{\circ} \mathrm{C}$. The observed retention factor for $n-\mathrm{C}_{12} \mathrm{H}_{26}$ is 8.0. Measurements were made of plate height, $H$, at various values of linear velocity, $u_{\mathrm{x}}(\mathrm{m} / \mathrm{s})$. A least-squares curve through the data points is given by

$$
H(\mathrm{~m})=\left(6.0 \times 10^{-5} \mathrm{~m}^{2} / \mathrm{s}\right) / u_{\mathrm{x}}+\left(2.09 \times 10^{-3} \mathrm{~s}\right) u_{\mathrm{x}}
$$

From the coefficients of the van Deemter equation, find the diffusion coefficient of $n-\mathrm{C}_{12} \mathrm{H}_{26}$ in the mobile and stationary phases. Why is one of these diffusion coefficients so much greater than the other?

23-29. Efficiency of solid-phase microextraction. Equation 23-3 gives the mass of analyte extracted into a solid-phase microextraction fiber as a function of the partition coefficient between the fiber coating and the solution.
(a) A commercial fiber with a $100-\mu \mathrm{m}$-thick coating has a film volume of $6.9 \times 10^{-4} \mathrm{~mL} .{ }^{26}$ Suppose that the initial concentration of analyte in solution is $c_{0}=0.10 \mu \mathrm{~g} / \mathrm{mL}(100 \mathrm{ppb})$. Use a spreadsheet to prepare a graph showing the mass of analyte extracted into the fiber as a function of solution volume for partition coefficients of $10000,5000,1000$, and 100. Let the solution volume vary from 0 to 100 mL .
(b) Evaluate the limit of Equation 23-3 as $V_{\mathrm{s}}$ gets big relative to $K V_{\mathrm{f}}$. Does the extracted mass in your graph approach this limit?
(c) What percentage of the analyte from 10.0 mL of solution is extracted into the fiber when $K=100$ and when $K=10000$ ?

23-30. Mass spectral interpretation. Box 23-1 shows the separation of enantiomers with the formula $\mathrm{C}_{9} \mathrm{H}_{4} \mathrm{~N}_{2} \mathrm{Cl}_{6}$.
(a) Verify that the formula for rings + double bonds (21-3) agrees with the structure.
(b) Find the nominal mass of $\mathrm{C}_{9} \mathrm{H}_{4} \mathrm{~N}_{2} \mathrm{Cl}_{6}$ (Box 21-1)
(c) The high-mass region of the electron impact mass spectrum of one enantiomer is shown on page 594. Suggest an assignment for $\mathrm{m} / \mathrm{z} 350,315,280,245$, and 210.
(d) The relative abundance of ${ }^{35} \mathrm{Cl}$ and ${ }^{37} \mathrm{Cl}$ in a molecule containing $n \mathrm{Cl}$ atoms is given by the terms of the binomial expansion $(a+b)^{n}=a^{n}+n a^{n-1} b+\frac{n(n-1)}{2!} a^{n-2} b^{2}+\frac{n(n-1)(n-2)}{3!}$ $a^{n-3} b^{3}+\cdots$, where $a$ is the natural abundance of ${ }^{35} \mathrm{Cl}(0.7577)$ and $b$ is the natural abundance of ${ }^{37} \mathrm{Cl}(0.2423)$. The first term gives

Mass spectrum of one enantiomer of $\mathrm{C}_{9} \mathrm{H}_{4} \mathrm{~N}_{2} \mathrm{Cl}_{6}$ from Box 23-1. [From W. Vetter and W. Jun, "Elucidation of a Polychlorinated Bipyrrole Structure Using Enantioselective GC," Anal. Chem. 2002, 74, 4287.]
the abundance of ${ }^{35} \mathrm{Cl}_{n}{ }^{37} \mathrm{Cl}_{0}$, the second term gives ${ }^{35} \mathrm{Cl}_{n-1}{ }^{37} \mathrm{Cl}_{1}$, and so forth. The spreadsheet below shows how to compute the terms of $(a+b)^{6}$ with Excel in cells D8:D14. In cell D8, the function is " $=\mathrm{BINOMDIST}(\mathrm{A} 8, \$ \mathrm{~B} \$ 5, \$ \mathrm{~B} \$ 3$,FALSE)" = BINOMDIST $(6,6,0.7577$, FALSE $)$, which translates into D8 $=(0.7577)^{6}$. When you highlight cell D8 and Fill Down, the function in cell D9 is $"=$ BINOMDIST (A9, $\$ \mathrm{~B} \$ 5, \$ \mathrm{~B} \$ 3$,FALSE)" $=$ BINOMDIST $(5,6,0.7577$, FALSE $)$, which translates into D9 $=6(0.7577)^{5}$ $(0.2423)^{1}$-the second term of the expansion. Column E normalizes the abundances in column D so that the most intense peak is 100 . The spreadsheet predicts that a molecule with 6 Cl atoms will have a ratio of intensities $\mathrm{M}: \mathrm{M}+2: \mathrm{M}+4: \mathrm{M}+6: \mathrm{M}+8: \mathrm{M}+10: \mathrm{M}+12$ $=52.12: 100: 79.95: 34.09: 8.18: 1.05: 0.06$ (if there are no other significant isotopes of other elements in the molecule). Compute the expected abundances of Cl isotopes for species with $5,4,3$, and 2 Cl atoms and compare your results with the observed clusters in the mass spectrum.

Spreadsheet illustrating use of binomial distribution function.

## PALEOTHERMOMETRY: HOW TO MEASURE HISTORICAL OCEAN TEMPERATURES

Liquid chromatogram of archaeal cell membrane lipids extracted from sea floor sediment. Compounds 4 and $4^{\prime}$ are isomers with an unknown relationship. Chromatography was run on a ( $2.1 \times 150 \mathrm{~mm}$ ) column containing $3 \mu \mathrm{~m}$ Prevail Cyano phase. [From S. Schouten, C. Huguet, E. C. Hopmans, M. V. Kienhuis, and J. S. Sinninghe Damsté, "Analytical Methodology for TEX ${ }_{86}$ Paleothermometry by High-Performance Liquid Chromatography/Atmospheric Pressure Chemical lonization-Mass Spectrometry," Anal. Chem. 2007, 79, 2940.]

$[\mathrm{M}+\mathrm{H}]^{+}=1298$

$[\mathrm{M}+\mathrm{H}]^{+}=1296$

4' Regio-isomer of 4
$[\mathrm{M}+\mathrm{H}]^{+}=1292$

Correlation of today's sea surface temperature with $\mathrm{TEX}_{86}$ in 223 core-top sediments from the Atlantic, Pacific, and Indian Oceans. [Data from J.-H. Kim, S. Schouten, E. C. Hopmans, B. Donner, and J. S. Sinninghe Damsté, "Global Sediment Core-top Calibration of the TEX 86 Paleothermometer in the Ocean," Geochim. Cosmochim. Acta 2008, 72, 1154.]

Archaea are single-cell organisms that constitute a substantial fraction of life in the ocean. They manufacture cell membrane lipids, which can be measured by liquid chromatography. Lipids 0 and 4 are the major components. Of the minor components, type 1 is predominant in archaea living at low temperature (near $0^{\circ} \mathrm{C}$ ). Types 2,3 , and $4^{\prime}$ are manufactured in increasing amounts at warmer ocean temperatures, presumably giving membranes proper fluidity. When archaea die, they fall to the ocean floor, where their lipids remain in the sediment. The surface of the sediment contains remains of the most recent archaea. The deeper we dig into the sediment, the older are the remains.

The graph shows the correlation between today's sea surface temperature and membrane lipid types found in the topmost sediment. The function in the graph is the sum of lipids 2,3 , and $4^{\prime}$ expressed as a fraction of lipids $1,2,3$, and $4^{\prime}$ :

$$
\mathrm{TEX}_{86} \equiv \frac{[2]+[3]+\left[4^{\prime}\right]}{[1]+[2]+[3]+\left[4^{\prime}\right]} \text { (measured by chromatography) }
$$

Empirical correlation: $\quad$ Sea surface temperature $\left({ }^{\circ} \mathrm{C}\right)=-10.78+56.2\left(\mathrm{TEX}_{86}\right)$
By measuring archaeal membrane lipids as a function of depth in ocean sediment and in sedimentary rock on land, it is possible to construct a history of ocean temperature and to compare the membrane lipid ratio to other indicators of climate. ${ }^{1}$

FIGURE 24-1 High-performance liquid chromatography (HPLC) equipment including a mass spectrometer for detection. The column is enlarged at the right. In operation, the door to the column oven would be closed to maintain constant temperature. [Courtesy E. Erickson, Michelson Laboratory, China Lake, CA.]

The pioneer of high-performance liquid chromatography was C. Horváth at Yale University in 1965.

Autosampler

High-performance liquid chromatography (HPLC) uses high pressure to force solvent through closed columns containing fine particles that give high-resolution separations. ${ }^{2-6}$ The HPLC system in Figure 24-1 consists of an autosampler, a solvent delivery system, a sample injection valve, a high-pressure chromatography column, and a mass spectrometer, which serves as a detector. Not shown in the photograph are solvent reservoirs, a photodiode array absorbance detector, and a computer to control the hardware and display results. The column is housed in an oven whose door is normally closed to keep the column at constant temperature. In this chapter, we discuss liquid-liquid partition and liquid-solid adsorption chromatography. Chapter 25 deals with ion-exchange, molecular exclusion, affinity, and hydrophobic interaction chromatography.

Chromatographers generally choose gas chromatography over liquid chromatography when there is a choice, because gas chromatography is normally less expensive and generates much less waste. Liquid chromatography is important because most compounds are not sufficiently volatile for gas chromatography.

## 24-1 The Chromatographic Process

Increasing the rate at which solute equilibrates between stationary and mobile phases increases the efficiency of chromatography. For gas chromatography with an open tubular column, rapid equilibration is accomplished by reducing the diameter of the column so that molecules can diffuse quickly between the channel and the stationary phase on the wall. Diffusion in liquids is 100 times slower than diffusion in gases. Therefore, in liquid chromatography, it is not generally feasible to use open tubular columns, because the diameter of the solvent channel is too great to be traversed by a solute molecule in a short time. Liquid chromatography is conducted with packed columns so that a solute molecule does not have to diffuse very far to encounter the stationary phase.

## Small Particles Give High Efficiency but Require High Pressure

The efficiency of a packed column increases as the size of the stationary phase particles decreases. Typical particle sizes in HPLC are 1.7 to $5 \mu \mathrm{~m}$. Figure $24-2 \mathrm{a}$ and b illustrate the increased resolution afforded by decreasing particle size. Plate number increased from 2000 to 7500 when the particle size decreased, so the peaks are sharper with the smaller particle size. In Figure 24-2c, a stronger solvent was used to elute the peaks in less time. Decreasing particle size permits us to improve resolution or to maintain the same resolution while decreasing run time.

## EXAMPLE Scaling Relations Between Columns

Commonly, silica particles occupy $\sim 40 \%$ of the column volume and solvent occupies $\sim 60 \%$ of the column volume, regardless of particle size. The column used in Figure 24-2a has an inside diameter of 4.6 mm and was run at a volume flow rate $\left(u_{\mathrm{v}}\right)$ of $3.0 \mathrm{~mL} / \mathrm{min}$ with a
sample size of $20 \mu \mathrm{~L}$. The column used in Figure $24-2 \mathrm{~b}$ has a diameter of $d_{\mathrm{c}}=2.1 \mathrm{~mm}$. What flow rate should be used in trace $b$ to achieve the same linear velocity $\left(u_{\mathrm{x}}\right)$ as in trace $a$ ? What sample volume should be injected?

Solution Column volume is proportional to the square of column diameter. Changing the diameter from 4.6 to 2.1 mm , reduces volume by a factor of $(2.1 / 4.6)^{2}=0.208$. Therefore, $u_{\mathrm{v}}$ should be reduced by a factor of 0.208 to maintain the same linear velocity.

$$
u_{\mathrm{v}}(\mathrm{small} \text { column })=0.208 \times u_{\mathrm{v}}(\text { large column })=(0.208)(3.0 \mathrm{~mL} / \mathrm{min})=0.62 \mathrm{~mL} / \mathrm{min}
$$

To maintain the same ratio of injected sample to column volume,
Injection volume in small column $=0.208 \times$ (injection volume in large column)

$$
=(0.208)(20 \mu \mathrm{~L})=4.2 \mu \mathrm{~L}
$$

Test Yourself What should be the volume flow rate and injected volume for a $1.5-\mathrm{mm}$ diameter column? (Answer: $0.32 \mathrm{~mL} / \mathrm{min}, 2.1 \mu \mathrm{~L}$ )
van Deemter plots of plate height versus linear flow rate in Figure 24-3 show that small particles reduce plate height and that plate height is not very sensitive to increased flow rate when the particles are small. At the optimum flow rate for each column (minimum plate height in Figure 24-3), the number of theoretical plates in a column of length $L$ (cm) is approximately ${ }^{7}$

$$
\begin{equation*}
N \approx \frac{3000 L(\mathrm{~cm})}{d_{\mathrm{p}}(\mu \mathrm{~m})} \tag{24-1}
\end{equation*}
$$

where $d_{\mathrm{p}}$ is the particle diameter in $\mu \mathrm{m}$. The $5.0-\mathrm{cm}$-long column in Figure 24-2a with $4.0-\mu \mathrm{m}$-diameter particles is predicted to provide $\sim(3000)(5.0) / 4.0=3800$ plates. The observed plate number for the second peak is 2000 . Perhaps the column was not run at optimum flow rate. When the stationary phase particle diameter is reduced to $1.7 \mu \mathrm{~m}$, the optimum plate number is expected to be $\sim(3000)(5.0) / 1.7=8800$. The observed value is 7500 .

One reason why small particles give better resolution is that they provide more uniform flow through the column, thereby reducing the multiple path term, $A$, in the van Deemter equation (22-33). A second reason is that the distance through which solute must diffuse in the mobile and stationary phases is on the order of the particle size. The smaller the particles, the less distance solute must diffuse. This effect decreases the $C$ term in the van Deemter equation for finite equilibration time. Optimum flow rate for small particles is faster than for large particles because solutes diffuse through smaller distances.

FIGURE 24-3 van Deemter curves: Plate height as a function of linear flow rate ( $\mathrm{mm} / \mathrm{s}$ ) for microporous (Figure 24-5) stationary phase particle diameters of $5.0,3.5$, and $1.8 \mu \mathrm{~m}$, as well as superficially porous particles (Figure 24-9) with a diameter of $2.7 \mu \mathrm{~m}$ ( $0.5 \mu \mathrm{~m}$ porous layer thickness). Measurements for naphthalene eluted from $\mathrm{C}_{18}$-silica ( 50 mm long $\times 4.6 \mathrm{~mm}$ diameter) with 60 vol $\%$ acetonitrile/40 vol $\% \mathrm{H}_{2} \mathrm{O}$ at $24^{\circ} \mathrm{C}$. [Courtesy MAC-MOD Analytical, Chadds Ford, PA.]

Increasing efficiency is equivalent to decreasing plate height, $H$, in the van Deemter equation (22-33):

$$
\begin{aligned}
& H \approx A+\frac{B}{u_{\mathrm{x}}}+C u_{\mathrm{x}} \\
& u_{\mathrm{x}}=\text { linear flow rate }
\end{aligned}
$$

Smaller particle size leads to

- higher plate number
- higher pressure
- shorter optimum run time
- lower detection limit

Viscosity measures resistance of a fluid to flow. The more viscous a liquid, the slower it flows at a given pressure.

Analogy of fluid flow with electric current:
Electric power $(W)=$ current $\times$ voltage
Chromatographic heat generation:
Power $(W)=\underbrace{\text { volume flow rate }}_{\mathrm{m}^{3} / \mathrm{s}} \times \underbrace{\text { pressure drop }}_{\mathrm{Pa}=\mathrm{kg} /\left(\mathrm{m} \cdot \mathrm{s}^{2}\right)}$

FIGURE 24-4 HPLC column with replaceable guard column to collect irreversibly adsorbed impurities. Titanium frits contain the stationary phase and distribute liquid evenly over the diameter of the column. [Courtesy Upchurch Scientific, Oak Harbor, WA.] In Figure 24-1, flow direction is bottom to top, which is opposite the flow direction in this figure.

An added benefit of small particle size, coupled with a narrow column and higher flow is that analyte is not diluted so much as it travels through the column. The limit of quantitation for conditions in Figure 24-2c $(50 \mu \mathrm{~g} / \mathrm{L})$ is four times lower than the limit of quantitation in Figure 24-2a ( $200 \mu \mathrm{~g} / \mathrm{L}$ ).

The penalty for small particle size is resistance to solvent flow. The pressure required to drive solvent through a column is

$$
\begin{equation*}
\text { Column pressure: } \quad P=f \frac{u_{\mathrm{x}} \eta L}{\pi r^{2} d_{\mathrm{p}}^{2}} \tag{24-2}
\end{equation*}
$$

where $u_{\mathrm{x}}$ is linear flow rate, $\eta$ is the viscosity of the solvent, $L$ is the length of the column, $r$ is column radius, and $d_{\mathrm{p}}$ is the particle diameter. The factor $f$ depends on particle shape and particle packing. The physical significance of Equation 24-2 is that pressure in HPLC is proportional to flow rate and column length and inversely proportional to the square of column radius (or diameter) and the square of particle size. The difference between traces $a$ and $b$ in Figure $24-2$ is that particle size was decreased from $4.0 \mu \mathrm{~m}$ to $1.7 \mu \mathrm{~m}$ and column diameter was decreased from 4.6 mm to 2.1 mm . Therefore, the required pressure increases by a factor of $(4.6 \mathrm{~mm} / 2.1 \mathrm{~mm})^{2}(4.0 \mu \mathrm{~m} / 1.7 \mu \mathrm{~m})^{2}=27$. That is, 27 times more pressure is required to operate the column in Figure 24-2b.

Until recently, HPLC operated at pressures of $\sim 7-40 \mathrm{MPa}$ (70-400 bar, 1 000-6 000 pounds $/$ inch $^{2}$ ) to attain flow rates of $\sim 0.5-5 \mathrm{~mL} / \mathrm{min}$. In 2004, commercial equipment became available to employ $1.5-$ to $2-\mu \mathrm{m}$-diameter particles at pressures up to $100 \mathrm{MPa}(1000 \mathrm{bar}$, 15000 pounds/inch ${ }^{2}$ ). These instruments provide substantially increased resolution or decreased run time. Table $24-1$ shows theoretical performance for different particle sizes; such performance was realized in research with ultrahigh-pressure equipment. Chromatography with 1.5- to $2-\mu \mathrm{m}$-diameter particles at high pressure is commonly called UPLC (Ultra Performance Liquid Chromatography), which is a trademark of Waters Corporation. Peaks eluted from a UPLC column could be so narrow that there is not enough time for mass spectral detection.

Another penalty of small particle size is increased frictional heating as solvent is forced through the particle bed. ${ }^{8}$ The center of a column is warmer than the outer wall, and the outlet is warmer than the inlet. A $100-\mathrm{mm}$-long $\times 2.1-\mathrm{mm}$-diameter column containing $1.7-\mu \mathrm{m}$ particles eluted with acetonitrile generates a temperature difference of $\sim 10^{\circ} \mathrm{C}$ from the inlet to the outlet at a flow rate of $1.0 \mathrm{~mL} / \mathrm{min}$. The centerline of the column can be $\sim 2^{\circ} \mathrm{C}$ warmer than the wall. To avoid undue band broadening from temperature differences, column diameter should be $\leq 2.1 \mathrm{~mm}$ for $1.7-\mu \mathrm{m}$ particles.

## The Column

Columns are expensive and easily degraded by dust or particles in the sample or solvent and by irreversible adsorption of impurities from the sample or solvent. To avoid introducing particulate matter into the column, samples should be centrifuged and/or filtered through a $0.5-\mu \mathrm{m}$ filter before they are loaded into vials for an autosampler or taken into a syringe for manual injection. An in-line $0.5-\mu \mathrm{m}$ filter should be installed immediately downsteam of the autosampler.

The HPLC equipment in Figure $24-1$ uses steel or plastic columns that are $5-30 \mathrm{~cm}$ in length, with an inner diameter of $1-5 \mathrm{~mm}$ (Figure $24-4$ ). The entrance to the main column is protected by a short guard column containing the same stationary phase as the main column.

TABLE 24-1 Performance as a function of particle diameter

| Particle size <br> $d_{\mathrm{p}}(\mu \mathrm{m})$ | Retention time <br> $(\mathrm{min})$ | Plate number <br> $(N)$ | Required pressure <br> $(\mathrm{bar})$ |
| :--- | :--- | :---: | :---: |
| 5.0 | 30 | 25000 | 19 |
| 3.0 | 18 | 42000 | 87 |
| 1.5 | 9 | 83000 | 700 |
| 1.0 | 6 | 125000 | 2300 |

NOTE: Theoretical performance of 33- $\mu \mathrm{m}$-diameter $\times 25$-cm-long capillary for minimum plate height for solute with retention factor $k=2$ and diffusion coefficient $=6.7 \times 10^{-10} \mathrm{~m}^{2} / \mathrm{s}$ in water-acetonitrile eluent.
source: J. E. MacNair, K. D. Patel, and J. W. Jorgenson, "Ultrahigh-Pressure Reversed-Phase Capillary Liquid Chromatography with $1.0-\mu \mathrm{m}$ Particles," Anal. Chem. 1999, 71, 700.

Fine particles and strongly adsorbed solutes are retained in the guard column, which is periodically replaced when column pressure increases or after a set number of injections or time in service. While guard columns make sense with $10-$ to $30-\mathrm{cm}$-long chromatography columns, many people do not consider a guard column to be cost effective for a $5-\mathrm{cm}$ column.

Heating a chromatography column ${ }^{9}$ usually decreases the viscosity of the solvent, thereby reducing the required pressure or permitting faster flow. Increased temperature decreases retention times (Figure 22-19) and improves resolution by hastening diffusion of solutes. However, increased temperature can degrade the stationary phase and decrease column lifetime. When column temperature is not controlled, it fluctuates with the ambient temperature. Using a column heater set $10^{\circ} \mathrm{C}$ above room temperature improves the reproducibility of retention times and the precision of quantitative analysis. Some chromatographers routinely conduct all separations at $50^{\circ}$ or $60^{\circ} \mathrm{C}$. For a heated column, the mobile phase should be passed through a preheating metal coil between the injector and the column so that the solvent and column are at the same temperature. If their temperatures are different, peaks become distorted and retention times change.

In the recent past, the most common HPLC column diameter was 4.6 mm . Now, 2.1 mm is becoming most common. The narrow column is more compatible with mass spectrometry, which requires low solvent flow. The narrow column requires less sample and produces less waste. Instruments that used the $4.6-\mathrm{mm}$ column also operate with the $2.1-\mathrm{mm}$ column. Columns narrower than 2.1 mm require specially designed instruments to reduce band broadening outside the column. Capillary columns as narrow as $25 \mu \mathrm{~m}$ can be used.

## The Stationary Phase

The most common support is highly pure, spherical, microporous particles of silica (Figure 24-5) that are permeable to solvent and have a surface area of several hundred square meters per gram. Most silica cannot be used above pH 8 , because it dissolves in base. Figure 24-6 shows the structure of ordinary silica and silica with ethylene bridges, which resist hydrolysis up to $\mathrm{pH} 12 .{ }^{10}$ For separation of basic compounds at $\mathrm{pH} 8-12$, ethylene-bridged silica or polymeric supports such as polystyrene (Figure 25-1) can be used. Stationary phase is covalently attached to the polymer.

A silica surface (Figure 24-6) has up to $8 \mu \mathrm{~mol}$ of silanol groups ( $\mathrm{Si}-\mathrm{OH}$ ) per square meter. Silanol groups are protonated at $\mathrm{pH} \sim 2-3$. They dissociate to negative $\mathrm{Si}-\mathrm{O}^{-}$over a

FIGURE 24-6 (a) Schematic structure of silica particle. [From R. E. Majors, LCGC, May 1997, p. S8.]
(b) Base-hydrolysis-resistant silica incorporates ethylene bridges in place of oxide bridges between some silicon atoms. Ethylene-bridged structure is more rigid and well suited for particles that are $<2 \mu \mathrm{~m}$ in diameter, which must withstand high pressure.

(b)

(b)

FIGURE 24-7 Tailing of amine bases on silica: (a) Type A silica support gives distorted peaks. (b) Less acidic Type B silica with fewer $\mathrm{Si}-\mathrm{OH}$ groups and less metallic impurity gives symmetric peaks with shorter retention time. In both cases, chromatography was performed with a $0.46 \times 15 \mathrm{~cm}$ column eluted at $1.0 \mathrm{~mL} / \mathrm{min}$ at $40^{\circ} \mathrm{C}$ with 30 vol $\%$ acetonitrile/70 vol\% sodium phosphate buffer ( pH 2.5 ) containing $0.2 \mathrm{wt} \%$ triethylamine and 0.2 wt\% trifluoroacetic acid. The detector measured ultraviolet absorbance at 254 nm . Additives such as triethylamine and trifluoroacetic acid are often used to mask strong adsorption sites and thereby reduce tailing. [From J. J. Kirkland, Am. Lab., June 1994, p. 28K.]

Residual silanol groups on the silica surface are capped with trimethylsilyl groups by reaction with $\mathrm{ClSi}\left(\mathrm{CH}_{3}\right)_{3}$ to eliminate polar adsorption sites that cause tailing.

broad pH range above 3 . In the old Type A silica, exposed $\mathrm{Si}^{-} \mathrm{O}^{-}$groups strongly retain protonated bases (for example, $\mathrm{RNH}_{3}^{+}$) and lead to tailing (Figure 24-7). Metallic impurities in Type A silica also cause tailing. Type B silica in Figure 24-7, which has fewer exposed silanol groups and fewer metallic impurities, is the most common form used today. Type C silica causes even less tailing because $90 \%$ of the $\mathrm{Si}-\mathrm{OH}$ groups are replaced by $\mathrm{Si}-\mathrm{H}$ bonds, which do not retain solutes by hydrogen bonding.

Bare silica can be used as the stationary phase for adsorption chromatography. Most commonly, liquid-liquid partition chromatography is conducted with a bonded stationary phase covalently attached to the silica surface by reactions such as

Common polar phases
Common nonpolar phases
$\mathrm{R}=\left(\mathrm{CH}_{2}\right)_{3} \mathrm{NH}_{2}$
$\mathrm{R}=\left(\mathrm{CH}_{2}\right)_{3} \mathrm{C}=\mathrm{N}$
$\mathrm{R}=\left(\mathrm{CH}_{2}\right)_{2} \mathrm{OCH} 2 \mathrm{CH}(\mathrm{OH}) \mathrm{CH}_{2} \mathrm{OH}$
amino
cyano diol

| $\mathrm{R}=\left(\mathrm{CH}_{2}\right)_{17} \mathrm{CH}_{3}$ | octadecyl |
| :--- | :--- |
| $\mathrm{R}=\left(\mathrm{CH}_{2}\right)_{7} \mathrm{CH}_{3}$ | octyl |
| $\mathrm{R}=\left(\mathrm{CH}_{2}\right)_{3} \mathrm{C}_{6} \mathrm{H}_{5}$ | phenyl |
| $\mathrm{R}=\left(\mathrm{CH}_{2}\right)_{3} \mathrm{C}_{6} \mathrm{~F}_{5}$ | $\mathrm{~F}_{5}$-phenyl |

There are $\sim 4 \mu \mathrm{~mol}$ of R groups per square meter of support surface area, with little bleeding of the stationary phase from the column during chromatography.

The octadecyl $\left(\mathrm{C}_{18}\right)$ stationary phase (often abbreviated ODS) is by far the most common in HPLC. Retention factors for a given solute on columns with the same nominal stationary phase from different manufacturers are quite variable. Different surface areas of different columns account for much of the variation. ${ }^{11}$ The nonpolar perfluorophenyl ( $\mathrm{F}_{5}$-phenyl)
phase provides selectivities different from those of the octadecyl phase and can be especially useful for separating aromatic compounds. The separation of cell membrane lipids at the opening of this chapter was done with a polar cyano column.

The siloxane ( $\mathrm{Si}-\mathrm{O}-\mathrm{SiR}$ ) bond hydrolyzes below pH 2 , so HPLC with a bonded phase on a silica support is generally limited to the pH range $2-8$. If bulky isobutyl groups are attached to the silicon atom of the bonded phase (Figure 24-8), the stationary phase is protected from attack by $\mathrm{H}_{3} \mathrm{O}^{+}$and is stable for long periods at low pH , even at elevated temperature (for example, pH 0.9 at $90^{\circ} \mathrm{C}$ ). Box $24-1$ describes monolithic stationary phases.

Bidentate $\mathrm{C}_{18}$ stationary phase provides increased stability above pH 8 :

## BOX 24-1 Monolithic SHifa Columns

[Photos courtesy D. Cunningham, Merck KGaA, Darmstadt, Germany.]

Time is money. In commercial laboratories, the faster an analysis can be done, the less it costs. Monolithic silica columns enable us to increase the flow rate in liquid chromatography while retaining good separation. ${ }^{12}$

Each column in the left-hand photograph is a single, porous silica rod polymerized from liquid precursors. The adjacent micrographs show the silica skeleton with a network of $\sim 2-\mu \mathrm{m}$ pores. The inside of the skeleton contains a finer network of $\sim 13-\mathrm{nm}$ pores that are too small to be seen in the micrographs. Approximately $80 \%$ of the volume of the rod is empty space. The surface area is $300 \mathrm{~m}^{2} / \mathrm{g}$, which compares favorably with that of excellent stationary phase materials. $\mathrm{C}_{18}$ or other bonded phases are attached to the silica for reversed-phase chromatography. After fabrication, the silica rod is tightly encased in a chemically resistant plastic tube made of polyether ether ketone (PEEK).

Solvent flows through the open, rigid structure of the monolithic column with relatively low resistance. The same pressure required to obtain a flow rate of $1 \mathrm{~mL} / \mathrm{min}$ with $3.5-\mu \mathrm{m}$ spherical particles provides a flow rate of $9 \mathrm{~mL} / \mathrm{min}$ in the monolithic column. At $9 \mathrm{~mL} / \mathrm{min}$, the plate height in the monolithic column is only $50 \%$ greater than the minimum plate height observed at $2 \mathrm{~mL} / \mathrm{min}$.

With low resistance to solvent flow, monolithic columns can be made very long to achieve exquisite separations at ordinary HPLC pressures. The chromatogram shows the resolution of deuterated benzene and toluene molecules achieved with a $440-\mathrm{cm}$ long $\times 0.1 \mathrm{~mm}$-diameter-column run by ordinary HPLC hardware at a pressure of 396 bar.

Separation of isotopic molecules on a $440-\mathrm{cm}$-long monolithic $\mathrm{C}_{18}$-silica column eluted with $\mathrm{CH}_{3} \mathrm{CN} / \mathrm{H}_{2} \mathrm{O}$ ( $30: 70 \mathrm{vol} / \mathrm{vol}$ ) at $30^{\circ} \mathrm{C}$. Tanake, "High-Efficiency Liquid Chromatographic Separation Utilizing Long Monolithic Silica Capillary Columns," Anal. Chem. 2008, 80, 8741.]

FIGURE 24-8 Bulky isobutyl groups protect siloxane bonds from hydrolysis at low pH. [From J. J. Kirkland, Am. Lab., June 1994, p. 28K.]

Nonpolar bonded phase with embedded polar amide group offers different selectivity from $\mathrm{C}_{18}$, has improved peak shape for bases, and tolerates $100 \%$ aqueous eluent.

FIGURE 24-9 Rapid separation of proteins on superficially porous $\mathrm{C}_{18}$-silica in $2.1 \times 75 \mathrm{~mm}$ column containing Poroshell 300SB-C18. Mobile phase A: $0.1 \mathrm{wt} \%$ trifluoroacetic acid in $\mathrm{H}_{2} \mathrm{O}$. Mobile phase B: 0.07 wt $\%$ trifluoroacetic acid in acetonitrile. Solvent was changed continuously from 95 vol $\% \mathrm{~A} / 5 \mathrm{vol} \% \mathrm{~B}$ to $100 \%$ B over 1 min . Flow $=3 \mathrm{~mL} / \mathrm{min}$ at $70^{\circ} \mathrm{C}$ at 26 MPa ( 260 bar ) with ultraviolet detection at 215 nm . Peaks: 1, angiotensin II; 2, neurotensin; 3, ribonuclease; 4, insulin; 5, lysozyme; 6, myoglobin; 7, carbonic anhydrase; 8, ovalbumin. [From R. E. Majors, LCGC Column Technology Supplement, June 2004, p. 8K. Courtesy Agilent Technologies.]

Another type of nonpolar stationary phase has a polar embedded group. The example in the margin consists of a long hydrocarbon chain with a polar amide group near its base. Embedded polar groups provide alternate selectivities from $\mathrm{C}_{18}$ stationary phases, improved peak shapes for bases, and compatibility with $100 \%$ aqueous phase. Other nonpolar stationary phases should not be exposed to $100 \%$ aqueous phase because they become very difficult to re-equilibrate with organic phase.

Figure 24-9 shows a rapid separation of proteins on superficially porous particles (also called fused-core particles), which consist of a $0.25-\mu \mathrm{m}$-thick porous silica layer on a $5-\mu \mathrm{m}$ diameter nonporous silica core. A stationary phase such as $\mathrm{C}_{18}$ is bonded throughout the thin, porous outer layer. Mass transfer of solute into a $0.25-\mu$ m-thick layer is 10 times faster than mass transfer into fully porous particles with a radius of $2.5 \mu \mathrm{~m}$, thus enabling high efficiency at high flow rate. Superficially porous particles are especially suitable for separation of macromolecules such as proteins, which diffuse more slowly than small molecules. Figure 24-3 showed that the van Deemter curve for superficially porous particles with a total diameter of $2.7 \mu \mathrm{~m}$ and a porous layer thickness of $0.5 \mu \mathrm{~m}$ is similar to that of a conventional, totally porous particle with a diameter of $1.8 \mu \mathrm{~m}$. The superficially porous particle enables separations similar to those achieved with $1.8-\mu \mathrm{m}$ totally porous particles without requiring such high pressure.

Porous graphitic carbon deposited on silica ${ }^{13}$ is a stationary phase that exhibits increased retention of nonpolar compounds relative to retention by $\mathrm{C}_{18}$. Graphite has high affinity for polar compounds and separates isomers that cannot be separated on $\mathrm{C}_{18}$. The stationary phase is stable in 10 M acid and 10 M base.

Pharmaceutical companies often separate the two enantiomers (mirror image isomers) of a drug because each enantiomer has a different pharmacological effect. To resolve enantiomers, optically active bonded phases, such as those shown in Figure 24-10 and Exercise 24-B, are used. ${ }^{14}$ Figure $24-10$ shows the calculated geometry of the chiral drug naproxen binding to one enantiomer of the stationary phase. Mirror image forms of the drug are designated $R$ and $S$. Mirror image forms of the stationary phase are designated $(R, R)$ and $(S, S)$. Binding of ( $S$ )-naproxen to $(S, S)$-stationary phase is stronger than binding of $(R)$-naproxen to $(S, S)$-stationary phase. Therefore, $(R)$-naproxen is eluted before $(S)$-naproxen from $(S, S)$-stationary phase. Some other chiral stationary phases are based on substituted cellulose, on cyclic peptides with sugar substituents, and on cyclodextrins (Box 23-1).

## The Elution Process

In adsorption chromatography, solvent molecules compete with solute molecules for sites on the stationary phase (Figure $24-11$ and Color Plate 28). The relative abilities of different solvents to elute a given solute from the adsorbent are nearly independent of the nature of the solute. Elution occurs when solvent displaces solute from the stationary phase.
(S)-Naproxen

(R)-Naproxen

An eluotropic series ranks solvents by their relative abilities to displace solutes from a given adsorbent. The eluent strength, $\boldsymbol{\varepsilon}^{0}$, is a measure of the solvent adsorption energy, with the value for pentane defined as 0 for adsorption on bare silica. Table 24-2 ranks solvents by their eluent strength on bare silica. The more polar the solvent, the greater is its eluent strength for adsorption chromatography with bare silica. The greater the eluent strength, the more rapidly will solutes be eluted from the column.

Adsorption chromatography on bare silica is an example of normal-phase chromatography, in which we use a polar stationary phase and a less polar solvent. A more polar solvent has a higher eluent strength. Reversed-phase chromatography is the more common scheme in which the stationary phase is nonpolar or weakly polar and the solvent is more polar. A less polar solvent has a higher eluent strength. In general, eluent strength is increased by making the mobile phase more like the stationary phase. Reversed-phase chromatography eliminates peak tailing because the stationary phase has few sites that can strongly adsorb a solute to cause tailing (Figure 22-21). Normal-phase chromatography is sensitive to small amounts of

(a)
(b)

FIGURE 24-10 Interaction of enantiomers of the drug naproxen with $(S, S)$ chiral stationary phase Whelk-O 1. (S)-Naproxen is adsorbed more strongly and is therefore retained longer by the column. [From S. Ahuja, "A Strategy for Developing HPLC Methods for Chiral Drugs," LCGC 2007, 25, 1112 .]

Normal-phase chromatography:

- polar stationary phase
- more polar solvent has higher eluent strength
Reversed-phase chromatography:
- nonpolar stationary phase
- less polar solvent has higher eluent strength

FIGURE 24-11 Solvent molecules compete with solute molecules for binding sites on the stationary phase. The greater the eluent strength of the solvent, the more easily it displaces the solute.

Isocratic elution: one solvent Gradient elution: continuous change of solvent composition to increase eluent strength. Gradient elution in HPLC is analogous to temperature programming in gas chromatography. Increased eluent strength is required to elute more strongly retained solutes.

TABLE 24-2 Eluotropic series and ultraviolet cutoff wavelengths of solvents for adsorption chromatography on silica

| Solvent | Eluent strength $\left(\varepsilon^{\circ}\right)$ | Ultraviolet cutoff $(\mathbf{n m})$ |
| :--- | :--- | :--- |
| Pentane | 0.00 | 190 |
| Hexane | 0.01 | 195 |
| Heptane | 0.01 | 200 |
| Trichlorotrifluoroethane | 0.02 | 231 |

water in the eluent, but reversed-phase chromatography is not. Box 24-2 describes the solventstationary phase interface in reversed-phase chromatography.

## Isocratic and Gradient Elution

Isocratic elution is performed with a single solvent (or constant solvent mixture). If one solvent does not provide sufficiently rapid elution of all components, then gradient elution can be used. In this case, increasing amounts of solvent B are added to solvent A to create a continuous gradient.

## BOX 24-2 Structure of the Solvent-Bonded Phase Interface

Structured layers of solvent at the interface between the stationary and mobile phases influence the separation in liquid chromatography. The diagrams show solvent layers at the surface of $\mathrm{C}_{18}$-silica in the presence of methanol/water ( $40: 60$ vol:vol) and acetonitrile/ water ( $30: 70$ vol:vol), as deduced from adsorption studies of phenol and caffeine. The $40: 60$ and $30: 70$ compositions were chosen because they have nearly the same eluent strength.

Methanol forms a monolayer (one molecule thick) of adsorbed solvent on the $\mathrm{C}_{18}$ surface with a thickness of 0.25 nm . Acetonitrile
forms a pool of adsorbed solvent with a thickness of 1.3 nm and a high capacity for dissolved solute. Adsorbed phenol and caffeine molecules can reside inside the $\mathrm{C}_{18}$ layer or on the outer surface of the $\mathrm{C}_{18}$ layer, or they can be dissolved in the $\mathrm{CH}_{3} \mathrm{CN}$ pool. Each type of adsorption site has a different binding energy and binding capacity and affects the shape of the eluted solute band differently at different solute concentrations. The pool of adsorbed $\mathrm{CH}_{3} \mathrm{CN}$ is a stronger eluent than the bulk organic/aqueous solution and explains why acetonitrile is a stronger eluent than methanol.

Structure of adsorbed solvent on $\mathrm{C}_{18}$ bonded phase in reversed-phase chromatography. [Adapted from F. Gritti and G. Guiochon, "Adsorption Mechanism in RPLC. Effect of the Nature of the Organic Modifier," Anal. Chem. 2005, 77, 4257.]

Figure 24-12 shows the effect of increasing eluent strength in the isocratic elution of eight compounds from a reversed-phase column. In a reversed-phase separation, eluent strength decreases as the solvent becomes more polar. The first chromatogram (upper left) was obtained with a solvent consisting of $90 \mathrm{vol} \%$ acetonitrile and $10 \mathrm{vol} \%$ aqueous buffer. Acetonitrile has a high eluent strength, and all compounds are eluted rapidly. Only

- Aqueous buffer for HPLC is prepared and the pH adjusted prior to mixing with organic solvent. ${ }^{15}$
- Ultrapure water for HPLC should be freshly prepared by a purification train or by distillation. Water extracts impurities from polyethylene or glass after storage for a few hours.
- To prepare $70 \%$ B, for example, mix 70 mL of $B$ with 30 mL of $A$. The result is different from placing 70 mL of $B$ in a volumetric flask and diluting to 100 mL with A because there is a volume change when $A$ and $B$ are mixed.

General elution problem: For a complex mixture, isocratic conditions can often be found to produce adequate separation of early-eluting peaks or late-eluting peaks, but not both. This problem drives us to use gradient elution.

FIGURE 24-12 Isocratic HPLC separation of a mixture of aromatic compounds at $1.0 \mathrm{~mL} / \mathrm{min}$ on a $0.46 \times 25 \mathrm{~cm}$ Hypersil ODS column ( $\mathrm{C}_{18}$ on $5-\mu \mathrm{m}$ silica) at ambient temperature ( $\sim 22^{\circ} \mathrm{C}$ ): (1) benzyl alcohol;
(2) phenol; (3) $3^{\prime}, 4^{\prime}$-dimethoxyacetophenone;
(4) benzoin; (5) ethyl benzoate; (6) toluene;
(7) 2,6-dimethoxytoluene; (8) o-methoxybiphenyl. Eluent consisted of aqueous buffer (designated A) and acetonitrile (designated B). The notation " $90 \%$ B" in the first chromatogram means $10 \mathrm{vol} \% \mathrm{~A}$ and 90 vol\% B. The buffer contained $25 \mathrm{mM} \mathrm{KH} 2 \mathrm{PO}_{4}$ plus $0.1 \mathrm{~g} / \mathrm{L}$ sodium azide adjusted to pH 3.5 with HCl .

Box 24-3 describes gradient elution in supercritical fluid chromatography.

Hydrophilic: "water loving"-soluble in water, surface is wetted by water
Hydrophobic: "water hating"-insoluble in water, surface is not wetted by water
three peaks are observed because of overlap. It is customary to call the aqueous solvent A and the organic solvent B. The first chromatogram was obtained with $90 \%$ B. When eluent strength is reduced by changing the solvent to $80 \% \mathrm{~B}$, there is slightly more separation and five peaks are observed. At $60 \%$ B, we begin to see a sixth peak. At $40 \%$ B, there are eight clear peaks, but compounds 2 and 3 are not fully resolved. At $30 \% \mathrm{~B}$, all peaks would be resolved, but the separation takes too long. Backing up to $35 \%$ B (the bottom trace) separates all peaks in a little over 2 h (which is still too long for many purposes).

From the isocratic elutions in Figure 24-12, the gradient in Figure 24-13 was selected to resolve all peaks in 38 min . First, $30 \%$ B ( $\mathrm{B}=$ acetonitrile $)$ was run for 8 min to separate components 1, 2, and 3. Then eluent strength was increased over 5 min to $45 \%$ B and held there for 15 min to elute peaks 4 and 5. Finally, the solvent was changed to $80 \%$ B over 2 min and held there to elute the last peaks.

## Hydrophilic Interaction Chromatography (HILIC)

Hydrophilic substances are soluble in water or attract water to their surfaces. Polar organic molecules have hydrophilic regions. Hydrophilic interaction chromatography is most useful

## BoX 24-3 "Green" Technology: Supercritical Fluid Chromatography

In the phase diagram for carbon dioxide, solid $\mathrm{CO}_{2}$ (Dry Ice) is in equilibrium with gaseous $\mathrm{CO}_{2}$ at a temperature of $-78.7^{\circ} \mathrm{C}$ and a pressure of 1.00 bar. The solid sublimes without turning into liquid. Above the triple point at $-56.6^{\circ} \mathrm{C}$, liquid and vapor coexist as separate phases. For example, at $0^{\circ} \mathrm{C}$, liquid is in equilibrium with gas at 34.9 bar. Moving up the liquid-gas boundary, we see that two phases always exist until the critical point is reached at $31.3^{\circ} \mathrm{C}$ and 73.9 bar. Above this temperature, only one phase exists, no matter what the pressure. We call this phase a supercritical fluid (Color Plate 29). Its density and viscosity are between those of the gas and liquid, as is its ability to act as a solvent.

An interesting supercritical fluid to demonstrate is $\mathrm{SF}_{6}{ }^{16}$ The photographs at the right show different changes as fluid is warmed and cooled through its supercritical temperature.

Supercritical fluid chromatography with a mixture of $\mathrm{CO}_{2}$ and organic solvent is a "green" technology that reduces organic solvent use by up to $90 \%$ for the separation of kilograms of compounds and enantiomers in the pharmaceutical industry. ${ }^{17}$ The low viscosity of the supercritical fluid also permits faster flow to increase productivity. Though $\mathrm{CO}_{2}$ is a weak solvent by itself, when mixed with some organic solvent, it is capable of dissolving a variety of compounds.

Supercritical fluid chromatography provides increased speed and resolution, relative to liquid chromatography, because of higher diffusion coefficients of solutes in supercritical fluids. Unlike gases, supercritical fluids can dissolve nonvolatile solutes. When pressure is released, the solvent turns to gas, leaving the solute in the gas phase for easy detection. Carbon dioxide is the supercritical fluid of choice for chromatography because it is compatible with flame ionization and ultraviolet detectors, it has a low critical temperature, and it is nontoxic.

Equipment for supercritical fluid chromatography is similar to that for HPLC with packed columns or open tubular columns. Eluent strength is increased in HPLC by gradient elution and in gas chromatography by raising the temperature. In supercritical fluid chromatography, eluent strength is increased by making the solvent denser by increasing the pressure. The chromatogram shows a density-gradient elution.

## Critical constants

| Compound | Critical temperature <br> $\left({ }^{\circ} \mathrm{C}\right)$ | Critical pressure <br> $(\mathrm{bar})$ | Critical density <br> $(\mathrm{g} / \mathrm{mL})$ |
| :--- | :--- | :---: | :--- |
| Argon | -122.5 | 47 | 0.53 |
| Carbon dioxide | 31.3 | 73.9 | 0.448 |
| Sulfur hexafluoride | 45.6 | 37.0 | 0.755 |
| Ammonia | 132.2 | 113.0 | 0.24 |
| Diethyl ether | 193.6 | 36.8 | 0.267 |
| Methanol | 240.5 | 79.9 | 0.272 |
| Water | 374.4 | 229.8 | 0.344 |

for small molecules that are too polar to be retained by reversed-phase columns. Stationary phases for hydrophilic interaction chromatography, such as those in Figure 24-14, are strongly polar. The mobile phase typically contains ( $25-97 \mathrm{vol} \%$ ) $\mathrm{CH}_{3} \mathrm{CN}$ or other polar organic solvent mixed with aqueous buffer. Solutes equilibrate between the mobile phase and a layer of aqueous phase on the surface of the stationary phase. In biochemistry, HILIC is useful for separating peptides and saccharides (sugars).

In HILIC, eluent strength is increased by increasing the fraction of water in the mobile phase. Gradient elution goes from low aqueous content to high aqueous content. In normalphase chromatography, the solvent is nonaqueous. To increase eluent strength, we increase the polarity of the nonaqueous solvent. In reversed-phase chromatography, the solvent is usually aqueous, and eluent strength is increased by decreasing the fraction of water in the mobile phase to increase the solubility of solutes in the mobile phase.

## Selecting the Separation Mode

There can be many ways to separate components of a given mixture. Figure $24-15$ is a decision tree for choosing a starting point. If the molecular mass of analyte is below 2000 , use the upper part of the figure; if the molecular mass is greater than 2000 , use the lower part. In

There are no firm rules in Figure 24-15. Methods in either part of the diagram might work for molecules whose size belongs to the other part.

Warming and cooling $\mathrm{SF}_{6}$ through its supercritical temperature. Upon warming (upper panel), liquid boils and the meniscus rises as the liquid expands. Upon cooling (lower panel), droplets of liquid form throughout the fluid. Gravity pulls droplets down, creating a "storm" before separation into two distinct phases. [From P. Licence, D. Litchfield, M. P. Dellar, and M. Poliakoff, "'Supercriticality'; a Dramatic but Safe Demonstration of the Critical Point," Green Chem. 2004, 6, 352. Courtesy Peter Licence, University of Nottingham.]

Open tubular capillary supercritical chromatogram of aromatic compounds with $\mathrm{CO}_{2}$, using density-gradient elution at $140^{\circ}$ C. [From R. D. Smith, B. W. Wright, and C. R. Yonker, "Supercritical Fluid Chromatography," Anal. Chem. 1988, 60, 1323A.]

FIGURE 24-13 Gradient elution of the same mixture of aromatic compounds in Figure 24-12 with the same column, flow rate, and solvents. The upper trace is the segmented gradient profile, so named because it is divided into several different segments.
either part, the first question is whether the solutes dissolve in water or in organic solvents. Suppose we have a mixture of small molecules (molecular mass $<2000$ ) soluble in dichloromethane. Table 24-2 is essentially a ranking of solvent polarity, with the most polar solvents at the bottom. The eluent strength of dichloromethane ( 0.30 ) is closer to that of chloroform ( 0.26 ) than it is to those of alcohols, acetonitrile, or ethyl acetate $(\geq 0.48)$. Therefore, Figure $24-15$ suggests that we try adsorption chromatography on silica. The decision path is highlighted in color.

FIGURE 24-14 Stationary phases for hydrophilic interaction chromatography (HILIC).

FIGURE 24-15 Guide to HPLC mode selection.
If solutes dissolve only in nonpolar or weakly polar solvents, the decision tree suggests that we try reversed-phase chromatography. Our choices include bonded phases containing octadecyl ( $\mathrm{C}_{18}$ ), octyl, phenyl, pentafluorophenyl, and cyano groups.

If molecular masses of solutes are $>2000$ and if they are soluble in organic solvents and their molecular diameter is $>30 \mathrm{~nm}$, Figure 24-15 tells us to try molecular exclusion chromatography, described in Section 25-3. If molecular masses of solutes are $>2000$, and they are soluble in water, but not ionic, and have diameters $<30 \mathrm{~nm}$, the decision tree says to use reversed-phase chromatography, or hydrophobic interaction chromatography, which is described in Section 25-5.

## Purging with gas is called sparging.

$V_{\mathrm{m}}=$ volume of solvent in column between stationary phase particles and inside pores of particles.
If time for mobile phase or unretained solute to transit the column is $t_{\mathrm{m}}$, and flow rate is $F$, then $V_{\mathrm{m}}=t_{\mathrm{m}} \mathrm{F}$.
If you don't know $t_{m}$, you can estimate
$V_{\mathrm{m}}(\mathrm{mL}) \approx \frac{1}{2} d_{\mathrm{c}}^{2} L$, where $d_{\mathrm{c}}=$ column inner
diameter (cm) and $L=$ column length (cm).

## Reduce Waste Solvent Without Sacrificing Resolution

- Use shorter columns with smaller diameter particles.
- Switch from 4.6-mm-diameter column to 2.1 mm .
- For isocratic separations, use an electronic recycler that recycles eluate when no peak is being eluted.

A standard mixture should be injected each day to evaluate the HPLC system. Changes in peak shapes or retention times alert you to a problem.

## Solvents

Pure HPLC-grade (expensive) solvents are required to prevent degradation of costly columns with impurities and to minimize detector background signals from contaminants. Before use, solvents are purged with He or evacuated to remove dissolved air. Air bubbles create difficulties for pumps, columns, and detectors. Dissolved $\mathrm{O}_{2}$ absorbs ultraviolet radiation in the 250- to $200-\mathrm{nm}$ wavelength range, ${ }^{18}$ interfering with ultraviolet detection. A filter is used on the intake tubing in the solvent reservoir to exclude $>0.5-\mu \mathrm{m}$ particles.

Sample and solvent are passed through a short, expendable guard column (Figures 24-1 and 24-4) that has the same stationary phase as the analytical column and retains strongly adsorbed species. At the end of a reversed-phase separation, the column should be washed with $10-20$ mobile phase volumes $\left(V_{\mathrm{m}}\right)$ of strong eluent to remove strongly retained solutes. ${ }^{19}$ To clean the column after a series of runs, first replace aqueous buffer by water. For example, if the last eluent was acetonitrile-aqueous buffer ( $40: 60 \mathrm{vol} / \mathrm{vol}$ ), wash the column with 5-10 volumes ( $V_{\mathrm{m}}$ ) of acetonitrile-water ( $40: 60 \mathrm{vol} / \mathrm{vol}$ ). Then wash the column with 10-20 mobile phase volumes of strong solvent such as acetonitrile-water ( $95: 5 \mathrm{vol} / \mathrm{vol}$ ) and store the column with this solvent. This procedure is suitable for alkyl, aryl, cyano, and embedded polar-phase columns. A different procedure is recommended for normal-phase columns. ${ }^{20}$

Normal-phase separations are sensitive to water in the solvent. To speed the equilibration of stationary phase with changing eluents, organic solvents for normal-phase chromatography should be $50 \%$ saturated with water. Saturation can be achieved by adding a few milliliters of water to dry solvent and stirring. Then the wet solvent is separated from the excess water and mixed with an equal volume of dry solvent.

For gradient elution in reversed-phase separations, $10-20$ volumes ( $V_{\mathrm{m}}$ ) of initial solvent should be passed through the column after a run to equilibrate the stationary phase with solvent for the next run. Equilibration can take as long as the separation. By adding $3 \mathrm{vol} \%$ 1-propanol to each solvent (so that there is always $3 \% 1$-propanol at any point in the gradient), you can reduce the re-equilibration volume down to $3 V_{\mathrm{m}}{ }^{21}$ Propanol is thought to coat the stationary phase with a monolayer of alcohol that does not change much throughout the gradient.

## Maintaining Symmetric Bandshape

HPLC columns should provide narrow, symmetric peaks. If a new column does not reproduce the quality of the separation of a standard mixture whose chromatogram comes with the column, and if you have satisfied yourself that the problem is not in the rest of your system, return the column.

The asymmetry factor $A / B$ in Figure 22-14 should rarely be outside the range $0.9-1.5$. Tailing of amines (Figure 24-7) might be eliminated by adding 30 mM triethylamine to the mobile phase. The additive binds to sites on silica that would otherwise strongly bind analyte. Tailing of acidic compounds might be eliminated by adding 30 mM ammonium acetate. For unknown mixtures, 30 mM triethylammonium acetate is useful. If tailing persists, 10 mM dimethyloctylamine or dimethyloctylammonium acetate might be effective. A problem with additives is that they increase the equilibration time required when changing solvents. Improved grades of silica (types B and C) have reduced tailing and, therefore, reduced the need for additives.

Tailing or splitting of peaks can occur if the frit at the beginning of the column becomes clogged with particles. ${ }^{22}$ You can try to unclog the frit by disconnecting and reversing the column and flushing it with $20-30 \mathrm{~mL}$. The column should not be connected to the detector during reverse flushing. If peaks remain distorted, replace the column.

Doubled peaks or altered retention times (Figure 24-16) sometimes occur if the solvent in which sample is dissolved has much greater eluent strength than the mobile phase. Try to dissolve the sample in a solvent of lower eluent strength or in the mobile phase itself.

Overloading causes the distorted shape shown in Figure 22-21. ${ }^{23}$ To see if overloading is occurring, reduce the sample mass by a factor of 10 and see if retention times increase or peaks become narrower. If either change occurs, reduce the mass again until the injection size does not affect retention time and peak shape. In general, reversed-phase columns can handle $1-10 \mu \mathrm{~g}$ of sample per gram of silica. A 4.6-mm-diameter column contains 1 g of silica in a length of 10 cm . To prevent peak broadening from too large an injection volume, the injected volume should be less than $15 \%$ of the peak volume measured at the baseline. For example, if a peak eluted at $1 \mathrm{~mL} / \mathrm{min}$ has a width of 0.2 min , the peak volume is 0.2 mL . The injection volume should not exceed $15 \%$ of 0.2 mL , or $30 \mu \mathrm{~L}$.

The volume of a chromatography system outside of the column from the point of injection to the point of detection is called the dead volume, or the extra-column volume. Excessive dead volume allows bands to broaden by diffusion or mixing. Use short, narrow tubing whenever possible, and be sure that connections are made with matched fittings to minimize dead volume and thereby minimize extra-column band spreading.

HPLC columns have a typical lifetime of 500 to 2000 injections. ${ }^{7}$ You can monitor the health of a column by keeping a record of pressure, resolution, and peak shape. The pressure required to maintain a given flow rate increases as a column ages. System wear becomes serious when pressure exceeds 17 MPa ( 2500 pounds $/$ inch $^{2}$ ). It is desirable to develop methods in which pressure does not exceed 14 MPa ( 2000 pounds/inch ${ }^{2}$ ). When the pressure reaches 17 MPa , the in-line $0.5-\mu \mathrm{m}$ frit between the autosampler and the column should be replaced. If this does not help, it is probably time for a new column. If you use a column for repetitive analyses, replace the column when the required resolution is lost or when tailing becomes significant. Resolution and tailing criteria should be established during method development.

## 24-2 Injection and Detection in HPLC

We now consider the hardware required to inject sample and solvent onto the column and to detect compounds as they leave the column. Mass spectrometric detection, which is extremely powerful and important, was discussed in Section 21-4.

## Pumps and Injection Valves

The quality of a pump for HPLC is measured by how steady and reproducible a flow it can produce. A fluctuating flow rate can create detector noise that obscures weak signals. Figure 24-17 shows a pump with two sapphire pistons that produce a programmable, constant flow rate up to $10 \mathrm{~mL} / \mathrm{min}$ at pressures up to 40 MPa ( $400 \mathrm{bar}, 6000$ pounds $/ \mathrm{inch}^{2}$ ). Gradients made from up to four solvents are constructed by proportioning the liquids through a fourway valve at low pressure and then pumping the mixture at high pressure into the column. The gradient is electronically controlled and programmable in $0.1 \mathrm{vol} \%$ increments.

The injection valve in Figure 24-18 has interchangeable sample loops, each of which holds a fixed volume. Loops of different sizes hold volumes that range from 2 to $1000 \mu \mathrm{~L}$. In the load position, a syringe is used to wash and load the loop with fresh sample at atmospheric pressure. High-pressure flow from the pump to the column passes through the lower left segment of the valve. When the valve is rotated $60^{\circ}$ counterclockwise, the content of the sample loop is injected into the column at high pressure.

FIGURE 24-17 High-pressure piston pump for HPLC. Solvent at the left passes through an electronic inlet valve synchronized with the large piston and designed to minimize the formation of solvent vapor bubbles during the intake stroke. The spring-loaded outlet valve maintains a constant outlet pressure, and the damper further reduces pressure surges. Pressure surges from the first piston are decreased in the damper that "breathes" against a constant outside pressure. Pressure surges are typically $<1 \%$ of the operating pressure. As the large piston draws in liquid, the small piston propels liquid to the column. During the return stroke of the small piston, the large piston delivers solvent into the expanding chamber of the small piston. Part of the solvent fills the chamber while the remainder flows to the column. Delivery rate is controlled by the stroke volumes. [Adapted from Hewlett-Packard Co., Palo Alto, CA.]

FIGURE 24-16 Effect of sample solvent on retention time and peak shape of $n$-butylaniline. Eluent ( $1 \mathrm{~mL} / \mathrm{min}$ ) is $90: 10$ (vol/vol) $\mathrm{H}_{2} \mathrm{O} / a c e t o n i t r i l e ~ w i t h ~ 0.1 ~ w t \% ~$ trifluoroacetic acid. Lower sample was dissolved in eluent. Upper sample was dissolved in methanol, which is a much stronger solvent than eluent. Column: $15 \mathrm{~cm} \times 4.6 \mathrm{~mm}, 5-\mu \mathrm{m}$ diameter $\mathrm{C}_{18}$-silica, $30^{\circ} \mathrm{C}$. Injection: $10 \mu \mathrm{~L}$ containing $0.5 \mu \mathrm{~g}$ analyte. Ultraviolet detection at 254 nm . [Courtesy Supelco, Bellefonte, PA.]

- Pass samples through a $0.5-\mu \mathrm{m}$ filter to remove particles prior to injection.
- The HPLC syringe needle is blunt, not pointed, to prevent damage to the injection port.

FIGURE 24-18 Injection valve for HPLC.

## Spectrophotometric Detectors

An ideal detector of any type (Table 24-3) is sensitive to low concentrations of every analyte, provides linear response, and does not broaden the eluted peaks. It is also insensitive to changes in temperature and solvent composition. To prevent peak broadening, the detector volume should be less than $20 \%$ of the volume of the chromatographic band. Gas bubbles in the detector create noise, so back pressure may be applied to the detector to prevent bubble formation during depressurization of eluate.

An ultraviolet detector using a flow cell such as that in Figure 24-19 is the most common HPLC detector, because many solutes absorb ultraviolet light. Simple systems employ the intense $254-n m$ emission of a mercury vapor lamp or other discrete ultraviolet wavelengths from zinc or cadmium vapor lamps. More versatile instruments have broadband deuterium, xenon, or tungsten lamps and a monochromator, so you can choose an optimum wavelength for your analytes. The system in Figure 24-20 uses a photodiode array to record the spectrum of each solute as it is eluted. High-quality detectors provide full-scale absorbance ranges from 0.0005 to 3 absorbance units, with a noise level near $1 \%$ of full scale. The linear range extends over five orders of magnitude of solute concentration (which is another way of saying that Beer's law is obeyed over this range). Ultraviolet detectors are

TABLE 24-3 Comparison of commercial HPLC detectors

| Detector | Approximate limit <br> of detection ${ }^{a}(\mathrm{ng})$ | Useful with <br> gradient? |
| :--- | :--- | :--- |
| Ultraviolet | $0.1-1$ | Yes |

good for gradient elution with nonabsorbing solvents. Table 24-2 lists approximate cutoff wavelengths below which a solvent absorbs too strongly.

Fluorescence detectors excite the eluate with a laser and measure fluorescence (Figure 17-21). These detectors are very sensitive but respond only to the few analytes that fluoresce. To increase the utility of fluorescence and electrochemical detectors (described later), fluorescent or electroactive groups can be covalently attached to the analyte. This process of derivatization can be performed on the mixture prior to chromatography or by addition of reagents to the eluate between the column and the detector (called post-column derivatization). For example, $\mathrm{Tb}(E D T A)^{-}$can be added to the hormones epinephrine, norepinephrine, and dopamine emerging from a chromatography column. ${ }^{25}$ These compounds form complexes with $\mathrm{Tb}(\mathrm{III})$, which can be excited near 300 nm and emit strongly at $500-600 \mathrm{~nm}$. The detection limit is 10 to 100 nM with Tb fluorescence.

## Evaporative Light-Scattering Detector

An evaporative light-scattering detector responds to any analyte that is significantly less volatile than the mobile phase. ${ }^{26}$ In Figure 24-21, eluate enters the detector at the top. In the nebulizer, eluate is mixed with nitrogen gas and forced through a small-bore needle to form a uniform dispersion of droplets. Solvent evaporates from the droplets in the heated drift tube, leaving a fine mist of solid particles to enter the detection zone at the bottom. The particles are detected by the light that they scatter from a diode laser to a photodiode.

The evaporative light-scattering detector response is related to the mass of analyte, not to the structure or molecular mass of the analyte. If you see a large peak and a small peak, you can be pretty sure that there is less material in the small peak than in the large peak. With an ultraviolet detector, a small mass of strongly absorbing analyte can give a stronger signal than a large mass of weakly absorbing analyte. The evaporative light-scattering detector response is fit to the equation

$$
\begin{equation*}
\log A=a+b \log m \tag{24-3}
\end{equation*}
$$

FIGURE 24-21 (a) Operation of an evaporative light-scattering detector. [Courtesy Alltech Associates, Deerfield, IL.] (b) Comparison of ultraviolet absorbance and evaporative light-scattering detector response. Soluble components were extracted from a drug tablet and separated by reversed-phase liquid chromatography on a $4.6 \times 150 \mathrm{~mm}$ column containing $\mathrm{C}_{8}$-silica with a $30-\mathrm{nm}$ pore size for separating polymers. Solvent A is $0.01 \mathrm{wt} \%$ trifluoroacetic acid in $\mathrm{H}_{2} \mathrm{O}$. Solvent B is $45 \mathrm{wt} \%$ propanol and $0.01 \mathrm{wt} \%$ trifluoroacetic acid in $\mathrm{H}_{2} \mathrm{O}$. A gradient was run from $10 \mathrm{vol} \% \mathrm{~B}$ up to 90 vol $\% \mathrm{~B}$ at $1 \mathrm{~mL} / \mathrm{min}$. Gradient time was not stated. [From L. A. Doshier, J. Hepp, and K. Benedek, "Method Development Tools for the Analysis of Complex Pharmaceutical Samples," Am. Lab., December 2002, p. 18.]
where $A$ is the area of the signal (in a graph of scattered light intensity versus time), $m$ is the mass of analyte, and $a$ and $b$ are constants to fit the calibration curve.

The evaporative light-scattering detector is compatible with gradient elution. Also, there are no peaks associated with the solvent front, so there is no interference with early eluting peaks. What do we mean by solvent front? In Figure 24-13, you can see small positive and negative signals at 3-4 min. These signals arise from changes in the refractive index of the mobile phase due to solvent in which the sample was dissolved. This change displaces the ultraviolet detector signal at the time $t_{\mathrm{m}}$ required for unretained mobile phase to pass through the column. If a peak is eluted close to the time $t_{\mathrm{m}}$, it can be distorted by the solvent front peaks. An evaporative light-scattering detector has no solvent front peaks.

If you use a buffer in the eluent, it must be volatile or else it will evaporate down to solid particles that scatter light and obscure the analyte. Low-concentration buffers made from acetic, formic, or trifluoroacetic acid, ammonium acetate, diammonium phosphate, ammonia, or triethylamine are suitable. Buffers for evaporative light scattering are the same as those for mass spectrometric detection.

Figure 24-21b compares evaporative light scattering with ultraviolet absorbance for the detection of soluble components of a drug tablet containing polymers and small-molecule active ingredients. Two components have absorbance at 232 nm . Four or five components are evident with $205-\mathrm{nm}$ detection. The solvent gradient produces a sloping baseline at 205 nm . All components are observed by evaporative light scattering, and there is no slope to the baseline. Some broad peaks arise from polymers with a distribution of molecular masses.

## Charged Aerosol Detector

The charged aerosol detector is a sensitive, almost universal detector with nearly equal response to equal masses of nonvolatile analytes. ${ }^{27}$ Introduced in 2005, it already has a prominent place in industry. For example, it is useful for measuring the material balance in

pharmaceutical preparations because the relative area of each peak in the chromatogram is nearly equal to the relative mass of that component in the preparation. Lipids and carbohydrates, which have little response from an ultraviolet detector, give the same response as other components of the mixture. A minor peak in the charged aerosol chromatogram must be a minor component of the mixture, whereas it could be a major component in the ultraviolet chromatogram.

At the top left of the charged aerosol nebulizer in Figure 24-22, eluate and $\mathrm{N}_{2}$ gas enter a nebulizer similar to the premix burner in Figure 20-5. Fine mist from the nebulizer reaches the drying tube, while larger droplets fall to the drain. In the drying tube, solvent evaporates at ambient temperature, leaving an aerosol containing $\sim 1 \%$ of the original analyte. Meanwhile, part of the $\mathrm{N}_{2}$ stream passes over a Pt needle held at $\sim+10 \mathrm{kV}$ with respect to the outer case of the corona charging chamber to form $\mathrm{N}_{2}^{+}$. A chain of events, perhaps as written for atmospheric pressure chemical ionization on page 522, transfers positive charge to aerosol particles that flow out of the charging chamber through a small-ion trap. Charged plates of the trap attract small mobile ions. Aerosol particles are too massive to be deflected and pass through the trap to the collector. Total charge reaching the collector is measured by an electrometer, which produces the detector signal for the chromatogram.

The dynamic range of the detector spans 4-5 orders of magnitude in concentration. Response is approximately proportional to $\sqrt{m}$. Equal masses of different analytes give equal response within $\sim 15 \%$ in isocratic elution. Response depends on solvent composition, with higher response for higher percentage of volatile organic solvent and lower response for water. As the organic composition of a gradient increases, so does the response. However, the detector can still be used with gradient elution. ${ }^{28}$

## Electrochemical Detector

An electrochemical detector responds to analytes that can be oxidized or reduced, such as phenols, aromatic amines, peroxides, mercaptans, ketones, aldehydes, conjugated nitriles, aromatic halogen compounds, and aromatic nitro compounds. The opening of Chapter 16 shows a detector in which eluate is oxidized or reduced at the working electrode. The potential is maintained at a selected value with respect to the $\mathrm{Ag} \mid \mathrm{AgCl}$ reference electrode, and current is measured between the working electrode and the stainless steel auxiliary electrode. For oxidizable solutes, copper or glassy carbon working electrodes are common. For reducible solutes, a drop of mercury is a good working electrode. Current is proportional to solute concentration over six orders of magnitude. Aqueous or other polar solvents containing dissolved electrolytes are required, and they must be rigorously freed of oxygen. Metal ions extracted from tubing can be masked by adding EDTA to the solvent. The detector is sensitive to flow rate and temperature changes.

FIGURE 24-22 Operation of the charged aerosol detector. [Courtesy ESA, Inc., Chelmsford MA.]

FIGURE 24-23 Pulsed electrochemical detection of alcohols separated on Dionex AS-1 anion-exchange column with $0.05 \mathrm{M} \mathrm{HClO}_{4}$. Peaks: 1, glycerol; 2, ethylene glycol; 3, propylene glycol; 4, methanol; 5, ethanol; 6, 2-propanol; 7, 1-propanol; 8, 2-butanol; 9, 2-methyl-1-propanol; 10, 1-butanol; 11, 3-methyl-1butanol; 12, 1-pentanol; 13, cyclohexanol; 14, 1-hexanol; 15, diethylene glycol. [From D. C. Johnson and W. R. LaCourse, "Liquid Chromatography with Pulsed Electrochemical Detection at Gold and Platinum Electrodes," Anal. Chem. 1990, 62, 589A.]

Pulsed electrochemical measurements at Au or Pt working electrodes expand the classes of detectable compounds to include alcohols, carbohydrates, and sulfur compounds. ${ }^{29}$ The electrode is held at +0.8 V (versus a saturated calomel electrode) for 120 ms to oxidatively desorb organic compounds from the electrode surface and to oxidize the metal surface. Then the electrode is brought to -0.6 V for 200 ms to reduce the oxide to pristine metal. The electrode is then brought to a constant working potential (typically in the range +0.4 to -0.4 V ), at which analyte is oxidized or reduced. After a delay of 400 ms to allow the charging current (Figure 16-17) to decay to 0 , current is integrated for the next 200 ms to measure analyte. The sequence of pulses just described is then repeated to measure successive data points as eluate emerges from the column. By this means, 10 ppb ethylene glycol $\left(\mathrm{HOCH}_{2} \mathrm{CH}_{2} \mathrm{OH}\right)$ in the chromatographic system in Figure 24-23 would give a signal-to-noise ratio of 3 .

## Refractive Index Detector

A refractive index detector responds to almost every solute, but its detection limit is about 1000 times poorer than that of the ultraviolet detector. A deflection-type detector has two triangular 5 - to $10-\mu \mathrm{L}$ compartments through which pure solvent or eluate passes. Collimated (parallel) visible light, filtered to remove infrared radiation that would heat the sample, passes through the cell with pure solvent in both compartments and is directed to a photodiode array. When solute with a different refractive index enters the cell, the beam is deflected and different pixels of the array are irradiated.

A refractive index detector is useless in gradient elution because we cannot match the sample and reference while solvent composition is changing. Refractive index is sensitive to changes in pressure and temperature $\left(\sim 0.01^{\circ} \mathrm{C}\right)$. With its low sensitivity, a refractive index detector is not useful for trace analysis. It also has a small linear range, spanning only a factor of 500 in solute concentration. The primary appeal of this detector is its universal response to all solutes, including those that have little ultraviolet absorption.

## Comments on Mass Spectrometric Detection in Liquid Chromatography

Atmospheric pressure chemical ionization (Figure 21-23) and electrospray ionization (Figure 21-21) are the most common liquid chromatography-mass spectrometry interfaces. Atmospheric pressure chemical ionization creates ions from analyte, as well as from other species in solution. Electrospray requires that analyte be charged in solution.

Volatile, low-concentration ( $\leq 10 \mathrm{mM}$ ) buffers used with mass spectrometers are made from formic acid, acetic acid, and ammonia. HCl should not be used because it corrodes the metal interface. Blank injections should be run to observe background ions generated in the absence of sample. Suitable organic solvents include acetonitrile, methanol, ethanol, propanol, and acetone. Tetrahydrofuran is less desirable because, for some types of samples, it can lead to large background signals in a total ion chromatogram and because it is not compatible with commonly used polyether ether ketone (PEEK) tubing with mass spectrometric detection. Ion-pair agents (Section 25-2) and surfactants should not be used because they
create background signals and suppress electrospray signals. Triethylamine suppresses ionization and gives an intense $\mathrm{MH}^{+}$peak at $\mathrm{m} / \mathrm{z} 102$.

Mass spectral sensitivity is reduced by aqueous mobile phase. More organic phase can be added through a " $T$ " connection between the column and the mass spectrometer. Alternatively, a different stationary phase can be chosen to require more organic phase. The pH of the mobile phase can be adjusted between the column and the detector so that acidic or basic analytes are ionized. Atmospheric pressure chemical ionization and electrospray with positive and negative ion modes can all be tried to obtain adequate sensitivity. Eluate emerging from the column prior to $t_{\mathrm{m}}$ can be diverted to waste to avoid introducing unnecessary salts into the mass spectrometer.

Run a performance qualification sample or an internal standard frequently to verify that the separation and the mass spectrometer are behaving normally. When a liquid chromatographymass spectrometry method develops a problem, but the performance qualification check is normal, the problem is most likely in the chromatography of the unknown. If the performance qualification check fails, the problem is likely in the mass spectrometer. You can test the mass spectrometer alone by direct flow injection of a standard sample or calibration solution into the mass spectrometer.

## 24-3 Method Development for Reversed-Phase Separations ${ }^{2,3,30}$

Many separations encountered in industrial and research laboratories can be handled by reversed-phase chromatography. We now describe a general procedure for developing an isocratic separation of an unknown mixture with a reversed-phase column. The next section deals with gradient separations. In method development, the goals are to obtain adequate separation in a reasonable time. Ideally, the procedure should be rugged, which means that the separation will not be seriously degraded by gradual deterioration of the column, by small variations in solvent composition, pH , and temperature, or by use of a different batch of the same stationary phase, perhaps from a different manufacturer. If your column does not have temperature control, you can at least insulate it to reduce temperature fluctuations.

Reversed-phase chromatography is usually adequate to separate mixtures of low-molecularmass neutral or charged organic compounds. If isomers do not separate well, normal-phase chromatography or porous graphitic carbon are recommended because solutes have stronger, more specific interactions with the stationary phase. For enantiomers, chiral stationary phases (Figure 24-10) are required. Separations of inorganic ions, polymers, and biological macromolecules are described in Chapter 25.

As in gas chromatography (Section 23-5), the first steps in method development are to (1) determine the goal of the analysis, (2) select a method of sample preparation to ensure a "clean" sample, and (3) choose a detector that allows you to observe the desired analytes in the mixture. The remainder of method development described in the following sections assumes that steps 1 through 3 have been carried out.

## Criteria for an Adequate Separation

The retention factor $k$ in Equation 22-17 measures corrected retention time, $t_{\mathrm{r}}-t_{\mathrm{m}}$, in units of the time $t_{\mathrm{m}}$ required for mobile phase to pass through the column. Reasonable separations demand that $k$ for all peaks be in the range $0.5-20$. If $k$ is too small, the first peak is distorted by the solvent front. If $k$ is too great, the run takes too long. In the lowest trace in Figure $24-12, t_{\mathrm{m}}$ is the time when the first baseline disturbance is observed near 3 min . If you do not observe a baseline disturbance, you can estimate

$$
\begin{equation*}
\text { Solvent front: } \quad V_{\mathrm{m}} \approx \frac{L d_{\mathrm{c}}^{2}}{2} \quad \text { or, equivalently, } \quad t_{\mathrm{m}} \approx \frac{L d_{\mathrm{c}}^{2}}{2 F} \tag{24-4}
\end{equation*}
$$

where $V_{\mathrm{m}}$ is the volume at which unretained solute is eluted (= volume at which solvent front appears), $L$ is column length (cm), $d_{\mathrm{c}}$ is column diameter ( cm ), and $F$ is flow rate ( $\mathrm{mL} / \mathrm{min}$ ). In reversed-phase chromatography, $t_{\mathrm{m}}$ could be measured by running the unretained solutes uracil (detected at 260 nm ) or $\mathrm{NaNO}_{3}$ (detected at 210 nm ) through the column.

For quantitation, a minimum resolution (Figure 22-10) of 1.5 between the two closest peaks is desired. For ruggedness, a resolution of 2 is desirable so that resolution remains adequate despite small changes in conditions or slow deterioration of the column.

Desired attributes of a new chromatographic method:

- adequate resolution of desired analytes
- short run time
- rugged (not drastically affected by small variations in conditions)

## Initial steps in method development:

1. determine goal
2. select method of sample preparation
3. choose detector

Retention factor: $k=\frac{t_{\mathrm{r}}-t_{\mathrm{m}}}{t_{\mathrm{m}}}$
$t_{\mathrm{r}}=$ retention time of analyte
$t_{\mathrm{m}}=$ elution time for mobile phase or unretained solute

Attributes of a good separation:

- $0.5 \leq k \leq 20$
- resolution $\geq 2$
- operating pressure $\leq 15 \mathrm{MPa}$
- $0.9 \leq$ asymmetry factor $\leq 1.5$

Choice of organic solvent:

1. acetonitrile
2. methanol
3. tetrahydrofuran

To avoid disposing of acetonitrile as hazardous waste, you can hydrolyze it to sodium acetate and flush it down the drain. ${ }^{31}$

A chromatographic method must not exceed the upper allowable operating pressure for the hardware. Keeping pressure below $\sim 15 \mathrm{MPa}$ ( $150 \mathrm{bar}, 2200$ pounds/inch ${ }^{2}$ ) prolongs the life of the pump, valves, seals, and autosampler. Pressure can double during the life of a column because of progressive clogging. Establishing an operating pressure of $\leq 15 \mathrm{MPa}$ during method development allows for column degradation.

All peaks (certainly all peaks that need to be measured) should be symmetric, with an asymmetry factor $A / B$ in Figure 22-14 in the range $0.9-1.5$. Asymmetric peak shapes should be corrected as described at the end of Section 24-1 (page 610) before optimizing a separation.

## Optimization with One Organic Solvent

Combinations of acetonitrile, methanol, and tetrahydrofuran with water (or aqueous buffer) provide a sufficient range of dipolar and hydrogen-bonding interactions with solutes to separate a vast number of compounds in reversed-phase chromatography. The first solvent mixture to try is acetonitrile and water. Acetonitrile has low viscosity, which allows relatively low operating pressure, and it permits ultraviolet detection down to 190 nm (Table 24-2). At 190 nm , many analytes have some absorbance. Methanol is the second choice for organic solvent because it has a higher viscosity and longer wavelength ultraviolet cutoff. Tetrahydrofuran is the third choice because it has less usable ultraviolet range, it is slowly oxidized, ${ }^{32}$ and it equilibrates more slowly with stationary phase. Starting conditions for reversed-phase HPLC are listed in Table 24-4.

TABLE 24-4 Starting conditions for reversed-phase chromatography

| Stationary phase: | $\mathrm{C}_{18}$ or $\mathrm{C}_{8}$ on 5- or 3- $\mu \mathrm{m}$-diameter spherical type B silica for operation in the $\mathrm{pH} 2-7.5$ range. For operation in the $\mathrm{pH} 8-12$ range, use ethylene-bridged silica (Figure 24-6). For operation above $50^{\circ} \mathrm{C}$, use sterically protected silica (Figure 24-8). Alternatively, polymer or zirconia stationary phases are stable over wide pH and temperature ranges. |
| :---: | :---: |
| Column: | $0.21 \times 15 \mathrm{~cm}$ column for $5-\mu \mathrm{m}$ particles <br> $0.21 \times 10 \mathrm{~cm}$ column for $3-\mu \mathrm{m}$ particles (shorter run, similar resolution) <br> When changing particle size, maintain constant (column length/particle diameter) for similar resolution at same linear flow rate. <br> $0.46 \times 15 \mathrm{~cm}$ column for $5-\mu \mathrm{m}$ particles <br> $0.46 \times 10 \mathrm{~cm}$ column for $3-\mu \mathrm{m}$ particles (shorter run, similar resolution) |
| Flow rate: | $1.0 \mathrm{~mL} / \mathrm{min}$ for $0.46-\mathrm{cm}$-diameter column $0.2 \mathrm{~mL} / \mathrm{min} \text { for } 0.21-\mathrm{cm} \text {-diameter column }=\left(\frac{0.21 \mathrm{~cm}}{0.46 \mathrm{~cm}}\right)^{2}\left(1.0 \frac{\mathrm{~mL}}{\mathrm{~min}}\right)$ |
| Mobile phase: | $\mathrm{CH}_{3} \mathrm{CN} / \mathrm{H}_{2} \mathrm{O}$ for neutral analytes <br> $\mathrm{CH}_{3} \mathrm{CN} /$ aqueous buffer ${ }^{a}$ for ionic organic analytes <br> $5 \mathrm{vol} \% \mathrm{CH}_{3} \mathrm{CN}$ in $\mathrm{H}_{2} \mathrm{O}$ to $95 \mathrm{vol} \% \mathrm{CH}_{3} \mathrm{CN}$ in $\mathrm{H}_{2} \mathrm{O}$ for gradient elution |
| Temperature: | $30^{\circ}-40^{\circ} \mathrm{C}$ with temperature control Some people routinely prefer $50^{\circ}-60^{\circ} \mathrm{C}$ |
| Sample size: | $0.21-\mathrm{cm}$-diameter column: $2 \mu \mathrm{~L}$ containing $25-50 \mu \mathrm{~g}$ of each analyte $0.46-\mathrm{cm}$-diameter column: $5-10 \mu \mathrm{~L}$ containing $25-50 \mu \mathrm{~g}$ of each analyte (Older ultraviolet absorbance detectors might require more sample.) |
| For mass spectrometry: | $0.21 \times 5 \mathrm{~cm}$ column with $3-\mu \mathrm{m}$ particles of $\mathrm{C}_{18}$-silica run at $30^{\circ}-60^{\circ} \mathrm{C}$ <br> Mobile phase is acetonitrile or methanol plus volatile, aqueous buffer. <br> Aqueous buffer is made from 2 mM ammonium formate plus $1-10 \mathrm{~g}$ formic acid per L (giving $\mathrm{pH} \approx 2.7-1.7$ ). Ammonium formate buffer can be used for $\mathrm{pH} \approx 2.8-4.8$. Ammonium acetate buffer can be used for $\mathrm{pH} \approx 3.8-5.8$. Use $\mathrm{NH}_{3}$, formic acid, or acetic acid to adjust pH . <br> Ammonium carbonate can be used for $\mathrm{pH} \approx 8-11$. <br> Atmospheric pressure chemical ionization or electrospray interface. <br> Electrospray requires analyte to be charged in solution. |

[^15]Figure 24-12 showed a succession of experiments to establish that 35 vol $\% \mathrm{CH}_{3} \mathrm{CN}$ (designated B) plus 65 vol\% buffer is a good solvent to separate the particular mixture of analytes. The initial experiment was done with a high concentration of $\mathrm{CH}_{3} \mathrm{CN}(90 \% \mathrm{~B})$ to ensure the elution of all components of the unknown. Then \%B was successively lowered to separate all the components. Eluent containing $40 \%$ B did not separate peaks 2 and 3 adequately, and 30\% B took too long to elute peak 8 . Therefore, $35 \%$ B was selected.

With $35 \%$ B, peak 1 is eluted at 4.9 min and peak 8 is eluted at 125.2 min . The solvent front appears at $t_{\mathrm{m}}=2.7 \mathrm{~min}$. Therefore, $k$ for peak 1 is $(4.9-2.7) / 2.7=0.8$ and $k$ for peak 8 is $(125.2-2.7) / 2.7=45$. If $k>20$, gradient elution is suggested (Section 24-4). If all peaks in Figure 24-12 could be resolved while maintaining $0.5 \leq k \leq 20$, then we would have a successful isocratic separation. If we were not concerned about measuring peaks 2 and 3 , then $45 \%$ B would probably be a good choice.

## Optimization with Two or Three Organic Solvents

Figures 24-24 and 24-25 illustrate a systematic process to develop a separation with combinations of solvents. Method development is finished as soon as the separation meets your criteria. There is a good chance of attaining adequate separation without going through all the steps.

Step 1 Optimize the separation with acetonitrile/buffer to generate chromatogram A in Figure 24-25.
Step 2 Optimize the separation with methanol/buffer to generate chromatogram B.
Step 3 Optimize the separation with tetrahydrofuran/buffer to generate chromatogram C.
Step 4 Mix the solvents used in A, B, and C, one pair at a time, in 1:1 proportion, to generate chromatograms D, E, and F.
Step 5 Construct a 1:1:1 mixture of the solvents for $\mathrm{A}, \mathrm{B}$, and C to generate chromatogram G.
Step 6 If some of the results A through G are almost good enough, select the two best points and mix the solvents to obtain points between those two.

Let's examine Figure $24-25$ to see how the systematic procedure works. Step 1 is to generate chromatogram A by varying the proportions of acetonitrile and aqueous buffer (as in Figure 24-12) to obtain the best separation within the constraint that $0.5 \leq k \leq 20$. At the best composition, $30 \mathrm{vol} \%$ acetonitrile/70 vol $\%$ buffer, peaks 4 and 5 are not resolved adequately for quantitative analysis.

In HPLC, lowering the flow rate usually improves resolution. With the flow rate of $1.0 \mathrm{~mL} / \mathrm{min}$ in Figure 24-25, we chose to keep $k<10$ (instead of $<20$ ) to obtain a run time below $\sim 25 \mathrm{~min}$. In chromatogram $\mathrm{A}, k=1.1$ for peak 1 and $k=8.1$ for peak 7. If the flow rate had been $2.0 \mathrm{~mL} / \mathrm{min}$, then $k<20$ would give a run time below $\sim 25 \mathrm{~min}$.

Step 2 seeks a methanol/buffer solvent to obtain the best separation at point B. It is not necessary to start all over again with $90 \%$ methanol. Figure 24-26 allows us to select a methanol/water mixture that has approximately the same eluent strength as a particular acetonitrile/water mixture. A vertical line drawn at $30 \%$ acetonitrile (the composition used in chromatogram A) intersects the methanol line near $40 \%$. Therefore, $40 \%$ methanol has about the same eluent strength as $30 \%$ acetonitrile. The first experiment carried out to establish point B in Figure 24-25 utilized $40 \%$ methanol. A little trial-and-error (with $45 \%$ methanol and $35 \%$ methanol) demonstrated that $40 \%$ methanol gave the best separation, but the separation is poor. In chromatogram B in Figure 24-25, the seven components give only five peaks. When we changed from acetonitrile to methanol, the order of elution of some compounds changed.

Step 3 generates chromatogram C in Figure 24-25, using tetrahydrofuran. Figure 24-26 tells us that $22 \%$ tetrahydrofuran has the same eluent strength as $30 \%$ acetonitrile. When $22 \%$ tetrahydrofuran was tried, elution times were too long. Trial-and-error demonstrated that $32 \%$ tetrahydrofuran was best. All seven compounds are cleanly separated in chromatogram C in an acceptable time. However, a baseline dip associated with the solvent front between peaks 3 and 1 interferes with quantitative analysis of compound 1 . The order of elution with tetrahydrofuran is quite different from the order with acetonitrile. In general, changing solvent is a powerful way to change relative retention of different compounds.

Step 4 generates chromatograms $\mathrm{D}, \mathrm{E}$, and F . The composition at D is a $1: 1$ mixture of the solvents used in A and B. Because we used $30 \%$ acetonitrile at A and $40 \%$ methanol at B,
"Rule of Three": Decreasing \%B by 10\% increases retention factor, $k$, by a factor of $\sim 3$.

If $k>20$, try gradient elution.

If the separation does not look promising after step 5 , try a different stationary phase or a different form of chromatography.

FIGURE 24-24 HPLC method development triangle. THF stands for tetrahydrofuran. Figure $24-25$ shows how the procedure is applied to a real chromatographic separation.

The way we know which peak is which is to record the entire ultraviolet spectrum of each peak as it is eluted, using a photodiode array spectrometer.

FIGURE 24-25 Application of the method development triangle to the separation of seven aromatic compounds by HPLC. Column: $0.46 \times 25 \mathrm{~cm}$ Hypersil ODS ( $\mathrm{C}_{18}$ on $5-\mu \mathrm{m}$ silica) at ambient temperature $\left(\sim 22^{\circ} \mathrm{C}\right)$. Elution rate was $1.0 \mathrm{~mL} / \mathrm{min}$ with the following solvents: $(\mathrm{A}) 30$ vol $\%$ acetonitrile $/ 70$ vol $\%$ buffer; (B) $40 \%$ methanol/60\% buffer; (C) $32 \%$ tetrahydrofuran/68\% buffer. The aqueous buffer contained $25 \mathrm{mM} \mathrm{KH} \mathrm{KO}_{4}$ plus $0.1 \mathrm{~g} / \mathrm{L} \mathrm{NaN}_{3}$ adjusted to pH 3.5 with HCl . Points D , E , and F are midway between the vertices: (D) $15 \%$ acetonitrile/20\% methanol/65\% buffer; (E) $15 \%$ acetonitrile/16\% tetrahydrofuran/69\% buffer; (F) 20\% methanol/16\% tetrahydrofuran/64\% buffer. Point G at the center of the triangle is an equal blend of $\mathrm{A}, \mathrm{B}$, and C with the composition $10 \%$ acetonitrile/ $13 \%$ methanol/ $11 \%$ tetrahydrofuran/66\% buffer. The negative dip in C between peaks 3 and 1 is associated with the solvent front. Peak identities were tracked with a photodiode array ultraviolet spectrophotometer:
(1) benzyl alcohol; (2) phenol; (3) $3^{\prime}, 4^{\prime}$-dimethoxyacetophenone; (4), m-dinitrobenzene;
(5) p-dinitrobenzene; (6) o-dinitrobenzene; (7) benzoin.

D was obtained with $15 \%$ acetonitrile/20\% methanol/65\% buffer. Similarly, E was obtained with a $1: 1$ mixture of the solvents for A and $\mathrm{C} . \mathrm{F}$ was obtained with a $1: 1$ mixture of the solvents for B and C.

Chromatogram D is not acceptable, because peaks 4 and 5 overlap. Chromatogram E is terrible because peaks 1 and 3 overlap and peaks 4,5 , and 6 overlap. But (hurrah!) chromatogram

FIGURE 24-26 Nomogram showing volume percentage of solvents having the same eluent strength. A vertical line intersects each solvent line at the same eluent strength. For example, 30 vol $\%$ acetonitrile/70 vol\% water has about the same eluent strength as 40 vol \% methanol or 22 vol $\%$ tetrahydrofuran. [From L. R. Snyder, J. J. Kirkland, and J. L. Glajch, Practical HPLC Method Development (New York: Wiley, 1997).]

F is what we have been looking for: All peaks are separated and the first peak (3) is adequately removed from the solvent dip. We are finished! The solvent composition at F (20\% methanol/16\% tetrahydrofuran/64\% buffer) does the job. Peaks 4 and 6 have the minimum resolution of 1.8 . (We would have preferred resolution $>2.0$.) All peaks are symmetric and within the range $k=0.9-7.5$. The operating pressure remained reasonable.

If none of the trials had worked, step 5 would generate chromatogram G in Figure 24-25, using a $1: 1: 1$ mixture of solvents from $\mathrm{A}, \mathrm{B}$, and C . For completeness, the result at G is shown. Peaks 1 and 3 overlap and peaks 4 and 7 overlap.

If some of the compositions A through G were almost good enough, compositions between the points might have been better. For example, if A and D were almost good enough, perhaps a mixture of the solvents for A and D might have been better.

## Temperature as a Variable

Column temperature affects the relative retention of different compounds, and elevated temperature permits high-speed chromatography to be conducted. ${ }^{33}$ Figure 24-27 suggests a systematic procedure for method development in which solvent composition and temperature are the two independent variables. For elevated temperature operation, pH should be below 6 to retard dissolution of silica. Alternatively, zirconia-based stationary phases work up to at least $200^{\circ} \mathrm{C}$.

## Choosing a Stationary Phase

$\mathrm{C}_{18}$-silica is the most common stationary phase, and it separates a wide range of mixtures when the solvent is chosen carefully, as in Figure 24-25. However, it cannot achieve all separations. Table 24-5 is a guide to selecting other bonded phases. A quantitative "hydrophobic subtraction model" with a database of several hundred commercial HPLC columns is freely available to help analysts select columns for particular types of separations. ${ }^{34}$

Resolution $=\frac{\Delta t_{\mathrm{r}}}{w_{\mathrm{av}}}=\frac{0.589 \Delta t_{\mathrm{r}}}{w_{1 / 2}}$
$\Delta t_{\mathrm{r}}=$ separation between peaks
$w_{\mathrm{av}}=$ average width at baseline
$w_{1 / 2}=$ average width at half-height
After optimizing the solvent, you might still need to improve resolution. To increase resolution, you can

- decrease flow rate
- increase column length
- decrease particle size

FIGURE 24-27 Isocratic method development for HPLC, using solvent composition, \%B, and temperature, $T$, as independent variables. \%B and $T$ are each varied between selected low and high values. From the appearance of chromatograms resulting from conditions A-D, we can select intermediate conditions to improve the separation.

TABLE 24-5 Selection of bonded stationary phases for HPLC

| Bonded group | Polarity | Retention mechanisms | Comments |
| :--- | :--- | :--- | :--- |
| $\mathrm{C}_{18}, \mathrm{C}_{8}, \mathrm{C}_{4}$ | Nonpolar | van der Waals | $\mathrm{C}_{8}$ does not retain hydrophobic compounds as strongly <br> as $\mathrm{C}_{18}$ |
| Phenyl | Nonpolar | Hydrophobic and pi-pi | Hydrophobic, dipole-dipole, | | Resolves polar organic compounds by reversed-phase |
| :--- |
| Cyano |

## EXAMPLE Selecting a Bonded Phase

Suggest an approach to resolve the following compounds in a short time.

1. Rutin

2. Chatechin

3. Apigenin

4. Myricetin

5. Quercitin

6. Naringenin

Solution Compounds with the most similar structures are likely to be hardest to separate. Of the compounds in the mixture, $\mathbf{5}$ and $\mathbf{6}$ are most similar, differing by just one $\mathrm{C}=\mathrm{C}$ bond. Table $24-5$ suggests that a stationary phase with phenyl or cyano groups, which retain analytes by pi-pi interactions, might be good for distinguishing 5 and $\mathbf{6}$. For rapid analysis but good resolution, select a short column with small particle size and run it at a rapid flow rate. Figure 24-28 shows that $\mathbf{5}$ and $\mathbf{6}$ are resolved by a phenyl column but not by a $\mathrm{C}_{18}$ column.

FIGURE 24-28 Separation of six compounds on (a) phenyl- and (b) $\mathrm{C}_{18}$-silica columns with $3-\mu \mathrm{m}$ particle size, using $35: 65$ ( $\mathrm{vol} / \mathrm{vol}$ ) acetonitrile/0.2\% aqueous trifluoroacetic acid. Column size: $7 \times 53 \mathrm{~mm}$; flow rate $=2.5 \mathrm{~mL} / \mathrm{min}$. [From C. S. Young and R. J. Weigand, "An Efficient Approach to Column Selection in HPLC Method Development," LCGC 2002, 20, 464. Courtesy Alltech Associates.]

Test Yourself What other stationary phase in Table 24-5 might separate the six compounds? (Answer: I would try bare silica to separate these polar compounds.)

We have discussed several ways to change the relative retention of two closely spaced peaks. Some methods are harder to implement than others. One suggested order of steps to try-from easiest to hardest-is (1) change the solvent strength by varying the fraction of each solvent; (2) change the temperature; (3) change the pH (in small steps); (4) use a different solvent; (5) use a different kind of stationary phase. ${ }^{35}$

## 24-4 Gradient Separations ${ }^{3}$

Figure 24-12 shows an isocratic separation of eight compounds that required a run time of more than 2 h . When eluent strength was low enough to resolve early peaks ( 2 and 3 ), the elution of later peaks was very slow. To retain the desired resolution but decrease the analysis time, the segmented gradient (a gradient with several distinct parts) in Figure 24-13 was selected. Peaks $1-3$ were separated with a low eluent strength ( $30 \%$ B). Between 8 and $13 \mathrm{~min}, \mathrm{~B}$ was increased linearly from 30 to $45 \%$ to elute the middle peaks. Between 28 and 30 min , B was increased linearly from 45 to $80 \%$ to elute the final peaks.

## Dwell Volume and Dwell Time

The volume between the point at which solvents are mixed and the beginning of the column is called the dwell volume. The dwell time, $t_{\mathrm{D}}$, is the time required for the gradient to reach the column. Dwell volumes range from 0.5 to 10 mL in different systems. For Figure 24-13, the dwell volume is 5 mL , and the flow rate is $1.0 \mathrm{~mL} / \mathrm{min}$. Therefore, the dwell time is 5 min . A solvent change initiated at 8 min does not reach the column until 13 min .

Differences in dwell volumes between different systems are an important reason why gradient separations on one chromatograph do not necessarily transfer to another. It is helpful to state the dwell volume for your system when you report a gradient separation. One way to compensate for dwell volume is to inject sample at the time $t_{\mathrm{D}}$ instead of at $t=0$.

You can measure dwell volume by first disconnecting the column and connecting the inlet tube directly to the outlet tube. Place water in reservoirs A and B of the solvent delivery system. Add $0.1 \mathrm{vol} \%$ acetone to reservoir B. Program the gradient to go from 0 to $100 \%$ B in 20 min and begin the gradient at $t=0$. With the detector set to 260 nm , the response will ideally look like that in Figure 24-29. The delay between the start of the gradient and the first response at the detector is the dwell time, $t_{\mathrm{D}}$.

FIGURE 24-29 Measurement of dwell time, using nonabsorbing solvent in reservoir $A$ and a weak absorber in reservoir $B$. The gradient from 0 to $100 \% \mathrm{~B}$ is begun at time $t=0$ but does not reach the detector until time $t_{\mathrm{D}}$. The column is removed from the system for this measurement. Real response will be rounded instead of having the sharp intersections shown in this illustration.

## Begin Method Development with a Scouting Gradient

The quickest way to survey a new mixture to decide whether to use isocratic or gradient elution is to run a broad gradient, as in Figure 24-30a. ${ }^{36}$ This figure shows how the sample mixture in Figure 24-12 is separated by a linear gradient from 10 to $90 \%$ acetonitrile in 40 min . The gradient time, $t_{\mathrm{G}}$, is the time over which the solvent composition is changed ( 40 min ). Let $\Delta t$ be the difference in the retention time between the first and the last peak in the chromatogram. In Figure 24-30a, $\Delta t=35.5-14.0=21.5 \mathrm{~min}$. The criterion to choose whether to use a gradient is

$$
\text { Use a gradient if } \Delta t / t_{\mathrm{G}}>0.25 \quad \text { Use isocratic elution if } \Delta t / t_{\mathrm{G}}<0.25
$$

If all peaks are eluted over a narrow solvent range, then isocratic elution is feasible. If a wide solvent range is required, then gradient elution is more practical. In Figure 24-30a, $\Delta t / t_{\mathrm{G}}=$ $21.5 / 40=0.54>0.25$. Therefore, gradient elution is recommended. Isocratic elution is possible, but the time required in Figure 24-12 is impractically long.

If isocratic elution is indicated because $\Delta t / t_{\mathrm{G}}<0.25$, then a good starting solvent is the composition at the point halfway through the interval $\Delta t$. That is, if the first peak is eluted at 10 min and the last peak is eluted at 20 min , a reasonable isocratic solvent has the composition at 15 min in the gradient.

## Developing a Gradient Separation

The first run should survey a broad range of eluent strength such as 10 to $90 \%$ B in 40 min in Figure 24-30a. Because the dwell time was 5 min and the gradient began at $t=0$, the gradient did not reach the column until $t=5 \mathrm{~min}$. (It would have been better to inject the
$t_{\mathrm{D}}=\frac{\text { dwell volume }(\mathrm{mL})}{\text { flow rate }(\mathrm{mL} / \mathrm{min})}$

- The first run on a new mixture should be a gradient.
- If $\Delta t / t_{\mathrm{G}}>0.25$, use gradient elution.
- If $\Delta t / t_{\mathrm{G}}<0.25$, use isocratic elution.
- Isocratic solvent should have the composition applied to the column halfway through the period $\Delta t$.

## Steps in gradient method development:

1. Run a wide gradient (e.g., 5 to $95 \%$ B) over 40-60 min. From this run, decide whether gradient or isocratic elution is best.
2. If gradient elution is chosen, eliminate portions of the gradient prior to the first peak and following the last peak. Use the same gradient time as in step 1.
3. If the separation in step 2 is acceptable, try reducing the gradient time to reduce the run time.

FIGURE 24-30 Linear gradient separations of the mixture from Figure 24-12 in the same column and solvent system [buffer (solvent A) with acetonitrile (solvent $B$ )] at a flow rate of $1.0 \mathrm{~mL} / \mathrm{min}$. Dwell time $=5 \mathrm{~min}$.

FIGURE 24-31 Solvent gradient for Figure 24-30a. The gradient was begun at the time of injection ( $t=0$ ), but the dwell time was 5 min . Therefore, the solvent was $10 \%$ B for the first 5 min . Then the composition increased linearly to $90 \%$ B over 40 min . After $t=45 \mathrm{~min}$, the composition was constant at $90 \%$ B.

sample at $t=5 \mathrm{~min}$, but this was not done.) Serendipitously, the first run in Figure 24-30 separated all eight peaks. We could stop at this point if we were willing to settle for a 36 -min run time.

The next step in developing a gradient method is to spread the peaks out by choosing a shallower gradient. For a dwell time of 5 min , the gradient profile for Figure 24-30a looks like Figure 24-31. Peak 1 was eluted at 14.0 min when the solvent was $28 \%$ B. Peak 8 was eluted near 35.5 min , when the solvent was $71 \%$ B. The portions of the gradient from 10 to $28 \%$ B and 71 to $90 \%$ B were not really needed. Therefore, the second run could be made with a

gradient from 28 to $71 \% \mathrm{~B}$ over the same $t_{\mathrm{G}}(40 \mathrm{~min})$. Conditions chosen for the run in Figure 24-30b were 30 to $82 \%$ B in 40 min . This gradient spread the peaks out and reduced the run time slightly to 32 min .

In Figure 24-30c, we want to see whether a steeper gradient could be used to reduce the run time. The gradient limits were the same as in trace $b$, but $t_{\mathrm{G}}$ was reduced to 20 min . Peaks 6 and 7 are not fully resolved with the shorter gradient time. Trace $b$ represents reasonable conditions for the gradient separation.

If the separation in Figure 24-30b were not acceptable, you could try to improve it by reducing the flow rate or going to a segmented gradient, as in Figure 24-13. The segmented gradient provides an appropriate solvent composition for each region of the chromatogram. It is easy to experiment with flow rate and gradient profiles. More difficult approaches to improve the separation are to change the solvent, use a longer column, use a smaller particle size, or change the stationary phase. Box 24-4 provides guidance on selecting gradient time and scaling gradients from one size column to another.

## 24-5 瘤 Do lit with a Computer

Method development is simplified by computer simulations using commercial software ${ }^{3,37}$ or your own spreadsheet. With data from a few experiments, you can predict the effects of solvent composition and temperature in isocratic or gradient separations. You can estimate what will be optimum conditions in hours of work instead of days of work.

The basis for most simulations of reversed-phase separations is the empirical linear-solventstrength model, which supposes a logarithmic relationship between retention factor $k$ for a given solute and the mobile phase composition $\Phi$ :

$$
\begin{equation*}
\log k \approx \log k_{\mathrm{w}}-S \Phi \tag{24-5}
\end{equation*}
$$

An empirical model is based on observations, not on theory. Equation 24-5 is empirical in that it approximately describes the relation between $k$ and $\Phi$. The relationship is not predicted by a theory based on first principles.

## B0X 24-4 Choosing Gradient Conditions and Scaling Gradients

We now discuss equations that allow you to select sensible linear gradient conditions and to scale gradients from one column to another. For gradient elution, the average retention factor $k^{*}$ for each solute is the value of $k$ when that solute is halfway through the column:

$$
\begin{equation*}
k^{*}=\frac{t_{\mathrm{G}} F}{\Delta \Phi V_{\mathrm{m}} S} \tag{24-10}
\end{equation*}
$$

where $t_{\mathrm{G}}$ is gradient time (min), $F$ is flow rate $(\mathrm{mL} / \mathrm{min}), \Delta \Phi$ is the change in solvent composition during the gradient, $V_{\mathrm{m}}$ is the volume of mobile phase in the column $(\mathrm{mL})$, and $S$ is the slope in the linear-solvent-strength model (Equation 24-5). We take a representative $S=4$ for this discussion.

In isocratic elution, a retention factor $k \approx 5$ provides separation from the solvent front and does not require excessive time. For gradient elution, $k^{*} \approx 5$ is a reasonable starting condition. Let's calculate a sensible gradient time for the experiment in Figure 24-30a, in which we chose a gradient from 10 to $90 \% \mathrm{~B}(\Delta \Phi=0.8)$ in a $0.46 \times 25 \mathrm{~cm}$ column eluted at $1.0 \mathrm{~mL} / \mathrm{min}$. From Equation 24-4, $V_{\mathrm{m}} \approx L d_{\mathrm{c}}^{2} / 2=(25 \mathrm{~cm})(0.46 \mathrm{~cm})^{2} / 2=2.6_{5} \mathrm{~mL}$. We calculate the required gradient time by rearranging Equation 24-10:

$$
\begin{equation*}
t_{\mathrm{G}}=\frac{k^{*} \Delta \Phi V_{\mathrm{m}} S}{F}=\frac{(5)(0.8)(2.65 \mathrm{~mL})(4)}{(1.0 \mathrm{~mL} / \mathrm{min})}=42 \mathrm{~min} \tag{24-11}
\end{equation*}
$$

A reasonable gradient time would be 42 min . In Figure 24-30a, $t_{\mathrm{G}}$ is 40 min , giving $k^{*}=4.7$. In Figure 24-30b, we changed the gradient to $\Delta \Phi=0.52$, giving better separation:

$$
k^{*}=\frac{t_{\mathrm{G}} F}{\Delta \Phi V_{\mathrm{m}} S}=\frac{(40 \mathrm{~min})(1.0 \mathrm{~mL} / \mathrm{min})}{(0.52)(2.65 \mathrm{~mL})(4)}=7.3
$$

The separation is poorer in Figure 24-30c, for which $k^{*}=3.6$.

If you have a successful gradient separation and want to transfer it from column 1 to column 2, whose dimensions are different, the scaling relations are

$$
\begin{equation*}
\frac{F_{2}}{F_{1}}=\frac{m_{2}}{m_{1}}=\frac{d_{2}}{d_{1}}=\frac{V_{2}}{V_{1}} \tag{24-12}
\end{equation*}
$$

where $F$ is volume flow rate ( $\mathrm{mL} / \mathrm{min}$ ), $m$ is the mass of sample, $d$ is the dwell time before the gradient reaches the column, and $V$ is total column volume. The gradient time, $t_{\mathrm{G}}$ should not be changed. In Figure 24-31, the dwell time $d=5 \mathrm{~min}$ is due to the dwell volume between the mixer and the column. Equation 24-12 tells us to change volume flow rate, sample mass, and dwell time in proportion to column volume. If dwell volume is small in comparison with the volume of solvent on the column, $V_{\mathrm{m}}$, the dwell time $d$ can be inconsequential. If dwell volume is large, it becomes an important factor over which you might have little control.

Suppose that you have optimized a gradient on a $0.46 \times 25 \mathrm{~cm}$ column and you want to transfer it to a $0.21 \times 10 \mathrm{~cm}$ column. The quotient $V_{2} / V_{1}$ is $\left(\pi r^{2} L\right)_{2} /\left(\pi r^{2} L\right)_{1}$, where $r$ is column radius and $L$ is column length. For these columns, $V_{2} / V_{1}=0.083$. Equation 24-12 tells us to decrease the volume flow rate, the sample mass, and the dwell time to 0.083 times the values used for the large column. The gradient time should not be changed.

When you make these changes, you will discover that $k^{*}$ is the same for both columns. If you change a condition that affects $k^{*}$, you should make a compensating change to restore $k^{*}$. For example, Equation 24-10 tells us that, if we choose to double $t_{\mathrm{G}}$, we could cut the flow rate in half so that the product $t_{\mathrm{G}} F$ is constant and $k^{*}$ remains constant.

FIGURE 24-32 Linear-solvent-strength model. Graph of $\log k$ versus $\Phi$ for nine organic compounds eluted from a $\mathrm{C}_{18}$ column by methanol : water. [From R. A. Shalliker, S. Kayillo, and G. R. Dennis, "Optimizing Chromatographic Separation: An Experiment Using an HPLC Simulator," J. Chem. Ed. 2008, 85, 1265.]

where $\log k_{\mathrm{w}}$ is the extrapolated retention factor for $100 \%$ aqueous eluent, $\Phi$ is the fraction of organic solvent ( $\Phi=0.4$ for $40 \mathrm{vol} \%$ organic solvent $/ 60 \mathrm{vol} \% \mathrm{H}_{2} \mathrm{O}$ ), and $S$ is a constant for each compound, with a typical value of $\sim 4$ for small molecules. Figure $24-32$ shows measurements for nine compounds in the range $\Phi=0.65$ to 0.8 in methanol:water on a $\mathrm{C}_{18}$ column. The parameters $S$ and $\log k_{\mathrm{w}}$ are the slopes and $y$-intercepts of the lines in Figure 24-32.

Equation 24-5 is not accurate over wide ranges of solvent composition $\Phi$. In Figure 24-32, the authors only varied $\Phi$ from 0.65 to 0.8 . When we extrapolate beyond the measured range of $\Phi$, we are in uncharted territory. Data for Figure 24-32 were collected at high values of $\Phi$ to keep the run time short. In the measured range of $\Phi, p$-nitrophenol is eluted first and phenol is eluted next. The extrapolated lines cross at $\Phi=0.61$. For $\Phi<0.61$, we predict that phenol will be eluted before $p$-nitrophenol.

To simulate a chromatogram for an isocratic solvent composition such as $\Phi=0.6$ for $60 \mathrm{vol} \% \mathrm{CH}_{3} \mathrm{OH} / 40 \mathrm{vol} \% \mathrm{H}_{2} \mathrm{O}$ on a particular HPLC column, we begin with solvent transit time $\left(t_{\mathrm{m}}\right)=1.85 \mathrm{~min}$ and plate number $(N)=7000$. Then, for a chosen value of solvent strength $\Phi$, the retention factor $k$ for each component is computed from

$$
\begin{equation*}
k=10^{\left(\log k_{\mathrm{w}}-S \Phi\right)} \tag{24-6}
\end{equation*}
$$

Retention time $t_{\mathrm{r}}$ is found by rearranging Equation 22-17 to the form:

$$
\begin{equation*}
t_{\mathrm{r}}=t_{\mathrm{m}}(k+1) \tag{24-7}
\end{equation*}
$$

Assuming Gaussian peak shape, the standard deviation of the band in Figure 22-9 is found by rearranging Equation 22-28a:

$$
\begin{equation*}
\sigma=t_{\mathrm{r}} / \sqrt{N} \tag{24-8}
\end{equation*}
$$

The spreadsheet in Figure 24-33 simulates an isocratic separation. Highlighted cells require your input. The time step in cell C 7 gives the interval between calculated points in the chromatogram. Relative areas in cells E14:E22 are arbitrary. You could set them all to 1 or you could try to vary them to match peak heights of an experimental chromatogram. The linear solvent strength parameters $\log k_{\mathrm{w}}$ and $S$ in cells C14:D22 are from experimental measurements in Figure 24-32. The spreadsheet computes $k$ in cells F14:F22 with Equation 24-6. It computes $t_{\mathrm{r}}$ in cells G14:G22 with Equation 24-7 and the standard deviation of each Gaussian peak with Equation 24-8.

The shape of each Gaussian chromatographic peak is given by

$$
\begin{equation*}
\text { Detector signal }(y)=\frac{\text { relative area }}{\sigma \sqrt{2 \pi}} \mathrm{e}^{-\left(t-t_{\mathrm{t}}\right)^{2} / 2 \sigma^{2}} \tag{24-9}
\end{equation*}
$$

where relative areas are the numbers you specified in cells E:14:E22, $t$ is time, $t_{\mathrm{r}}$ is the retention time in cells G14:G22, and $\sigma$ is the standard deviation in cells $\mathrm{H} 14: \mathrm{H} 22$. The detector signal beginning in cell E30 is the sum of nine terms of the form of Equation 24-9-one term for each compound in the mixture. Each compound has its own $\sigma, t_{\mathrm{r}}$, and relative area. The spreadsheet calculates detector signal for times beginning at $t=0$ and proceeding past elution of the last peak.

FIGURE 24-33 A spreadsheet to simulate isocratic chromatographic separation.

Figure 24-34 shows simulations done with the spreadsheet. At a solvent strength $\Phi=$ 0.75 , all nine compounds are eluted within 6 min , but resolution of peaks 5,6 , and 7 is poor. At $\Phi=0.60$, peaks 1 and 2 overlap and peaks 5 and 6 have changed their order of elution. At $\Phi=0.56$, all peaks are resolved and the last peak is eluted in 22 min .

Solvent composition $\Phi=0.56$ ( $56 \mathrm{vol} \%$ methanol $/ 44 \mathrm{vol} \%$ aqueous buffer) is not good enough to make the chromatographic method robust. A robust separation is one that maintains adequate resolution despite small changes in conditions such as $\Phi, \mathrm{pH}$, and temperature. Resolution between closely spaced peaks is 1.5 for peaks 2 and $1,1.8$ for peaks 6 and 5 , and 1.3 for peaks 5 and 7. For a robust separation, we desire a minimum resolution of 2.0 , but this value cannot always be achieved. At solvent composition $\Phi=0.54$, resolution of peaks 2 and 1 and peaks 6 and 5 is above 2.0, but the resolution of peaks 5 and 7 has decreased to 1.2. Peak 9 , which is off the chart, has a retention time of 26 min . The composition $\Phi=0.56$ appears to be about the best we can do with methanol and water on this column. To obtain better resolution, we could decrease flow rate, use smaller particles, increase column length, or change the temperature, solvent, or stationary phase.

From a few experiments to find $S$ and $\log k_{\mathrm{w}}$, we can use the spreadsheet to estimate that $\Phi=0.56$ is the optimum condition to try in the lab. Solvent composition $\Phi=0.56$ is outside the measured range in Figure 24-32. The only way to know if the curves in Figure 24-32 remain linear down to $\Phi=0.56$ is to try the experiment. With only a little more complexity, the linear-solvent-strength model enables us to simulate and optimize gradient separations. ${ }^{3}$

With the tools in this chapter, you can usually find a way to separate the components of a mixture if it does not contain too many compounds. If reversed-phase chromatography fails, normal-phase chromatography or one of the methods in Chapter 25 could be appropriate. Method development is part science, part art, and part luck.

Resolution $=\frac{\Delta t_{\mathrm{r}}}{w_{\mathrm{av}}} \quad$ (Equation 22-23)
$\Delta t_{\mathrm{r}}=$ difference in retention time $w_{\mathrm{av}}=$ average width at base of peak $=4 \sigma$

In supplementary topics at the Web site www.whfreeman.com/qca8e, you will find equations and a spreadsheet to simulate gradient and isocratic elution.

FIGURE 24-34 Chromatograms simulated with the spreadsheet in Figure 24-33. Peak numbers are $p$-nitrophenol (1), phenol (2), p-cresol (3), 2,5-xylenol (4), benzene (5), methyl benzoate (6), anisole (7), phenetole (8), and toluene (9).

## Summary

In high-performance liquid chromatography (HPLC), solvent is pumped at high pressure through a column containing stationary phase particles with diameters of $1.5-5 \mu \mathrm{~m}$. The smaller the particle size, the more efficient the column, but the greater the resistance to flow. Microporous silica particles with a covalently bonded liquid phase such as octadecyl groups $\left(-\mathrm{C}_{18} \mathrm{H}_{37}\right)$ are most common. Eluent strength measures the ability of a given solvent to elute solutes from the column. In normal-phase chromatography, the stationary phase is polar and a less polar solvent is used. Eluent strength increases as the polarity of the solvent increases. Reversed-phase chromatography employs a nonpolar stationary phase and polar solvent. Eluent strength increases as the polarity of the solvent decreases. Most separations of organic compounds can be done on reversed-phase columns. Polar compounds can be separated by normal-phase chromatography or hydrophilic interaction chromatography. Normal-phase chromatography or porous graphitic carbon is good for separating isomers. Chiral phases are used for optical isomers. Techniques for separating inorganic ions, polymers, and biological macromolecules are described in Chapter 25.

If a solution of organic solvent and water is used in reversedphase chromatography, eluent strength increases as the percentage
of organic solvent increases. If the solvent has a fixed composition, the process is called isocratic elution. In gradient elution, eluent strength is increased during chromatography by increasing the percentage of strong solvent.

A short guard column containing the same stationary phase as the analytical column is placed before the analytical column to protect it from contamination with particles or irreversibly adsorbed solutes. A high-quality pump provides smooth solvent flow. The injection valve allows rapid, precise sample introduction. The column is best housed in an oven to maintain a reproducible temperature. Column efficiency increases at elevated temperature because the rate of mass transfer between phases is increased. Mass spectrometric detection provides quantitative and qualitative information for each substance eluted from the column. Ultraviolet detection is most common, and it can provide qualitative information if a photodiode array is used to record a full spectrum of each analyte. Refractive index detection has universal response but is not very sensitive. Evaporative light scattering and the charged aerosol detector respond to the mass of each nonvolatile solute. Electrochemical and fluorescence detectors are extremely sensitive but selective. In supercritical fluid chromatography, nonvolatile solutes are separated by a process
whose efficiency, speed, and detectors more closely resemble those of gas chromatography than those of liquid chromatography.

Steps in method development: (1) determine the goal of the analysis, (2) select a method of sample preparation, (3) choose a detector, and (4) use a systematic procedure to select solvent for isocratic or gradient elution. Aqueous acetonitrile, methanol, and tetrahydrofuran are customary solvents for reversed-phase separations. A separation can be optimized by varying several solvents or by using one solvent and temperature as the principal variables. If further resolution is required, flow rate can be decreased, a longer
column can be employed, and smaller particle size can be selected. Criteria for a successful separation are $0.5 \leq k \leq 20$, resolution $\geq 2.0$, operating pressure $\leq 15 \mathrm{MPa}$ (for conventional equipment), and asymmetry factor in the range $0.9-1.5$. In gradient elution, solvent composition does not begin to change until the dwell volume has passed from the point of solvent mixing to the start of the column. A wide gradient is a good first choice to determine whether to use isocratic or gradient elution. Retention factors measured at a few solvent compositions can be fit to the linear-solvent-strength model to enable computer optimization of a separation.

## Exercises

24-A. A known mixture of compounds A and B gave the following HPLC results:

|  | Concentration <br> $(\mathrm{mg} / \mathrm{mL}$ in <br> mixture) | Peak area <br> (arbitrary units) |
| :--- | :--- | :---: |
| Compound | 1.03 | 10.86 |
| A | 1.16 | 4.37 |
| B |  |  |

A solution was prepared by mixing 12.49 mg of B plus 10.00 mL of unknown containing just A and diluting to 25.00 mL . Peak areas of 5.97 and 6.38 were observed for A and B, respectively. Find the concentration of $\mathrm{A}(\mathrm{mg} / \mathrm{mL})$ in the unknown.

24-B. A bonded stationary phase for the separation of optical isomers has the structure

To resolve the enantiomers of amines, alcohols, or thiols, the compounds are first derivatized with a nitroaromatic group that increases their interaction with the bonded phase and makes them observable with a spectrophotometric detector.

When the mixture is eluted with $20 \mathrm{vol} \%$ 2-propanol in hexane, the $(R)$-enantiomer is eluted before the $(S)$-enantiomer, with the following chromatographic parameters:

$$
\begin{array}{ll}
\text { Resolution }=\frac{\Delta t_{\mathrm{r}}}{w_{\mathrm{av}}}=7.7 & \text { Relative retention }(\alpha)=4.53 \\
k \text { for }(R) \text {-isomer }=1.35 & t_{\mathrm{m}}=1.00 \mathrm{~min}
\end{array}
$$

where $w_{\mathrm{av}}$ is the average width of the two Gaussian peaks at their base.

(a) Find $t_{1}, t_{2}$, and $w_{\mathrm{av}}$, with units of minutes.
(b) The width of a peak at half-height is $w_{1 / 2}$ (Figure 22-9). If the plate number for each peak is the same, find $w_{1 / 2}$ for each peak.
(c) The area of a Gaussian peak is $1.064 \times$ peak height $\times w_{1 / 2}$. Given that the areas under the two bands should be equal, find the relative peak heights (height $/$ height $_{S}$ ).

24-C. Two peaks emerge from a chromatography column as sketched in the illustration.

According to Equation 22-30, resolution is given by

$$
\text { Resolution }=\frac{\sqrt{N}}{4}(\gamma-1)
$$

where $N$ is plate number and $\gamma$ is the unadjusted relative retention (Equation 22-16).
(a) If you change the solvent or the stationary phase, you will change the relative retention. Sketch the chromatogram if $\gamma$ increases but $N$ is constant.
(b) If you increase column length or decrease particle size or flow rate, you can increase the plate number. Sketch the chromatogram if $N$ increases but $\gamma$ is constant.

24-D. After poisonous melamine and cyanuric acid appeared in milk in China (Box 10-3) in 2008, there was a flurry of activity to develop methods to measure these substances. An analytical method for milk is to treat 1 volume of milk with 9 volumes of $\mathrm{H}_{2} \mathrm{O}: \mathrm{CH}_{3} \mathrm{CN}(20: 80$ $\mathrm{vol} / \mathrm{vol}$ ) to precipitate proteins. The mixture is centrifuged for 5 min to remove precipitate. The supernatant liquid is filtered through a $0.5-\mu \mathrm{m}$ filter and injected into a HILIC liquid chromatography column (TSKgel Amide-80 stationary phase) and products are measured by mass spectrometry with selected reaction monitoring (Section 21-4). Melamine is measured in positive ion mode with the transition $\mathrm{m} / \mathrm{z}$
$127 \rightarrow 85$. Cyanuric acid is measured in negative ion mode with the transition $m / z 128 \rightarrow 42$.
(a) Write the formulas for the four ions and propose structures for all four ions.
(b) Even though milk is a complex substance, only one clean peak is observed for melamine and one for cyanuric acid spiked into milk. Explain why.
24-E. (a) Make a graph showing the retention time of each peak in Figure 24-25 in chromatograms A, D, and B as a function of position along the line AB . Predict the retention times for solvent compositions midway between A and D and midway between D and B . Draw a stick diagram (representing each peak as a vertical line) of the two predicted chromatograms.
(b) What would be the solvent compositions midway between A and D and midway between D and B ?

## Problems

## High-Performance Liquid Chromatography

24-1. (a) Why does eluent strength increase as solvent becomes less polar in reversed-phase chromatography, whereas eluent strength increases as solvent becomes more polar in normal-phase chromatography?
(b) What kind of gradient is used in supercritical fluid chromatography?

24-2. Why are the relative eluent strengths of solvents in adsorption chromatography fairly independent of solute?
24-3. In hydrophilic interaction chromatography (HILIC), why is eluent strength increased by increasing the fraction of water in the mobile phase.

24-4. (a) Why is high pressure needed in HPLC?
(b) What is a bonded phase in liquid chromatography?

24-5. (a) Use Equation 24-1 to estimate the length of column required to achieve $1.0 \times 10^{4}$ plates if the stationary phase particle size is 10.0 , $5.0,3.0$, or $1.5 \mu \mathrm{~m}$.
(b) Why do smaller particles give better resolution?

24-6. If a $15-\mathrm{cm}$-long column has a plate height of $5.0 \mu \mathrm{~m}$, what will be the half-width (in seconds) of a peak eluted at 10.0 min ? If plate height $=25 \mu \mathrm{~m}$, what will be $w_{1 / 2}$ ?
24-7. Why are silica stationary phases generally limited to operating in the pH range 2-8? Why does the silica in Figure 24-8 have improved stability at low pH ?

24-8. How do additives such as triethylamine reduce tailing of certain solutes?

24-9. HPLC peaks should generally not have an asymmetry factor $A / B$ in Figure 22-14 outside the range 0.9-1.5.
(a) Sketch the shape of a peak with an asymmetry of 1.8.
(b) What might you do to correct the asymmetry?

24-10. (a) Sketch a graph of the van Deemter equation (plate height versus linear flow rate). What would the curve look like if the multiple path term were 0 ? If the longitudinal diffusion term were 0 ? If the finite equilibration time term were 0 ?
(b) Explain why the van Deemter curve for $1.8-\mu \mathrm{m}$ particles in Figure $24-3$ is nearly flat at high flow rate. What can you say about each of the terms in the van Deemter equation for $1.8-\mu \mathrm{m}$ particles?
(c) Explain why the $2.7-\mu \mathrm{m}$ superficially porous particle enables separations similar to those achieved by $1.8-\mu \mathrm{m}$ totally porous particles, but the superficially porous particle requires lower pressure.
24-11. The figure below shows the separation of two enantiomers on a chiral stationary phase.

Separation of enantiomers of Ritalin by HPLC with a chiral stationary phase. [From R. Bakhtiar, L. Ramos, and F. L. S. Tse, "Quantification of Methylphenidate in Plasma Using Chiral Liquid-Chromatography/Tandem Mass Spectrometry: Application to Toxicokinetic Studies," Anal. Chim. Acta 2002, 469, 261.]
(a) From $t_{\mathrm{r}}$ and $w_{1 / 2}$, find $N$ for each peak.
(b) From $t_{\mathrm{r}}$ and $w_{1 / 2}$, find the resolution.
(c) Use Equation 22-30 with the average $N$ to predict the resolution.

24-12. (a) According to Equation 24-2, if all conditions are constant, but particle size is reduced from $3 \mu \mathrm{~m}$ to $0.7 \mu \mathrm{~m}$, by what factor must pressure be increased to maintain constant linear velocity?
(b) If all conditions except pressure are constant, by what factor will linear velocity increase if column pressure is increased by a factor of 10 ?
(c) With $0.7-\mu \mathrm{m}$ particles in a $50-\mu \mathrm{m}$-diameter $\times 9-\mathrm{cm}$-long column, increasing pressure from 70 MPa to 700 MPa decreased analysis time by approximately a factor of 10 while increasing plate count from 12000 to $45000 .{ }^{38}$ Explain why small particles permit 10 -fold faster flow without losing efficiency or, in this case, with improved efficiency.

24-13. Use Figure 24-15 to suggest which type of liquid chromatography you could use to separate compounds in each of the following categories:
(a) Molecular mass $<2000$, soluble in octane
(b) Molecular mass $<2000$, soluble in dioxane
(c) Molecular mass $<2000$, ionic
(d) Molecular mass $>2000$, soluble in water, nonionic, size 50 nm
(e) Molecular mass $>2000$, soluble in water, ionic
(f) Molecular mass $>2000$, soluble in tetrahydrofuran, size 50 nm

24-14. Microporous silica particles with a density of $2.2 \mathrm{~g} / \mathrm{mL}$ and a diameter of $10 \mu \mathrm{~m}$ have a measured surface area of $300 \mathrm{~m}^{2} / \mathrm{g}$. Calculate the surface area of the spherical silica as if it were simply solid particles. What does this calculation tell you about the shape or porosity of the particles?

24-15. (a) Nonpolar aromatic compounds were separated by HPLC on an octadecyl $\left(\mathrm{C}_{18}\right)$ bonded phase. The eluent was $65 \mathrm{vol} \%$ methanol in water. How would the retention times be affected if $90 \%$ methanol were used instead?
(b) Octanoic acid and 1-aminooctane were passed through the same column described in part (a), using an eluent of $20 \%$ methanol $/ 80 \%$ buffer ( pH 3.0 ). State which compound is expected to be eluted first and why.

$$
\begin{gathered}
\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CO}_{2} \mathrm{H} \\
\text { Octanoic acid } \\
\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{NH}_{2}
\end{gathered}
$$

24-16. Consider the chromatogram of deuterated benzenes in Box 24-1. (a) Unretained thiourea, is eluted in 41.7 min . Find the linear velocity $u_{\mathrm{x}}(\mathrm{mm} / \mathrm{s})$.
(b) Find the retention factor $k$ for $\mathrm{C}_{6} \mathrm{D}_{6}$.
(c) Find the plate number $N$ and plate height for $\mathrm{C}_{6} \mathrm{D}_{6}$.
(d) Assuming that the peak widths for $\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{D}$ and $\mathrm{C}_{6} \mathrm{H}_{6}$ are the same as that of $\mathrm{C}_{6} \mathrm{D}_{6}$, find the resolution of $\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{D}$ and $\mathrm{C}_{6} \mathrm{H}_{6}$.
(e) Retention times for $\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{D}$ and $\mathrm{C}_{6} \mathrm{H}_{6}$ are 193.3 and 194.3 min, respectively. Find the relative retention $(\alpha)$ and unadjusted relative retention $(\gamma)$ between $\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{D}$ and $\mathrm{C}_{6} \mathrm{H}_{6}$.
(f) If we just increased the column length to increase $N$, what value of $N$ and what column length would be required for a resolution of 1.000 ?
(g) Without increasing the length of the column, and without changing the stationary phase, how might you improve the resolution?
(h) When the solvent was changed from $\mathrm{CH}_{3} \mathrm{CN} / \mathrm{H}_{2} \mathrm{O}(30: 70 \mathrm{vol} / \mathrm{vol})$ to $\mathrm{CH}_{3} \mathrm{CN} / \mathrm{CH}_{3} \mathrm{OH} / \mathrm{H}_{2} \mathrm{O}(10: 5: 85)$, the unadjusted relative retention changed from $\gamma=1.005_{2}$ to $1.008_{3}$. If the plate number were unchanged, what would be the resolution?
24-17. The antitumor drug gimatecan is available as nearly pure $(S)$-enantiomer. Neither pure $(R)$-enantiomer nor a racemic (equal) mixture of the two enantiomers are available. To measure small quantites of $(R)$-enantiomer in nearly pure $(S)$-gimatecan, a prepara-

Chromatography of gimatecan on each enantiomer of a chiral stationary phase. Lower traces have enlarged vertical scale. [From E. Badaloni, W. Cabri, A. Ciogli, R. Deias, F. Gasparrini, F. Giorgi, A. Vigevani, and C. Villani, "Combination of HPLC 'Inverted Chirality Columns Approach' and MS/MS Detection for Extreme Enantiomeric Excess Determination Even in Absence of Reference Samples." Anal. Chem. 2007, 79, 6013.]
tion was subjected to normal-phase chromatography on each of the enantiomers of a commercial, chiral stationary phase designated $(S, S)$ - and $(R, R)$-DACH-DNB. Chromatography on the $(R, R)$-stationary phase gave a slightly asymmetric peak at $t_{\mathrm{r}}=6.10 \mathrm{~min}$ with retention factor $k=1.22$. Chromatography on the $(S, S)$-stationary phase gave a slightly asymmetric peak at $t_{\mathrm{r}}=6.96$ min with $k=1.50$. With the $(S, S)$-stationary phase, a small peak with $0.03 \%$ of the area of the main peak was observed at 6.10 min .
(a) Explain the appearance of the upper chromatograms. Dashed lines are position markers, not part of the chromatogram. What would the chromatogram of pure $(R)$-gimatecan look like on the same two stationary phases?
(b) Explain the appearance of the two lower chromatograms and why it can be concluded that the gimatecan contained $0.03 \%$ of the $(R)$-enantiomer. Why is the $(R)$-enantiomer not observed with the $(R, R)$-stationary phase?
(c) Find the adjusted relative retention ( $\alpha$ ) and unadjusted relative retention $(\gamma)$ for the two enantiomers on the $(S, S)$-stationary phase. (d) The column provides $N=6800$ plates. What would be the resolution between the two equal peaks in a racemic (equal) mixture of $(R)$ - and ( $S$ )-gimatecan? If the peaks were symmetric, does this resolution provide "baseline" separation in which signal returns to baseline before the next peak begins?

24-18. Suppose that an HPLC column produces Gaussian peaks. The detector measures absorbance at 254 nm . A sample containing equal moles of compounds $A$ and $B$ was injected into the column. Compound $\mathrm{A}\left(\varepsilon_{254}=2.26 \times 10^{4} \mathrm{M}^{-1} \mathrm{~cm}^{-1}\right)$ has a height $h=128 \mathrm{~mm}$ and a halfwidth $w_{1 / 2}=10.1 \mathrm{~mm}$. Compound $\mathrm{B}\left(\varepsilon_{254}=1.68 \times 10^{4} \mathrm{M}^{-1} \mathrm{~cm}^{-1}\right)$ has $w_{1 / 2}=7.6 \mathrm{~mm}$. What is the height of peak B in millimeters?
24-19. Retention factors for three solutes separated on a $\mathrm{C}_{8}$ nonpolar stationary phase are listed in the table on the next page. Eluent was a 70:30 ( vol/vol) mixture of 50 mM citrate buffer (adjusted to pH with $\mathrm{NH}_{3}$ ) plus methanol. Draw the dominant species of each compound at each pH in the table and explain the behavior of the retention factors.

|  | Retention factor |  |  |
| :--- | :---: | :---: | :---: |
| Analyte | pH 3 | pH 5 | pH 7 |
| Acetophenone | 4.21 | 4.28 | 4.37 |
| Salicylic acid | 2.97 | 0.65 | 0.62 |
| Nicotine | 0.00 | 0.13 | 3.11 |

Acetophenone

Salicylic acid $\mathrm{p} K_{\mathrm{a}}=2.97$

$\mathrm{p} K_{1}=3.15$ $\mathrm{p} K_{2}=7.85$

24-20. Morphine and morphine $3-\beta$-D-glucuronide were separated on two different $4.6-\mathrm{mm}$-diameter $\times 50-\mathrm{mm}$-long columns with $3-\mu \mathrm{m}$ particles. ${ }^{39}$ Column A was $\mathrm{C}_{18}$-silica run at $1.4 \mathrm{~mL} / \mathrm{min}$, and column $B$ was bare silica run at $2.0 \mathrm{~mL} / \mathrm{min}$.

Morphine

Morphine 3- $\beta$-D-glucuronide
(a) Estimate the volume, $V_{\mathrm{m}}$, and time, $t_{\mathrm{m}}$, at which unretained solute would emerge from each column. The observed times are 0.65 min for column A and 0.50 min for column B.
(b) Column A was eluted with $2 \mathrm{vol} \%$ acetonitrile in water containing 10 mM ammonium formate at pH 3 . Morphine 3- $\beta$-D-glucuronide emerged at 1.5 min and morphine at 2.8 min . Explain the order of elution.
(c) Column B was eluted with a $5.0-\mathrm{min}$ gradient beginning at 90 $\mathrm{vol} \%$ acetonitrile in water and ending at $50 \mathrm{vol} \%$ acetonitrile in water. Both solvents contained 10 mM ammonium formate, pH 3 . Morphine emerged at 1.3 min and morphine 3- $\beta-\mathrm{D}$-glucuronide emerged at 2.7 min . Explain the order of elution. Why does the gradient go from high to low acetonitrile volume fraction?
(d) Find the retention factor $k$ for each solute on column A, using $t_{\mathrm{m}}=0.65 \mathrm{~min}$.
(e) From Equation 24-10 in Box 24-4, estimate $k^{*}$, assuming $S=4$ and with $t_{\mathrm{m}}=0.50 \mathrm{~min}$.

24-21. The rate at which heat is generated inside a chromatography column from friction of flowing liquid is power (watts, $\mathrm{W}=\mathrm{J} / \mathrm{s}$ ) $=$ volume flow rate $\left(\mathrm{m}^{3} / \mathrm{s}\right) \times$ pressure drop (pascals, $\mathrm{Pa}=\mathrm{kg} /\left[\mathrm{m} \cdot \mathrm{s}^{2}\right]$ ).
(a) Explain the analogy between heat generated in a chromatography column and heat generated in an electric circuit (power $=$ current $\times$ voltage).
(b) At what rate (watts $=\mathrm{J} / \mathrm{s}$ ) is heat generated for a flow of $1 \mathrm{~mL} / \mathrm{min}$ with a pressure difference of 3500 bar between the inlet and outlet? You will need to convert $\mathrm{mL} / \mathrm{min}$ to $\mathrm{m}^{3} / \mathrm{s}$. Also $1 \mathrm{bar} \equiv 10^{5} \mathrm{~Pa}$.

24-22. Chromatography-mass spectrometry. Cocaine metabolism in rats can be studied by injecting the drug and periodically withdrawing blood to measure levels of metabolites by HPLC-mass spectrometry. For quantitative analysis, isotopically labeled internal standards are mixed with the blood sample. Blood was analyzed by reversed-phase chromatography with an acidic eluent and atmospheric pressure chemical ionization mass spectrometry for detection. The mass spectrum of the collisionally activated dissociation products from the $\mathrm{m} / \mathrm{z} 304$ positive ion is shown in the figure. Selected reaction monitoring ( $\mathrm{m} / \mathrm{z} 304$ from mass filter Q1 and $\mathrm{m} / \mathrm{z} 182$ from Q3 in Figure 21-26) gave a single chromatographic peak at 9.22 min for cocaine. The internal standard ${ }^{2} \mathrm{H}_{5}$-cocaine gave a single peak at 9.19 min for $\mathrm{m} / \mathrm{z} 309$ (Q1) $\rightarrow 182$ (Q3).
(a) Draw the structure of the ion at $m / z 304$.
(b) Suggest a structure for the ion at $m / z 182$.
(c) The intense peaks at $m / z 182$ and 304 do not have ${ }^{13} \mathrm{C}$ isotopic partners at $m / z 183$ and 305. Explain why.
(d) Rat plasma is exceedingly complex. Why does the chromatogram show just one clean peak?
(e) Given that ${ }^{2} \mathrm{H}_{5}$-cocaine has only two major mass spectral peaks at $\mathrm{m} / \mathrm{z} 309$ and 182 , which atoms are labeled with deuterium?
(f) Explain how you would use ${ }^{2} \mathrm{H}_{5}$-cocaine for measuring cocaine in blood.

Left: Mass spectrum of collisionally activated dissociation products from $\mathrm{m} / \mathrm{z}$ 304 positive ion from atmospheric pressure chemical ionization mass spectrum of cocaine. Right: Chromatograms obtained by selected reaction monitoring. [From G. Singh, V. Arora, P. T. Fenn, B. Mets, and I. A. Blair, "Isotope Dilution Liquid Chromatography Tandem Mass Spectrometry Assay for Trace Analysis of Cocaine and Its Metabolites in Plasma," Anal. Chem. 1999, 71, 2021.]

24－23．Chromatography－mass spectrometry．HPLC separation of enantiomers of the drug Ritalin on a chiral stationary phase was shown in Problem 24－11．

$\mathrm{C}_{14} \mathrm{H}_{19} \mathrm{O}_{2} \mathrm{~N}$
Nominal mass $=233$
（a）Detection is by atmospheric pressure chemical ionization with selected reaction monitoring of the $m / z 234 \rightarrow 84$ transition．Explain how this detection works and propose structures for $m / z 234$ and $m / z 84$ ． （b）For quantitative analysis，the internal standard ${ }^{2} \mathrm{H}_{3}$－Ritalin with a deuterated methyl group was added．Deuterated enantiomers have the same retention times as unlabeled enantiomers．Which selected reaction monitoring transition should be monitored to produce a chromatogram of the internal standard in which unlabeled Ritalin will be invisible？

## Method Development

24－24．（a）Explain how to measure $k$ and resolution．
（b）State three methods for measuring $t_{\mathrm{m}}$ in reversed－phase chromatography．
（c）Estimate $t_{\mathrm{m}}$ for a $0.46 \times 15 \mathrm{~cm}$ column containing $5-\mu \mathrm{m}$ particles operating at a flow rate of $1.5 \mathrm{~mL} / \mathrm{min}$ ．Estimate $t_{\mathrm{m}}$ if the particle size were $3.5 \mu \mathrm{~m}$ instead．

24－25．What is the difference between dead volume and dwell vol－ ume？How do each of these volumes affect a chromatogram？

24－26．What does it mean for a separation procedure to be＂rugged＂ and why is it desirable？

24－27．What are criteria for an adequate isocratic chromatographic separation？
24－28．Explain how to use a gradient for the first run to decide whether isocratic or gradient elution would be more appropriate．

24－29．What are the general steps in developing an isocratic separa－ tion for reversed－phase chromatography with one organic solvent？
24－30．What are the general steps in developing an isocratic separa－ tion for reversed－phase chromatography with two organic solvents？

24－31．What are the general steps in developing an isocratic separa－ tion for reversed－phase chromatography with one organic solvent and temperature as variables？

24－32．The＂rule of three＂states that the retention factor for a given solute decreases approximately threefold when the organic phase increases by $10 \%$ ．In Figure $24-12, t_{\mathrm{m}}=2.7 \mathrm{~min}$ ．Find $k$ for peak 5 at $50 \%$ B．Predict the retention time for peak 5 at $40 \%$ B and com－ pare the observed and predicted times．
24－33．（a）Make a graph showing retention times of peaks 6,7 ，and 8 in Figure $24-12$ as a function of $\%$ acetonitrile（\％B）．Predict the retention time of peak 8 at $45 \%$ B．
（b）Linear－solvent－strength model：In Figure $24-12, t_{\mathrm{m}}=2.7 \mathrm{~min}$ ． Compute $k$ for peaks 6,7 ，and 8 as a function of $\%$ B．Make a graph of $\log k$ versus $\Phi$ ，where $\Phi=\% \mathrm{~B} / 100$ ．Find the equation of a straight line through a suitable linear range for peak 8 ．The slope is $-S$ and the intercept is $\log k_{\mathrm{w}}$ ．From the line，predict $t_{\mathrm{r}}$ for peak 8 at 45\％B and compare your answer with part（a）．

24－34．（a）Make a graph showing the retention time of each peak in Figure $24-25$ in chromatograms $\mathrm{B}, \mathrm{F}$ ，and C as a function of position along the line BC ．Predict the retention times for solvent composi－ tions midway between B and F and midway between F and C ．Draw a stick diagram（representing each peak as a vertical line）of each of the two predicted chromatograms．
（b）What would be the solvent compositions midway between B and F and midway between F and C ？

24－35．Suppose that in Figure 24－25 the optimum concentrations of solvents at points $\mathrm{A}, \mathrm{B}$ ，and C are $50 \%$ acetonitrile， $60 \%$ methanol， and $40 \%$ tetrahydrofuran，respectively．What will be the solvent compositions at points $\mathrm{D}, \mathrm{E}, \mathrm{F}$ ，and G ？
24－36．A reversed－phase separation of a reaction mixture calls for isocratic elution with $48 \%$ methanol／52\％water．If you want to change the procedure to use acetonitrile／water，what is a good start－ ing percentage of acetonitrile to try？
24－37．（a）When you try separating an unknown mixture by reversed－ phase chromatography with $50 \%$ acetonitrile／ $50 \%$ water，the peaks are too close together and are eluted in the range $k=2-6$ ．Should you use a higher or lower concentration of acetonitrile in the next run？
（b）When you try separating an unknown mixture by normal－phase chromatography with pure $50 \%$ hexane $/ 50 \%$ methyl $t$－butyl ether， the peaks are too close together and are eluted in the range $k=2-6$ ． Should you use a higher or lower concentration of hexane in the next run？

24－38．A mixture of 14 compounds was subjected to a reversed－ phase gradient separation going from $5 \%$ to $100 \%$ acetonitrile with a gradient time of 60 min ．The sample was injected at $t=$ dwell time．All peaks were eluted between 22 and 41 min ．
（a）Is the mixture more suitable for isocratic or gradient elution？
（b）If the next run is a gradient，select the starting and ending \％acetonitrile and the gradient time．

24－39．（a）List ways in which the resolution between two closely spaced peaks might be changed．
（b）After optimization of an isocratic elution with several solvents， the resolution of two peaks is 1.2 ．How might you improve the res－ olution without changing solvents or the kind of stationary phase？
24－40．（a）You wish to use a wide gradient from $5 \mathrm{vol} \%$ to $95 \mathrm{vol} \%$ B for the first separation of a mixture of small molecules to decide whether to use gradient or isocratic elution．What should be the gra－ dient time，$t_{\mathrm{G}}$ ，for a $0.46 \times 15 \mathrm{~cm}$ column containing $3-\mu \mathrm{m}$ particles with a flow of $1.0 \mathrm{~mL} / \mathrm{min}$ ？
（b）You optimized the gradient separation going from $20 \mathrm{vol} \%$ to 34 $\mathrm{vol} \% \mathrm{~B}$ in 11.5 min at $1.0 \mathrm{~mL} / \mathrm{min}$ ．Find $k^{*}$ for this optimized sepa－ ration．To scale up to a $1.0 \times 15 \mathrm{~cm}$ column，what should be the gra－ dient time and the volume flow rate？If the sample load on the small column was 1 mg ，what sample load can be applied to the large col－ umn？Verify that $k^{*}$ is unchanged．

24－41．島邼㯇 Simulating a separation with a spreadsheet．Use the spreadsheet in Figure $24-33$ to simulate the chromatograms for $\Phi=0.75$ and $\Phi=0.56$ in Figure 24－34

# Chromatographic Methods and Capillary Electrophoresis 

## CAPILLARY ELECTROCHROMATOGRAPHY

The inside of a monolithic electrochromatography column contains silicate "fingers" coated with stationary phase. Aromatic compounds were separated with a mean plate number of 80000 in a $50-\mathrm{cm}$ column with 15 kV applied voltage. [From J. D. Hayes and A. Malik, "Sol-Gel Monolithic Columns with Reversed Electroosmotic Flow for Capillary Electrochromatography," Anal. Chem. 2000, 72, 4090. Photo courtesy A. Malik, University of South Florida.]

Electrochromatography ${ }^{1}$ uses an electric field, rather than pressure, to propel mobile phase through a capillary column with uniform, pluglike flow (Color Plate 30). The capillary in the photograph contains a monolithic silicate structure similar to that in Box 24-1. Polymerization of soluble precursors inside the capillary forms chemical structures such as that shown below. The surface is coated with covalently anchored, positively charged quaternary ammonium groups. Mobile anions in solution provide charge balance. A strong electric field draws anions toward the anode, pulling the entire solution in the capillary along with them.
$\mathrm{C}_{18}$ groups attached to the quaternary ammonium cations are the chromatographic stationary phase. Solutes passing through the capillary are separated when they partition between the mobile solvent and the stationary $\mathrm{C}_{18}$ phase.

This chapter continues our discussion of pressure-driven chromatographic methods including ion-exchange, molecular exclusion, affinity, and hydrophobic interaction chromatography. We then introduce separations driven by an electric field. In electrophoresis and electrochromatography, liquid moves through a capillary tube by electroosmosis. This process enables us to create miniature analytical chips in which fluids are driven through capillary channels etched into glass or plastic. Chemical reactions and chemical separations are carried out on these chips. In the future, people will carry a "lab-on-a-chip" into the field for investigations that require large instruments today.

## 25-1 Ion-Exchange Chromatography

In ion-exchange chromatography, retention is based on the attraction between solute ions and charged sites bound to the stationary phase (Figure 22-6). In anion exchangers, positively charged groups on the stationary phase attract solute anions. Cation exchangers contain covalently bound, negatively charged sites that attract solute cations.

## Ion Exchangers

Resins are amorphous (noncrystalline) particles of organic material. Polystyrene resins for ion exchange are made by the copolymerization of styrene and divinylbenzene (Figure 25-1). Divinylbenzene content is varied from 1 to $16 \%$ to increase the extent of cross-linking of the insoluble hydrocarbon polymer. Benzene rings can be modified to produce a cation-exchange resin, containing sulfonate groups ( $-\mathrm{SO}_{3}^{-}$), or an anion-exchange resin, containing ammonium groups $\left(-\mathrm{NR}_{3}^{+}\right)$. If methacrylic acid is used in place of styrene, a polymer with carboxyl groups results.

Table 25-1 classifies ion exchangers as strongly or weakly acidic or basic. Sulfonate groups ( $-\mathrm{SO}_{3}^{-}$) of strongly acidic resins remain ionized even in strongly acidic solutions. Carboxyl groups ( $-\mathrm{CO}_{2}^{-}$) of the weakly acidic resins are protonated near pH 4 and lose their cation-exchange capacity. "Strongly basic" quaternary ammonium groups ( $-\mathrm{CH}_{2} \mathrm{NR}_{3}^{+}$) (which are not really basic at all) remain cationic at all values of pH . Weakly basic tertiary

Anion exchangers contain bound positive groups.
Cation exchangers contain bound negative groups.

Methacrylic acid

Strongly acidic cation exchangers: $\mathrm{RSO}_{3}^{-}$ Weakly acidic cation exchangers: $\mathrm{RCO}_{2}^{-}$
"Strongly basic" anion exchangers: $\mathrm{RNR}^{\prime+}$ Weakly basic anion exchangers: $\mathrm{RNR}_{2}^{\prime} \mathrm{H}^{+}$

Strongly acidic cation-exchange resin

Strongly basic anion-exchange resin

SOURCE: Adapted from J. X. Khym, Analytical Ion-Exchange Procedures in Chemistry and Biology (Englewood Cliffs,
NJ: Prentice Hall, 1974).

Because they are much softer than polystyrene resins, dextran and its relatives are called gells.

Figure 25-15 shows the structure of polyacrylamide.
ammonium ( $-\mathrm{CH}_{2} \mathrm{NHR}_{2}^{+}$) anion exchangers are deprotonated in moderately basic solution and lose their ability to bind anions.

The extent of cross-linking is indicated by the notation "-XN" after the name of the resin. For example, Dowex 1-X4 contains 4\% divinylbenzene, and Bio-Rad AG 50W-X12 contains $12 \%$ divinylbenzene. The resin becomes more rigid and less porous as cross-linking increases. Lightly cross-linked resins permit rapid equilibration of solute between the inside and the outside of the particle. However, resins with little cross-linking swell in water. Hydration decreases both the density of ion-exchange sites and the selectivity of the resin for different ions. More heavily cross-linked resins exhibit less swelling and higher exchange capacity and selectivity, but they have longer equilibration times. The charge density of polystyrene ion exchangers is so great that highly charged macromolecules such as proteins may be irreversibly bound.

Cellulose and dextran ion exchangers, which are polymers of the sugar glucose, possess larger pore sizes and lower charge densities than those of polystyrene resins. They are well suited to ion exchange of macromolecules, such as proteins. Dextran, cross-linked by glycerin, is sold under the name Sephadex (Figure 25-2). Other macroporous ion exchangers are based on the polysaccharide agarose and on polyacrylamide. Table 25-2 lists charged functional groups used to derivatize polysaccharide hydroxyl groups. DEAESephadex, for example, is an anion-exchange Sephadex containing diethylaminoethyl groups.

FIGURE 25-2 Structure of Sephadex, a cross-linked dextran originally sold by Pharmacia Fine Chemicals.

TABLE 25-2 Common active groups of ion-exchange gels

| Type | Abbreviation | Name | Structure |
| :---: | :---: | :---: | :---: |
| Cation Exchangers |  |  |  |
| Strong acid | SP | Sulfopropyl | $-\mathrm{OCH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{SO}_{3} \mathrm{H}$ |
|  | SE | Sulfoethyl | $-\mathrm{OCH}_{2} \mathrm{CH}_{2} \mathrm{SO}_{3} \mathrm{H}$ |
| Intermediate acid | P | Phosphate | $-\mathrm{OPO}_{3} \mathrm{H}_{2}$ |
| Weak acid | CM | Carboxymethyl | $-\mathrm{OCH}_{2} \mathrm{CO}_{2} \mathrm{H}$ |
| Anion Exchangers |  |  |  |
| Strong base | TEAE | Triethylaminoethyl | - $\mathrm{OCH}_{2} \mathrm{CH}_{2} \stackrel{+}{\mathrm{N}}\left(\mathrm{CH}_{2} \mathrm{CH}_{3}\right)_{3}$ |
|  | QAE | Diethyl(2-hydroxypropyl) quaternary amino |  |
| Intermediate base | DEAE | Diethylaminoethyl | $-\mathrm{OCH}_{2} \mathrm{CH}_{2} \mathrm{~N}\left(\mathrm{CH}_{2} \mathrm{CH}_{3}\right)_{2}$ |
|  | ECTEOLA | Triethanolamine coupled to cellulose through glyceryl chains |  |
|  | BD | Benzoylated DEAE groups |  |
| Weak base | PAB | p-Aminobenzyl |  |

## Ion-Exchange Selectivity

Consider the competition of $\mathrm{Na}^{+}$and $\mathrm{Li}^{+}$for sites on the cation-exchange resin $\mathrm{R}^{-}$:
Selectivity

$$
\begin{equation*}
\mathrm{R}^{-} \mathrm{Na}^{+}+\mathrm{Li}^{+} \rightleftharpoons \mathrm{R}^{-} \mathrm{Li}^{+}+\mathrm{Na}^{+} \quad K=\frac{\left[\mathrm{R}^{-} \mathrm{Li}^{+}\right]\left[\mathrm{Na}^{+}\right]}{\left[\mathrm{R}^{-} \mathrm{Na}^{+}\right]\left[\mathrm{Li}^{+}\right]} \tag{25-1}
\end{equation*}
$$

coefficient:
The equilibrium constant is called the selectivity coefficient, because it describes the relative selectivity of the resin for $\mathrm{Li}^{+}$and $\mathrm{Na}^{+}$. Selectivities of polystyrene resins in Table 25-3 tend to increase with the extent of cross-linking, because the pore size of the resin shrinks as crosslinking increases. Ions such as $\mathrm{Li}^{+}$, with a large hydrated radius (Chapter 7 opener), do not have as much access to the resin as smaller ions, such as $\mathrm{Cs}^{+}$, do.

| Sulfonic acid cation-exchange resin |  |  |  | Quarternary ammonium anion-exchange resin |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | Relative selectivity for divinylbenzene content |  |  |  |  |
| Cation | 4\% | 8\% | 10\% | Anion | Relative selectivity |
| $\mathrm{Li}^{+}$ | 1.00 | 1.00 | 1.00 | $\mathrm{F}^{-}$ | 0.09 |
| $\mathrm{H}^{+}$ | 1.30 | 1.26 | 1.45 | $\mathrm{OH}^{-}$ | 0.09 |
| $\mathrm{Na}^{+}$ | 1.49 | 1.88 | 2.23 | $\mathrm{Cl}^{-}$ | 1.0 |
| $\mathrm{NH}_{4}^{+}$ | 1.75 | 2.22 | 3.07 | $\mathrm{Br}^{-}$ | 2.8 |
| $\mathrm{K}^{+}$ | 2.09 | 2.63 | 4.15 | $\mathrm{NO}_{3}^{-}$ | 3.8 |
| $\mathrm{Rb}^{+}$ | 2.22 | 2.89 | 4.19 | $\mathrm{I}^{-}$ | 8.7 |
| $\mathrm{Cs}^{+}$ | 2.37 | 2.91 | 4.15 | $\mathrm{ClO}_{4}^{-}$ | 10.0 |

| $\mathrm{Tl}^{+}$ | 5.20 | 9.66 | 22.2 |  |  |

source: Amberlite Ion Exchange Resins—Laboratory Guide (Rohm \& Haas Co., 1979).

In general, ion exchangers favor the binding of ions of higher charge, decreased hydrated radius, and increased polarizability. A fairly general order of selectivity for cations is

$$
\begin{aligned}
& \mathrm{Pu}^{4+}>\mathrm{La}^{3+}>\mathrm{Ce}^{3+}>\mathrm{Pr}^{3+}>\mathrm{Eu}^{3+}>\mathrm{Y}^{3+}>\mathrm{Sc}^{3+}>\mathrm{Al}^{3+} \gg \\
& \mathrm{Ba}^{+}>\mathrm{Pb}^{2+}>\mathrm{Sr}^{2+}>\mathrm{Ca}^{2+}>\mathrm{Ni}^{2+}>\mathrm{Cd}^{2+}>\mathrm{Cu}^{2+}> \\
& \mathrm{Co}^{2+}>\mathrm{Zn}^{2+}>\mathrm{Mg}^{2+}>\mathrm{UO}_{2}^{2+} \gg \mathrm{Tl}^{+}>\mathrm{Ag}^{+}>\mathrm{Rb}^{+}>\mathrm{K}^{+}> \\
& \mathrm{NH}_{4}^{+}>\mathrm{Na}^{+}>\mathrm{H}^{+}>\mathrm{Li}^{+}
\end{aligned}
$$

Reaction 25-1 can be driven in either direction, even though $\mathrm{Na}^{+}$is bound more tightly than $\mathrm{Li}^{+}$. Washing a column containing $\mathrm{Na}^{+}$with a substantial excess of $\mathrm{Li}^{+}$will replace $\mathrm{Na}^{+}$with $\mathrm{Li}^{+}$. Washing a column in the $\mathrm{Li}^{+}$form with $\mathrm{Na}^{+}$will convert it into the $\mathrm{Na}^{+}$form.

Ion exchangers loaded with one kind of ion bind small amounts of a different ion nearly quantitatively. $\mathrm{Na}^{+}$-loaded resin will bind small amounts of $\mathrm{Li}^{+}$nearly quantitatively, even though the selectivity is greater for $\mathrm{Na}^{+}$. The same column binds large quantities of $\mathrm{Ni}^{2+}$ or $\mathrm{Fe}^{3+}$ because the resin has greater selectivity for these ions than for $\mathrm{Na}^{+}$. Even though $\mathrm{Fe}^{3+}$ is bound more tightly than $\mathrm{H}^{+}, \mathrm{Fe}^{3+}$ is removed from the resin by washing with excess acid.

## Donnan Equilibrium

When an ion exchanger is placed in an electrolyte solution, the concentration of electrolyte is higher outside the resin than inside it. The equilibrium between ions in solution and ions inside the resin is called the Donnan equilibrium.

Consider a quaternary ammonium anion-exchange resin $\left(\mathrm{R}^{+}\right)$in its $\mathrm{Cl}^{-}$form immersed in a solution of KCl . Let the concentration of an ion inside the resin be $[\mathrm{X}]_{\mathrm{i}}$ and the concentration outside the resin be $[\mathrm{X}]_{0}$. It can be shown from thermodynamics that the ion product inside the resin is approximately equal to the product outside the resin:

$$
\begin{equation*}
\left[\mathrm{K}^{+}\right]_{\mathrm{i}}\left[\mathrm{Cl}^{-}\right]_{\mathrm{i}}=\left[\mathrm{K}^{+}\right]_{\mathrm{o}}\left[\mathrm{Cl}^{-}\right]_{\mathrm{o}} \tag{25-2}
\end{equation*}
$$

From considerations of charge balance, we know that

$$
\begin{equation*}
\left[\mathrm{K}^{+}\right]_{\mathrm{o}}=\left[\mathrm{Cl}^{-}\right]_{\mathrm{o}} \tag{25-3}
\end{equation*}
$$

Inside the resin, there are three charged species, and the charge balance is

$$
\begin{equation*}
\left[\mathrm{R}^{+}\right]_{\mathrm{i}}+\left[\mathrm{K}^{+}\right]_{\mathrm{i}}=\left[\mathrm{Cl}^{-}\right]_{\mathrm{i}} \tag{25-4}
\end{equation*}
$$

where $\left[\mathrm{R}^{+}\right]$is the concentration of quaternary ammonium ions attached to the resin. Substituting Equations 25-3 and 25-4 into Equation 25-2 gives

$$
\begin{equation*}
\left[\mathrm{K}^{+}\right]_{\mathrm{i}}\left(\left[\mathrm{~K}^{+}\right]_{\mathrm{i}}+\left[\mathrm{R}^{+}\right]_{\mathrm{i}}\right)=\left[\mathrm{K}^{+}\right]_{\mathrm{o}}^{2} \tag{25-5}
\end{equation*}
$$

which says that $\left[\mathrm{K}^{+}\right]_{\mathrm{o}}$ must be greater than $\left[\mathrm{K}^{+}\right]_{\mathrm{i}}$.

## EXAMPLE Exclusion of Cations by an Anion Exchanger

Suppose that the concentration of cationic sites in the resin is 6.0 M . When the $\mathrm{Cl}^{-}$form of this resin is immersed in 0.050 M KCl , what will be the ratio $\left[\mathrm{K}^{+}\right]_{\mathrm{o}} /\left[\mathrm{K}^{+}\right]_{\mathrm{i}}$ ?
Solution Let us assume that $\left[\mathrm{K}^{+}\right]_{\text {o }}$ remains 0.050 M . Equation $25-5$ gives

$$
\left[\mathrm{K}^{+}\right]_{\mathrm{i}}\left(\left[\mathrm{~K}^{+}\right]_{\mathrm{i}}+6.0\right)=(0.050)^{2} \Rightarrow\left[\mathrm{~K}^{+}\right]_{\mathrm{i}}=0.00042 \mathrm{M}
$$

The concentration of $\mathrm{K}^{+}$inside the resin is less than $1 \%$ of that outside the resin.
Test Yourself Find the $\left[\mathrm{K}^{+}\right]_{\mathrm{i}}$ if cationic sites in the resin were 3.0 M instead of 6.0 M . Does your answer make sense? (Answer: 0.00083 M)

Ions with the same charge as the resin are excluded. (The quaternary ammonium resin excludes $\mathrm{K}^{+}$.) The counterion, $\mathrm{Cl}^{-}$, is not excluded from the resin. There is no electrostatic barrier to penetration of an anion into the resin. Anion exchange takes place freely in the quaternary ammonium resin even though cations are repelled from the resin.

The Donnan equilibrium is the basis of ion-exclusion chromatography. Because dilute electrolytes are excluded from the resin, they pass through a column faster than nonelectrolytes, such as sugar, which freely penetrates the resin. When a solution of NaCl and sugar is applied to an ion-exchange column, NaCl emerges from the column before sugar.

## Conducting Ion-Exchange Chromatography

Ion-exchange resins are used for applications involving small molecules ( $\mathrm{FM} \lesssim 500$ ), which can penetrate the small pores of the resin. A mesh size (Table 27-2) of 100/200 is suitable for most work. Higher mesh numbers (smaller particle size) lead to finer separations but slower column operation. For preparative separations, the sample may occupy 10 to $20 \%$ of the column volume. Ion-exchange gels are used for large molecules (such as proteins and nucleic acids), which cannot penetrate the pores of resins. Separations involving harsh chemical conditions (high temperature, high radiation levels, strongly basic solution, or powerful oxidizing agents) employ inorganic ion exchangers, such as hydrous oxides of $\mathrm{Zr}, \mathrm{Ti}, \mathrm{Sn}$, and W .

Gradient elution with increasing ionic strength or changing pH is common in ion-exchange chromatography. Consider a column to which anion $\mathrm{A}^{-}$is bound more tightly than anion $\mathrm{B}^{-}$. We separate $\mathrm{A}^{-}$from $\mathrm{B}^{-}$by elution with $\mathrm{C}^{-}$, which is less tightly bound than either $\mathrm{A}^{-}$or $\mathrm{B}^{-}$. As the concentration of $\mathrm{C}^{-}$is increased, $\mathrm{B}^{-}$is eventually displaced and moves down the column. At a still higher concentration of $\mathrm{C}^{-}$, the anion $\mathrm{A}^{-}$also is eluted.

In Figure 25-3, a gradient of ammonium acetate was used for an anion-exchange separation of differently charged forms of the protein transferrin at pH 6.0. Transferrin (Figure 17-7)

The high concentration of positive charges within the resin repels cations from the resin.

Three classes of ion exchangers:

1. resins
2. gels
3. inorganic exchangers

An ionic strength gradient is analogous to a solvent or temperature gradient.

FIGURE 25-3 lonic-strength-gradient anionexchange separation of isoforms $\mathrm{S}_{2}$ to $\mathrm{S}_{6}$ of the protein transferrin bearing two to six sialic acid groups. The $5 \times 50 \mathrm{~mm}$ column contained Pharmacia Mono-Q resin, which consists of $10-\mu \mathrm{m}$-diameter beads with quaternary ammonium anion-exchange sites. [From S. A. Rodríguez, E. B. Gonzalez, G. A. Llamas, M. Montes-Bayón, and A. Sanz-Medel, "Detection of Transferrin Isoforms in Human Serum: Comparison of UV and ICP-MS Detection after CZE and HPLC Separations," Anal. Bioanal. Chem. 2005, 383, 390.]

Preconcentration: process of concentrating trace components of a sample prior to their analysis
has a molecular mass near 81000 and can bind two $\mathrm{Fe}^{3+}$ ions for transport through the blood. Attached to the protein are two carbohydrate chains, each terminated in one to four negatively charged sialic acid sugars. The most common form, designated $\mathrm{S}_{4}$ in Figure 25-3, contains four sialic acid groups. Transferrin molecules containing different numbers of sialic acid sugars are called isoforms and are labeled $\mathrm{S}_{2}$ through $\mathrm{S}_{6}$ in Figure 25-3. Relative amounts of different isoforms vary with certain pathological disorders. In Figure 25-3, transferrin was detected by directing eluate into an inductively coupled plasma-mass spectrometer to detect ${ }^{56} \mathrm{Fe}$ (Section 20-6). Serum species that do not contain iron are invisible to this detector.

## Applications of Ion Exchange

Ion exchange can be used to convert one salt into another. For example, we can prepare tetrapropylammonium hydroxide from a tetrapropylammonium salt of some other anion:

Ion exchange is used for preconcentration of trace components of a solution to obtain enough for analysis. For example, the GEOTRACES program (Box 20-2) is measuring Al, $\mathrm{Mn}, \mathrm{Fe}, \mathrm{Cu}, \mathrm{Zn}$, and Cd at part per trillion levels in the presence of orders-of-magnitude higher concentrations of $\mathrm{Na}^{+}, \mathrm{Ca}^{2+}$, and $\mathrm{Mg}^{2+}$ in the ocean. Trace elements are preconcentrated and separated from alkali (Group 1) and alkaline earth (Group 2) elements by passage through the Chelate-PA1 ion-exchange resin shown in Figure 25-4. Ethylenediaminetriacetic acid groups in the resin bind analyte elements quantitatively at pH 6 and above. Alkali and alkaline earth elements are weakly bound at pH 6 . The procedure is to pass 125 g of seawater (adjusted to pH 6 with ammonium acetate buffer) through 0.5 g of resin and wash away loosely bound metals with 40 mL of pH 6 buffer. Strongly retained metal ions are then quantitatively eluted in the reverse direction with 15 mL of $1 \mathrm{M} \mathrm{HNO}_{3}$. Trace metals are concentrated by a factor of 8 from 125 g of seawater into $\sim 15 \mathrm{~g}$ of eluate, and $>99.9 \%$ of alkali and alkaline earth metals are removed. Eluate is analyzed by inductively coupled plasma-mass spectrometry.

FIGURE 25-4 Nobias Chelate-PA1 resin used to preconcentrate trace metals from seawater contains ethylenediaminetriacetic acid and iminodiacetic acid groups covalently attached to hydrophilic methacrylate polymer resin. Graphs show fraction of metal ions retained by resin as a function of pH . $\mathrm{Mn}^{2+}$ and $\mathrm{Al}^{3+}$ are well retained at $\mathrm{pH} 6 . \mathrm{Na}^{+}$and $\mathrm{Ca}^{2+}$ are poorly retained at pH 6 . [Data from Y . Sohrin, S. Urushihara, S. Nakatsuka, T. Kono, E. Higo, T. Minami, K. Norisuye, and S. Umetani, "Multielemental Determination of GEOTRACES Key Trace Metals in Seawater by ICPMS after Preconcentration Using an Ethylenediaminetriacetic Acid Chelating Resin," Anal. Chem. 2008, 80, 6267.]

Ion exchange is used to purify water. Deionized water is prepared by passing water through an anion-exchange resin in its $\mathrm{OH}^{-}$form and a cation-exchange resin in its $\mathrm{H}^{+}$form. Suppose, for example, that $\mathrm{Cu}\left(\mathrm{NO}_{3}\right)_{2}$ is present in the solution. The cation-exchange resin binds $\mathrm{Cu}^{2+}$ and replaces it with $2 \mathrm{H}^{+}$. The anion-exchange resin binds $\mathrm{NO}_{3}^{-}$and replaces it with $\mathrm{OH}^{-}$. The eluate is pure water:

$$
\left.\begin{array}{cc}
\mathrm{Cu}^{2+} \xrightarrow{\mathrm{H}^{+} \text {ion exchange }} & 2 \mathrm{H}^{+} \\
2 \mathrm{NO}_{3}^{-} \xrightarrow{\mathrm{OH}^{-} \text {ion exchange }} & 2 \mathrm{OH}^{-}
\end{array}\right\} \longrightarrow \text { pure } \mathrm{H}_{2} \mathrm{O}
$$

In many laboratory buildings, tap water is purified, first, by passage through activated carbon to adsorb organic material, and then by reverse osmosis. In the latter process, water is forced by pressure through a membrane containing pores through which few molecules larger than $\mathrm{H}_{2} \mathrm{O}$ can pass. Ions do not pass through the pores because their hydrated radius is too large. Reverse osmosis removes $95-99 \%$ of ions, organic molecules, bacteria, and particles from water.
"Water polishing" equipment is used in many laboratories after reverse osmosis. The water is passed through activated carbon and then through several ion-exchange cartridges that convert ions into $\mathrm{H}^{+}$and $\mathrm{OH}^{-}$. The resulting high-purity water has a resistivity (Chapter 14, note 37) of $180000 \mathrm{ohm} \cdot \mathrm{m}(18 \mathrm{Mohm} \cdot \mathrm{cm})$, with concentrations of individual ions below $1 \mathrm{ng} / \mathrm{mL}(1 \mathrm{ppb}) .^{2}$

Cation-exchange chromatography has been used to separate enantiomers (mirror image isomers) of cationic metal complexes by elution with one enantiomer of tartrate anion. ${ }^{3}$ Tartrate has a different ion-pair formation constant with each cation enantiomer and therefore elutes one cation enantiomer from the column before the other.

In pharmaceuticals, ion-exchange resins are used for drug stabilization and as aids for tablet disintegration. Ion exchangers are also used for taste masking, for sustained-release products, as topical products for application to skin, and for ophthalmic or nasal delivery. ${ }^{4}$

Water softeners use ion exchange to remove $\mathrm{Ca}^{2+}$ and $\mathrm{Mg}^{2+}$ from "hard" water (Box 11-3).

(-)-Tartrate
(+)-Tartrate

## Simultaneous Separation of Anions and Cations on One Column

Section 24-1 described hydrophilic interaction chromatography (HILIC) with a polar stationary phase and a mixed organic-aqueous mobile phase. The zwitterionic bonded stationary phase in Figure 24-14 has fixed positive and negative charges and is useful for the simultaneous separation of cations and anions. HILIC utilizes a mixed aqueous-organic eluent. The gradient in Figure $25-5$ goes from $85 \mathrm{vol} \%$ acetonitrile to $10 \mathrm{vol} \%$ acetonitrile. Eluent strength increases as the fraction of acetonitrile decreases.

FIGURE 25-5 Separation of cations and anions on $5-\mu \mathrm{m}$ zwitterion stationary phase ZIC-HILIC ${ }^{\circledR}$ (Figure 24-14), using an evaporative light-scattering detector operating at $55^{\circ} \mathrm{C}$ and 3 bar $\mathrm{N}_{2}$. Column: $4.6 \times 250 \mathrm{~mm}$ eluted at $1 \mathrm{~mL} / \mathrm{min}$. Solvent A: 85 vol $\%$ acetonitrile- $15 \%$ aqueous buffer ( 100 mM ammonium acetate at pH 5). Solvent B: 10\% acetonitrile-90\% buffer. Gradient: 0-2 min, 100\% A; 2-22 min, linear gradient to $100 \%$ B. [From D. S. Risely and B. W. Pack, "Simultaneous Determination of Positive and Negative Counterions Using a Hydrophilic Interaction Chromatography Method," LCGC 2006, 24, 776.]

What are the ions in pristine snow? Antarctic snow provides a measure of global atmospheric chemistry because there are no local sources of pollution. One study found the following species by ion chromatography:

|  | Concentrations observed <br> $(\mu \mathrm{g} / \mathrm{L}=\mathrm{ppb})$ |  |
| :--- | :---: | :---: |
| Ion | Minimum | Maximum |
| $\mathrm{F}^{-}$ | 0.10 | 6.20 |
| $\mathrm{Cl}^{-}$ | 25 | 40100 |
| $\mathrm{Br}^{-}$ | 0.8 | 49.4 |
| $\mathrm{NO}_{3}^{-}$ | 8.6 | 354 |
| $\mathrm{SO}_{4}^{2-}$ | 10.6 | 4020 |
| $\mathrm{H}_{2} \mathrm{PO}_{4}^{-}$ | 1.8 | 49.0 |
| $\mathrm{HCO}_{2}^{-}$ | 1.1 | 45.7 |
| $\mathrm{CH}_{3} \mathrm{CO}_{2}^{-}$ | 5.0 | 182 |
| $\mathrm{CH}_{3} \mathrm{SO}_{3}^{-}$ | 1.1 | 281 |
| $\mathrm{NH}_{4}^{+}$ | 2.4 | 46.5 |
| $\mathrm{Na}^{+}$ | 15 | 17050 |
| $\mathrm{~K}^{+}$ | 3.1 | 740 |
| $\mathrm{Mg}^{2+}$ | 2.7 | 1450 |
| $\mathrm{Ca}^{2+}$ | 12.6 | 1010 |

## 25-2 Ion Chromatography

Ion chromatography, a high-performance version of ion-exchange chromatography, is generally the method of choice for anion analysis. ${ }^{5}$ In the semiconductor industry, it is used to monitor anions and cations at $0.1-\mathrm{ppb}$ levels in deionized water.

## Suppressed-Ion Anion and Cation Chromatography

In suppressed-ion anion chromatography (Figure 25-6a), a mixture of anions is separated by ion exchange and detected by electrical conductivity. The key feature of suppressed-ion chromatography is removal of unwanted electrolyte prior to conductivity measurement.

For the sake of illustration, consider a sample containing $\mathrm{NaNO}_{3}$ and $\mathrm{CaSO}_{4}$ injected into the separator column-an anion-exchange column in the hydroxide form-followed by elution with $\mathrm{KOH} . \mathrm{NO}_{3}^{-}$and $\mathrm{SO}_{4}^{2-}$ equilibrate with the resin and are slowly displaced by $\mathrm{OH}^{-}$ eluent. $\mathrm{Na}^{+}$and $\mathrm{Ca}^{2+}$ cations are not retained and simply wash through. Eventually, $\mathrm{KNO}_{3}$ and $\mathrm{K}_{2} \mathrm{SO}_{4}$ are eluted from the separator column, as shown in the upper graph of Figure 25-6a. These species cannot be easily detected, however, because eluate contains a high concentration of KOH , whose high conductivity obscures that of analyte.

To remedy this problem, the solution next passes through a suppressor, in which cations are replaced by $\mathrm{H}^{+} . \mathrm{H}^{+}$exchanges with $\mathrm{K}^{+}$, in this example, through a cation-exchange membrane in the suppressor. $\mathrm{H}^{+}$diffuses from high concentration outside the membrane to low concentration inside the membrane. $\mathrm{K}^{+}$diffuses from high concentration inside to low concentration outside. $\mathrm{K}^{+}$is carried away outside the membrane, so its concentration is always low on the outside. The net result is that KOH eluent, which has high conductivity, is converted into $\mathrm{H}_{2} \mathrm{O}$, which has low conductivity. When analyte is present, $\mathrm{HNO}_{3}$ or $\mathrm{H}_{2} \mathrm{SO}_{4}$ with high conductivity is produced and detected.

FIGURE 25-6 Schematic illustrations of (a) suppressed-ion anion chromatography and (b) suppressed-ion cation chromatography.

Suppressed-ion cation chromatography is conducted in a similar manner, but the suppressor replaces $\mathrm{Cl}^{-}$from eluent with $\mathrm{OH}^{-}$through an anion-exchange membrane. Figure 25-6b illustrates the separation of $\mathrm{NaNO}_{3}$ and $\mathrm{CaSO}_{4}$. With HCl eluent, NaCl and $\mathrm{CaCl}_{2}$ emerge from the cation-exchange separator column, and NaOH and $\mathrm{Ca}(\mathrm{OH})_{2}$ emerge from the suppressor column. HCl eluate is converted into $\mathrm{H}_{2} \mathrm{O}$ in the suppressor.

Figure 25-7 illustrates a student experiment to measure ions in pond water. Eluent for the anion separation was $\mathrm{NaHCO}_{3} / \mathrm{Na}_{2} \mathrm{CO}_{3}$ buffer. The product from eluent after passing through the suppressor is $\mathrm{H}_{2} \mathrm{CO}_{3}$, which has low conductivity.

In automated systems, $\mathrm{H}^{+}$and $\mathrm{OH}^{-}$eluents and suppressors are generated by electrolysis of $\mathrm{H}_{2} \mathrm{O}$. Figure 25-8 shows a system that generates KOH for $>1000$ hours of isocratic or gradient elution before it is necessary to refresh the reagents. Water in the reservoir of aqueous $\mathrm{K}_{2} \mathrm{HPO}_{4}$ reacts at the metal anode to produce $\mathrm{H}^{+}$and $\mathrm{O}_{2}(\mathrm{~g})$. $\mathrm{H}^{+}$combines with $\mathrm{HPO}_{4}^{-}$ to form $\mathrm{H}_{2} \mathrm{PO}_{4}^{2-}$. For each $\mathrm{H}^{+}$ion that is generated, one $\mathrm{K}^{+}$ion migrates through the cationexchange barrier membrane, which transports $\mathrm{K}^{+}$, but not anions, and allows negligible liquid to pass. The barrier membrane must withstand the high pressure of liquid in the KOH generation chamber destined for the chromatography column. For each $\mathrm{H}^{+}$generated at the

FIGURE 25-7 Ion chromatography of pond water. Upper chromatograms were obtained from mixtures of standards. Concentrations of ions in lower chromatograms from pond water are in units of $\mu \mathrm{g} / \mathrm{mL}$ (ppm). Anion analysis was done with an IonPac AS14 column with $1.0 \mathrm{mM} \mathrm{NaHCO} 3 / 3.5 \mathrm{mM} \mathrm{Na} 2 \mathrm{CO}_{3}$ eluent with ion suppression and conductivity detection. Cation analysis used an IonPac CS12A column with $11 \mathrm{mM} \mathrm{H} \mathrm{SO}_{4}$ eluent, ion suppression, and conductivity detection. [From K. Sinniah and K. Piers, "Ion Chromatography: Analysis of lons in Pond Waters," J. Chem. Ed. 2001, 78, 358.]

The separator column separates analytes, and the suppressor replaces ionic eluent with a nonionic species.

Benzene-1,4-diammonium cation is a stronger eluent that can be used instead of $\mathrm{H}^{+}$for suppressed-ion cation chromatography. After suppression, a neutral product is formed:

Benzene-1,4-diammonium ion

FIGURE 25-8 Electrolytic KOH eluent generator for ion chromatography. [Adapted from Y. Liu, K. Srinivasan, C. Pohl, and N. Avdalovic, "Recent Developments in Electrolytic Devices for Ion Chromatography," J. Biochem. Biophys. Methods 2004, 60, 205.]

FIGURE 25-9 Anion separation by ion chromatography with a gradient of electrolytically generated KOH and conductivity detection after suppression. Column: Dionex IonPac AS11; 4 mm diameter; flow = $2.0 \mathrm{~mL} / \mathrm{min}$, Eluent: 0.5 mM KOH for $2.5 \mathrm{~min}, 0.5$ to 5.0 mM KOH from 2.5 to $6 \mathrm{~min} ; 5.0$ to 38.2 mM KOH from 6 to 18 min . Peaks: (1) quinate, (2) $\mathrm{F}^{-}$, (3) acetate, (4) propanoate, (5) formate, (6) methylsulfonate, (7) pyruvate, (8) valerate, (9) chloroacetate, (10) $\mathrm{BrO}_{3}^{-}$, (11) $\mathrm{Cl}^{-}$, (12) $\mathrm{NO}_{2}^{-}$, (13) trifluoroacetate, (14) $\mathrm{Br}^{-}$,
(15) $\mathrm{NO}_{3}^{-}$, (16) $\mathrm{ClO}_{3}^{-}$, (17) selenite, (18) $\mathrm{CO}_{3}^{2-}$, (19) malonate, (20) maleate, (21) $\mathrm{SO}_{4}^{2-}$, (22) $\mathrm{C}_{2} \mathrm{O}_{4}^{2-}$, (23) tungstate, (24) phthalate, (25) phosphate, (26) chromate, (27) citrate, (28) tricarballylate, (29) isocitrate, (30) cis-aconitate, (31) trans-aconitate. [Courtesy Dionex Corp., Sunnywale CA.]
anode, one $\mathrm{K}^{+}$flows through the cation-exchange barrier and one $\mathrm{OH}^{-}$is generated at the cathode. Liquid exiting the KOH generation chamber contains KOH and $\mathrm{H}_{2}$. The stream passes through an anion trap that removes traces of anions such as carbonate and degradation products from the ion-exchange resin. The trap is continuously replenished with electrolytically generated $\mathrm{OH}^{-}$, which is not shown in the diagram. After the trap, liquid flows through a polymeric capillary that is permeable to $\mathrm{H}_{2}$, which diffuses into an external liquid stream and is removed. The concentration of KOH produced by the apparatus in Figure $25-8$ is governed by the liquid flow rate and the electric current. With computer control of the power supply, a precise gradient can be generated.

In the past, KOH eluent was usually contaminated with $\mathrm{CO}_{3}^{2-}$. When $\mathrm{CO}_{3}^{2-}$ passes through the suppressor after the ion chromatography column, it is converted into $\mathrm{H}_{2} \mathrm{CO}_{3}$, which has some electrical conductivity that interferes with detection of analytes. In gradient elution with increasing KOH , the concentration of $\mathrm{H}_{2} \mathrm{CO}_{3}$ also increases, and so does the background conductivity. The feedstock for the electrolytic generator is pure $\mathrm{H}_{2} \mathrm{O}$, and the product is aqueous KOH containing very little $\mathrm{CO}_{3}^{2-}$. Figure $25-9$ shows a separation of 31 anions with a hydroxide gradient.

Suppressors in Figure 25-6 have been replaced by electrolytic units such as that in Figure $25-10$, which generates $\mathrm{H}^{+}$or $\mathrm{OH}^{-}$to neutralize eluate and requires only $\mathrm{H}_{2} \mathrm{O}$ as feedstock. With electrolytic eluent generation and electrolytic suppression, ion chromatography has been

simplified and highly automated. Readily available software can be used to simulate and optimize ion chromatographic separations. ${ }^{6}$

## Ion Chromatography Without Suppression

If the ion-exchange capacity of the separator column is sufficiently low and if dilute eluent is used, ion suppression is unnecessary. Also, anions of weak acids, such as borate, silicate, sulfide, and cyanide, cannot be determined with ion suppression, because these anions are converted into very weakly conductive products (such as $\mathrm{H}_{2} \mathrm{~S}$ ).

For nonsuppressed anion chromatography, we use a resin with an exchange capacity near $5 \mu \mathrm{~mol} / \mathrm{g}$, with $10^{-4} \mathrm{M} \mathrm{Na}^{+}$or $\mathrm{K}^{+}$salts of benzoic, $p$-hydroxybenzoic, or phthalic acid as eluent. These eluents give a low background conductivity, and analyte anions are detected by a small change in conductivity as they emerge from the column. A judicious choice of pH produces an average eluent charge between 0 and -2 and provides control of eluent strength. Even dilute carboxylic acids, which are slightly ionized, are suitable eluents for some separations. Nonsuppressed cation chromatography is conducted with dilute $\mathrm{HNO}_{3}$ eluent for monovalent ions and with ethylenediammonium salts $\left({ }^{+} \mathrm{H}_{2} \mathrm{NCH}_{2} \mathrm{CH}_{2} \mathrm{NH}_{2}^{+}\right)$for divalent ions.

## Detectors

Conductivity detectors respond to all ions. In suppressed-ion chromatography, it is easy to measure analyte because eluent conductivity is reduced to near 0 by suppression. Suppression also allows us to use eluent concentration gradients.

In nonsuppressed anion chromatography, the conductivity of the analyte anion is higher than that of the eluent, so conductivity increases when analyte emerges from the column. Detection limits are normally in the mid-ppb to low-ppm range but can be lowered by a factor of 10 by using carboxylic acid eluents instead of carboxylate salts.

Benzoate or phthalate eluents enable sensitive ( $<1 \mathrm{ppm}$ ) indirect detection of anions. In Figure 25-11, eluate has strong, constant ultraviolet absorption. As each analyte emerges, nonabsorbing analyte anion replaces an equivalent amount of absorbing eluent anion. Absorbance therefore decreases when analyte appears. For cation chromatography, $\mathrm{CuSO}_{4}$ is a suitable ultraviolet-absorbing eluent.

## Ion-Pair Chromatography

Ion-pair chromatography uses a reversed-phase HPLC column instead of an ion-exchange column to separate polar or ionic compounds. ${ }^{8}$ To separate cations (for example, protonated organic bases), an anionic surfactant (Box 25-1) such as $n-\mathrm{C}_{8} \mathrm{H}_{17} \mathrm{SO}_{3}^{-}$is added to the mobile

FIGURE 25-11 Indirect spectrophotometric detection of transparent ions. The column was eluted with 1 mM sodium phthalate plus 1 mM borate buffer, pH 10. The principle of indirect detection is illustrated in Figure 25-35.

## B0X 25-1 Surfactants and Micelles

A surfactant is a molecule that accumulates at the interface between two phases and modifies the surface tension. (Surface tension is the energy per unit area needed to form a surface or interface.) Molecules with long hydrophobic tails and ionic headgroups are a common class of surfactants for aqueous solution:

Cetyltrimethylammonium bromide $\mathrm{C}_{16} \mathrm{H}_{33} \mathrm{~N}\left(\mathrm{CH}_{3}\right)_{3}^{+} \mathrm{Br}^{-}$

A micelle is an aggregate of surfactants. In water, the hydrophobic tails form clusters that are, in effect, little oil drops insulated from the aqueous phase by the ionic headgroups. At low concentration, surfactant molecules do not form micelles. When their concentration exceeds the critical micelle concentration, spontaneous aggregation into micelles occurs. ${ }^{7}$ Isolated surfactant molecules exist in equilibrium with micelles. Nonpolar organic solutes are soluble inside micelles. Cetyltrimethylammonium bromide forms micelles containing
$\sim 61$ molecules (mass $\approx 22000 \mathrm{Da}$ ) in water at $25^{\circ} \mathrm{C}$ at a critical micelle concentration of 0.9 mM .

Structure of a micelle formed when ionic molecules with long, nonpolar tails aggregate in aqueous solution. The interior of the micelle resembles a nonpolar organic solvent, whereas the exterior charged groups interact strongly with water. [From F. M. Menger, R. Zana, and B. Lindman, "Portraying the Structure of Micelles," J. Chem. Ed. 1998, 75, 115.]

FIGURE 25-12 Ion-pair chromatography. The surfactant sodium octanesulfonate added to the mobile phase binds to the nonpolar stationary phase. Negative sulfonate groups protruding from the stationary phase then act as ion-exchange sites for analyte cations such as protonated organic bases, $\mathrm{BH}^{+}$.
phase. The surfactant lodges in the stationary phase, effectively transforming the stationary phase into an ion exchanger (Figure 25-12). Analyte cations are attracted to the surfactant anions. ${ }^{9}$ The retention mechanism is a mixture of reversed-phase and ion-exchange interactions. To separate anions, tetrabutylammonium salts can be added to the mobile phase as the ion-pair reagent (Figure 25-13).

Ion-pair chromatography is more complex than reversed-phase chromatography because equilibration of the surfactant with the stationary phase is slow, the separation is more sensitive to variations in temperature and pH , and the concentration of surfactant affects the separation. Methanol is the organic solvent of choice because ionic surfactants are more soluble in methanol/water mixtures than in acetonitrile/water mixtures. Strategies for method development analogous to the scheme in Figure 24-27 vary the pH and surfactant concentration with fixed methanol concentration and temperature. ${ }^{10}$ Because of the slow equilibration of surfactant with the stationary phase, gradient elution is not recommended in ion-pair chromatography. Many ion-pair reagents have significant ultraviolet absorption, which makes ultraviolet detection of analytes problematic. Reversed-phase stationary phases with a polar embedded group (page 602) are a possible alternative to ion-pair chromatography for polar compounds.

FIGURE 25-13 Separation of carbohydrates by ion-pair chromatography. Carbohydrates were derivatized by covalently attaching $p$-aminobenzoate $\left(\mathrm{H}_{2} \mathrm{~N}-\mathrm{C}_{6} \mathrm{H}_{4}-\mathrm{CO}_{2}^{-}\right)$, which changes carbohydrates into fluorescent anions. The anions were separated on a $0.30 \times 25 \mathrm{~cm}$ column of AQUA $^{\circledR} \mathrm{C}_{18}$-silica, using tetrabutylammonium cation as the ion-pair reagent. Eluent was a linear $60-\mathrm{min}$ gradient starting with 20 mM aqueous $\left(n-\mathrm{C}_{4} \mathrm{H}_{9}\right)_{4} \mathrm{~N}^{+} \mathrm{HSO}_{4}^{-}, \mathrm{pH} 2.0$ (solvent A ) and ending with 50:50 A:methanol. The method was used to measure carbohydrates at $10-$ to $100-\mathrm{ng} / \mathrm{mL}$ levels in water leaching from landfills. [From A. Meyer, C. Raba, and K. Fischer, "Ion-Pair HPLC Determination of Sugars, Amino Sugars, and Uronic Acids," Anal. Chem. 2001, 73, 2377.]

## 25-3 Molecular Exclusion Chromatography

In molecular exclusion chromatography (also called size exclusion or gel filtration or gel permeation chromatography), molecules are separated according to size. ${ }^{11}$ Small molecules penetrate the pores in the stationary phase, but large molecules do not (Figure 22-6). Because small molecules must pass through an effectively larger volume, large molecules are eluted first (Figure 25-14). This technique is widely used in biochemistry to purify macromolecules.

Salts of low molecular mass (or any small molecule) can be removed from solutions of large molecules by gel filtration because the large molecules are eluted first. This technique, called desalting, is useful for changing the buffer composition of a macromolecule solution.

## The Elution Equation

The total volume of mobile phase in a chromatography column is $V_{\mathrm{m}}$, which includes solvent inside and outside the gel particles. The volume of mobile phase outside the gel particles is called the void volume, $V_{\mathrm{o}}$. The volume of solvent inside the gel is therefore $V_{\mathrm{m}}-V_{\mathrm{o}}$. The quantity $K_{\text {av }}$ (read " $K$ average") is defined as

$$
\begin{equation*}
K_{\mathrm{av}}=\frac{V_{\mathrm{r}}-V_{\mathrm{o}}}{V_{\mathrm{m}}-V_{\mathrm{o}}} \tag{25-6}
\end{equation*}
$$

where $V_{\mathrm{r}}$ is the retention volume for a solute. For a large molecule that does not penetrate the gel, $V_{\mathrm{r}}=V_{\mathrm{o}}$, and $K_{\mathrm{av}}=0$. For a small molecule that freely penetrates the gel, $V_{\mathrm{r}}=V_{\mathrm{m}}$, and $K_{\mathrm{av}}=1$. Molecules of intermediate size penetrate some gel pores, but not others, so $K_{\mathrm{av}}$ is between 0 and 1. Ideally, gel penetration is the only mechanism by which molecules are retained in this type of chromatography. In fact, there is always some adsorption, so $K_{\mathrm{av}}$ can be greater than 1 .

Void volume is measured by passing a large, inert molecule through the column. ${ }^{12}$ Its elution volume is defined as $V_{\text {o }}$. Blue Dextran 2000, a blue dye of molecular mass $2 \times 10^{6}$, is commonly used for this purpose. The volume $V_{\mathrm{m}}$ can be calculated from the measured column bed volume per gram of dry gel. For example, 1 g of dry Sephadex G-100 occupies 15 to 20 mL , when swollen with aqueous solution. The solid phase of the swollen gel occupies only $\sim 1 \mathrm{~mL}$, so $V_{\mathrm{m}}$ is 14 to 19 mL , or $93-95 \%$ of the total column volume. Equal masses of different solid phases produce widely varying volumes when swollen with solvent.

## Stationary Phase ${ }^{13}$

Gels for open-column, preparative-scale molecular exclusion include Sephadex (Table 25-4), whose structure was given in Figure 25-2, and Bio-Gel P, which is a polyacrylamide crosslinked by $N, N^{\prime}$-methylenebisacrylamide (Figure 25-15). The smallest pore sizes in highly cross-linked gels exclude molecules with a molecular mass $\gtrsim 700$, whereas the largest pore sizes exclude molecules with molecular mass $\gtrsim 10^{8}$. The finer the particle size of the gel, the greater the resolution and the slower the flow rate of the column. Hydrophilic HPLC packings for molecular exclusion are made of poly(vinyl alcohol), polyacrylamide, and sulfonated polystyrene. Silica (Table 25-4) with controlled pore size provides $10000-16000$ plates per meter. The silica is coated with a hydrophilic phase to minimize solute adsorption. A hydroxylated polyether resin with a well-defined pore size can be used over the pH range 2-12, whereas silica phases generally cannot be used above pH 8 . Particles with different pore sizes can be mixed to give a wider molecular size separation range.

Large molecules pass through the column faster than small molecules do.
Gel filtration: usually refers to a hydrophilic stationary phase and aqueous eluent Gel permeation: usually refers to hydrophobic stationary phase and organic eluent

In pure molecular exclusion, all molecules are eluted between $K_{\mathrm{av}}=0$ and $K_{\mathrm{av}}=1$.

FIGURE 25-14 (a) Large molecules cannot penetrate the pores of the stationary phase. They are eluted by a volume of solvent equal to the volume of mobile phase. (b) Small molecules, which can be found inside or outside the gel, require a larger volume for elution. $V_{\mathrm{t}}$ is the total column volume occupied by gel plus solvent. $V_{\mathrm{o}}$ is the volume of solvent outside the gel particles. $V_{\mathrm{m}}$ is the total volume of solvent inside and outside the gel particles.

TABLE 25-4 Representative molecular exclusion media

| Gel filtration in open columns |  |  | TSK SW silica for HPLC |  |
| :--- | :---: | :--- | :---: | :---: |
|  | Fractionation range for <br> globular proteins (Da) | Name | Pore size <br> $(\mathrm{nm})$ | Fractionation range for <br> globular proteins (Da) |
| Same | to 700 | G2000SW | 13 | $500-60000$ |
| Sephadex G-10 | $1000-5000$ | G3000SW | 24 | $1000-300000$ |
| Sephadex G-25 | $1500-30000$ | G4000SW | 45 | $5000-1000000$ |
| Sephadex G-75 | $3000-80000$ | G5000SW | 100 | $>1500000$ |
| Sephadex G-100 | $4000-150000$ |  |  |  |
| Sephadex G-200 | $5000-600000$ |  |  |  |

NOTE: Sephadex is manufactured by GE Amersham Biosciences. TSK SW silica is manufactured by Tosoh Corp.

FIGURE 25-15 Structure of polyacrylamide.

For HPLC of hydrophobic polymers, cross-linked polystyrene spheres are available, with pore sizes ranging from 5 nm up to hundreds of nanometers. Particles with a $5-\mu \mathrm{m}$ diameter yield up to 80000 plates per meter of column length.

## Molecular Mass Determination

Gel filtration is used mainly to separate molecules of significantly different molecular sizes (Figure 25-16). For each stationary phase, we construct a calibration curve, which is a graph of $\log$ (molecular mass) versus elution volume (Figure 25-17). We estimate the molecular mass of an unknown by comparing its elution volume with those of standards. We must exercise caution in interpreting results, however, because molecules with the same molecular mass but different shapes exhibit different elution characteristics. For proteins, it is important to use an ionic strength high enough ( $>0.05 \mathrm{M}$ ) to eliminate electrostatic adsorption of solute by occasional charged sites on the gel.

Nanoparticles can be separated by molecular exclusion chromatography just as proteins are separated. Figure 25-18 shows the relation between measured size and retention time of

FIGURE 25-17 Molecular mass calibration graph for polystyrene on Beckman $\mu$ Spherogel molecular exclusion column $(0.77 \times 30 \mathrm{~cm})$. Resin pore size labeled on the lines ranges from 5 nm to $100 \mu \mathrm{~m}$. [Courtesy Anspec Co., Ann Arbor, MI.]

FIGURE 25-18 Larger CdSe quantum dots are eluted before smaller quantum dots by 0.1 M trioctylphosphine in toluene at $1.0 \mathrm{~mL} / \mathrm{min}$ in size exclusion chromatography on a $7.5 \times 300 \mathrm{~mm}$ cross-linked polystyrene column of Polymer Labs PLgel $5 \mu \mathrm{~m}$ with 100 -nm pore size. Triangles are CdSe, and squares are polystyrene calibration standards. The size of the CdSe core was measured with a transmission electron microscope, and the length of 1-dodecanethiol endcaps ( 0.123 nm ) was added to the radius. [Data from K. M. Krueger, A. M. Al-Somali, J. C. Falkner, and V. L. Colvin, "Characterization of Nanocrystalline CdSe by Size Exclusion Chromatography," Anal. Chem. 2005, 77, 3511.]

CdSe quantum dots. These are particles containing $\sim 2000 \mathrm{CdSe}$ units in a dense, crystalline core capped by alkyl thiol (RS) groups on Cd and trialkylphosphine $\left(\mathrm{R}_{3} \mathrm{P}\right)$ groups on Se . Quantum dots are useful because the wavelength of their visible emission depends on their size. Size is controlled during synthesis of the quantum dot by reaction time or other conditions. Quantum dots with different sizes can be used as spectroscopic labels in biological experiments. ${ }^{14}$

## 25-4 Affinity Chromatography

Affinity chromatography is used to isolate a single compound from a complex mixture. The technique is based on specific binding of that one compound to the stationary phase (Figure 22-6). When sample is passed through the column, only one solute is bound. After everything else has washed through, the one adhering solute is eluted by changing a condition such as pH or ionic strength to weaken its binding. Affinity chromatography is especially applicable in biochemistry and is based on specific interactions between enzymes and substrates, antibodies and antigens, or receptors and hormones.

Figure 25-19 shows the isolation of the protein immunoglobulin $\mathrm{G}(\mathrm{IgG})$ by affinity chromatography on a column containing covalently bound protein A. Protein A binds to one specific region of $\operatorname{IgG}$ at $\mathrm{pH} \gtrsim 7.2$. When a crude mixture containing IgG and other proteins was passed through the column at pH 7.6 , everything except IgG was eluted within 0.3 min . At 1 min , the eluent pH was lowered to 2.6 and IgG was cleanly eluted at 1.3 min .

Optical isomers of a drug can have completely different therapeutic effects. Affinity chromatography can be used to isolate individual optical isomers for drug evaluation. ${ }^{15}$ The

FIGURE 25-19 Purification of monoclonal antibody $\lg G$ by affinity chromatography on a $0.46 \times 5 \mathrm{~cm}$ column containing protein A covalently attached to polymer support. Other proteins in the sample are eluted from 0 to 0.3 min at pH 7.6 . When eluent pH is lowered to $2.6, \operatorname{lgG}$ is freed from protein A and emerges from the column. [From B. J. Compton and L. Kreilgaard, "Chromatographic Analysis of Therapeutic Proteins," Anal. Chem. 1994, 66, 1175A.]

A molecularly imprinted polymer is synthesized in the presence of a template molecule to which components of the polymer have some affinity. When the template is removed, the polymer is "imprinted" with the shape of the template and with complementary functional groups that can bind the template. The template can be the analyte of interest, but it is better to use a structurally related molecule so that residual template in the polymer does not give false positive results when the polymer is employed. Imprinted polymer can be used as a stationary phase in affinity chromatography or a recognition element in a chemical sensor.

A molecularly imprinted polymer can be used to collect and preconcentrate penicillin antibiotics from river water for analysis. The figure shows a conceptual structure of a polymer pocket formed when monomers are polymerized with penicillin $G$ as a template. After removing penicillin $G$ by washing with methanol and HCl , the pocket retains its shape and arrangement of functional groups to bind similar molecules, such as penicillin V , which is shown in color.

When river water spiked with $30-\mathrm{ppb}$ levels of eight different penicillin variants was passed through a column containing imprinted polymer, $90-99 \%$ of six of the penicillins were retained by the column. Two penicillin variants did not bind as well. Penicillins retained by the
column were eluted by a small volume of 0.05 M tetrabutylammonium hydrogen sulfate in methanol and analyzed by HPLC.

Notional structure of pocket in a polymer imprinted to bind penicillin derivatives. [From J. L. Urraca, M. C. Moreno-Bondi, A. J. Hall, and B. Sellergren, "Direct Extraction of Penicillin G and Derivatives from Aqueous Samples Using a Stoichiometrically Imprinted Polymer," Anal. Chem. 2007, 79, 695.]

Water does not wet a hydrophobic surface made of carbon nanotubes, so a drop remains almost spherical. The drop would flatten out on a hydrophilic surface, such as glass. [Courtesy Karen Gleason, Massachusetts Institute of Technology. ${ }^{18}$ ]

drug candidate in the margin has two chiral carbon atoms indicated by colored dots. With two possible geometries at each site, there are four stereoisomers. The mixture of isomers was covalently attached to protein and injected into mice to raise a mixture of antibodies to all stereoisomers. Antibodies are produced by B cells in the spleen. One B cell produces only one kind of antibody. By isolating individual B cells, it is possible to isolate the gene for the antibody to each of the stereoisomers. The gene can be transplanted into E. coli cells for mass production of a single kind of antibody, called a monoclonal antibody. When the mixture of stereoisomers is passed through a column to which just one kind of antibody is attached, only one of the four stereoisomers is retained. By lowering the pH , the retained isomer is eluted in pure form.

Box 25-2 shows how molecularly imprinted polymers can be used as affinity media. Aptamers (Section 18-5) are another class of chromatographically useful compounds with high affinity for a selected target. ${ }^{17}$

## 25-5 Hydrophobic Interaction Chromatography

Hydrophobic substances repel water, and their surfaces are not wetted by water. A protein can have hydrophilic regions that make it soluble in water and hydrophobic regions capable of interacting with a hydrophobic stationary chromatography phase. High concentrations of ammonium sulfate cause proteins to salt out of solution. Ammonium, sodium, and potassium salts of phosphate and sulfate decrease the solubility of proteins in water. Thiocyanate, iodide, and perchlorate salts have the opposite effect of dissolving proteins.

Hydrophobic interaction chromatography is used principally for protein purification. ${ }^{19}$ A common stationary phase shown in Figure $25-20$ has hydrophobic phenyl or alkyl groups attached to agarose gel (a polysaccharide) whose pore size is large enough for proteins to enter. When protein solution with a high concentration (such as 1 M ) of ammonium sulfate is applied to the column, the salt induces the protein to bind to the hydrophobic surface of the stationary phase. Then a gradient of decreasing salt concentration is applied to increase the solubility of proteins in water and elute them from the column.

## 25-6 Principles of Capillary Electrophoresis ${ }^{20,21}$

Late in 2007, more than 200 people receiving the anticoagulant heparin suffered acute, allergic reactions and died. ${ }^{22}$ Heparin is a complex mixture of sulfate-substituted polysaccharides that have molecular masses of 2 to 50 kDa and are isolated from pig intestines. As soon as the
problem was recognized in January 2008, U.S. distributors recalled heparin products and the U.S. Food and Drug Administration launched an investigation. Heparin is administered thousands of times every day to manage life-threatening conditions, so an immediate understanding and solution to the problem were required.

When exposed to the enzyme heparinase, heparin is cleaved into disaccharide units. Tainted heparin contained 20 to $50 \mathrm{wt} \%$ of macromolecular components that did not react with heparinase. Capillary electrophoresis proved to be the tool of choice to observe two contaminants (Figure 25-21). ${ }^{23}$ One was dermatan sulfate, which was not known to cause allergic reactions. The other was identified by nuclear magnetic resonance as oversulfated chondroitin sulfate. An animal study verified that oversulfated chondroitin sulfate caused the allergic reaction. By March 2008, deaths from contaminated heparin had ceased and emergency regulations were issued to incorporate capillary electrophoresis and nuclear magnetic resonance into required testing of heparin imported into the U.S. Contaminated heparin had been prepared in China. Oversulfated chondroitin sulfate might have been added because it has anticoagulant activity and costs less than heparin.

Electrophoresis is the migration of ions in solution under the influence of an electric field. The technique was pioneered in the 1930s by the Swedish biophysical chemist A. Tiselius, who received the Nobel Prize in 1948 for his work on electrophoresis and "discoveries concerning the complex nature of serum proteins."

In capillary electrophoresis, shown in Figure 25-22, components of a solution are separated by applying a voltage of $\sim 30 \mathrm{kV}$ from end to end of a fused-silica $\left(\mathrm{SiO}_{2}\right)$ capillary tube that is 50 cm long and has an inner diameter of $25-75 \mu \mathrm{~m}$. Different ions have different mobilities and migrate through the capillary at different speeds. ${ }^{25}$ Modifications of this experiment described later allow neutral molecules, as well as ions, to be separated. Electrophoresis can separate whole cells for medical diagnosis and detection of food contamination. ${ }^{26}$ Electrophoresis can analyze single cells, nuclei, vesicles, or mitochondria. ${ }^{27}$ Single-cell enzyme assays have detection limits at the zeptomol ( $10^{-21} \mathrm{~mol}$ ) level. ${ }^{28}$

Capillary electrophoresis provides high resolution. When we conduct chromatography in a packed column, peaks are broadened by three mechanisms in the van Deemter equation (22-33): multiple flow paths, longitudinal diffusion, and finite rate of mass transfer. An open tubular column eliminates multiple paths and thereby reduces plate height and improves resolution. Capillary electrophoresis reduces plate height further by knocking out the mass transfer term that comes from the finite time needed for solute to equilibrate between the mobile and stationary phases. In capillary electrophoresis, there

FIGURE 25-21 Electropherogram of heparin ( $30 \mathrm{mg} / \mathrm{mL}$ ) spiked with oversulfated chondroitin sulfate and dermatan sulfate. Tainted heparin had $\sim 200$ times more oversulfated chondroitin sulfate than shown here. Conditions: $-16 \mathrm{kV}, 20^{\circ} \mathrm{C}, 25 \mu \mathrm{~m} \times 30 \mathrm{~cm}$ capillary, detector at 21.5 cm . Background buffer was made by adding $0.60 \mathrm{M} \mathrm{H}_{3} \mathrm{PO}_{4}$ to $0.60 \mathrm{M} \mathrm{Li}_{3} \mathrm{PO}_{4}$ to reach pH 2.8 . [Courtesy Robert Weinberger, CE Technologies and Todd Wielgos, Baxter Healthcare. For details, see T. Wielgos, K. Havel, N. Ivanova, and R. Weinberger, "Determination of Impurities in Heparin by Capillary Electrophoresis using High Molarity Phosphate Buffers," J. Pharma. Biomed. Anal. 2009, 49, 319.]

FIGURE 25-20 Stationary phase for hydrophobic interaction chromatography has ~ 10-20\% as many bonded phenyl or alkyl groups per unit volume as a reversed-phase stationary phase.

Cations are attracted to the negative terminal (the cathode).
Anions are attracted to the positive terminal (the anode).

Electric potential difference $=30 \mathrm{kV}$
Electric field $=\frac{30 \mathrm{kV}}{0.50 \mathrm{~m}}=60 \frac{\mathrm{kV}}{\mathrm{m}}$

FIGURE 25-22 Apparatus for capillary electrophoresis. One way to inject sample is to place the capillary in a sample vial and apply pressure to the vial or suction at the outlet of the capillary. The use of an electric field for sample injection is described in the text.

Electrophoresis in glass capillaries was first described by J. W. Jorgenson in 1981. ${ }^{24}$

FIGURE 25-23 Comparison of peak widths for benzyl alcohol $\left(\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{CH}_{2} \mathrm{OH}\right)$ in capillary electrophoresis and HPLC. [From S. Fazio, R. Vivilecchia, L. Lesueur, and J. Sheridan, Am. Biotech. Lab., January 1990, p. 10.]

is no stationary phase. The only fundamental source of broadening under ideal conditions is longitudinal diffusion:

Multiple path term eliminated by open tubular column
(Other sources of broadening in real systems are mentioned later.) Capillary electrophoresis routinely produces $50000-500000$ theoretical plates (Figure 25-23), a performance that is an order-of-magnitude better than that of chromatography.

## Electrophoresis

When an ion with charge $q$ (coulombs) is placed in an electric field $E(\mathrm{~V} / \mathrm{m})$, the force on the ion is $q E$ (newtons). In solution, the retarding frictional force is $f u_{\text {ep }}$, where $u_{\text {ep }}$ is the velocity of the ion and $f$ is the friction coefficient. The subscript "ep" stands for "electrophoresis." The ion quickly reaches a steady speed when the accelerating force equals the frictional force:

$$
\begin{array}{c|c|ccc}
+ \\
+ \\
+ & \stackrel{f u_{\mathrm{ep}}}{\hookleftarrow} & q E & q E & = \\
& & f u_{\mathrm{ep}} \\
- & \text { Accelerating } & \text { Frictional } \\
- & \text { force } & \text { force }
\end{array}
$$

Electrophoretic mobility:

$$
\begin{array}{r}
u_{\mathrm{ep}}=\frac{q}{f} E \equiv \mu_{\mathrm{ep}} E  \tag{25-8}\\
\uparrow \\
\text { Electrophoretic mobility }
\end{array}
$$

Electrophoretic mobility ( $\mu_{\mathrm{ep}}$ ) is the constant of proportionality between the speed of the ion and electric field strength. Mobility is proportional to the charge of the ion and inversely proportional to the friction coefficient. For molecules of similar size, mobility increases with charge:

$\mu_{\mathrm{ep}}=-2.54 \times 10^{-8} \frac{\mathrm{~m}^{2}}{\mathrm{~V} \cdot \mathrm{~s}}$

$$
\mu_{\mathrm{ep}}=-4.69 \times 10^{-8} \frac{\mathrm{~m}^{2}}{\mathrm{~V} \cdot \mathrm{~s}}
$$

$$
\mu_{\mathrm{ep}}=-5.95 \times 10^{-8} \frac{\mathrm{~m}^{2}}{\mathrm{~V} \cdot \mathrm{~s}}
$$

For a spherical particle of radius $r$ moving through a fluid of viscosity $\eta$, the friction coefficient, $f$, is

Stokes equation:

$$
\begin{equation*}
f=6 \pi \eta r \tag{25-9}
\end{equation*}
$$

Mobility is $q / f$, so the greater the radius, the lower the mobility. Most molecules are not spherical, but Equation 25-9 defines an effective hydrodynamic radius of a molecule, as if it were a sphere, based on its observed mobility.

## Electroosmosis

The inside wall of a fused-silica capillary is covered with silanol (Si-OH) groups, which have a negative charge $\left(\mathrm{Si}-\mathrm{O}^{-}\right)$above pH 3 . Figure 25-24a shows the electric double layer (Box 16-3) at the capillary surface. The double layer consists of fixed negative charges on the wall and excess cations near the wall. A tightly adsorbed, immobile layer of cations partially neutralizes the negative charge. The remaining negative charge is neutralized by mobile cations in the diffuse part of the double layer in solution near the wall. The thickness of the diffuse part of the double layer ranges from $\sim 10 \mathrm{~nm}$ when the ionic strength is 1 mM to $\sim 0.3 \mathrm{~nm}$ when the ionic strength is 1 M .

In an electric field, cations are attracted to the cathode and anions are attracted to the anode (Figure 25-24b). Excess cations in the diffuse part of the double layer impart net momentum toward the cathode. This pumping action, called electroosmosis (or electroendosmosis), is driven by cations within $\sim 10 \mathrm{~nm}$ of the walls and creates uniform pluglike electroosmotic flow of the entire solution toward the cathode (Figure 25-25a). This process is in sharp contrast with hydrodynamic flow, which is driven by a pressure difference. In hydrodynamic flow, the velocity profile through a cross section of the fluid is parabolic: It is fastest at the center and slows to 0 at the walls (Figure 25-25b and Color Plate 30).

FIGURE 25-24 (a) Electric double layer created by negatively charged silica surface and nearby cations. (b) Predominance of cations in diffuse part of the double layer produces net electroosmotic flow toward the cathode when an external field is applied.

Viscosity measures resistance to flow in a fluid. The units are $\mathrm{kg} \mathrm{m}^{-1} \mathrm{~s}^{-1}$. Relative to water, maple syrup is very viscous and hexane has low viscosity.

Ions in the diffuse part of the double layer adjacent to the capillary wall are the "pump" that drives electroosmotic flow.

FIGURE 25-25 (a) Electroosmosis gives uniform flow over more than $99.9 \%$ of the cross section of the capillary. The speed decreases immediately adjacent to the capillary wall. (b) Parabolic velocity profile of hydrodynamic flow (also called laminar flow), with the highest velocity at the center of the tube and zero velocity at the walls. Experimentally observed velocity profiles are shown in Color Plate 30.

Electroosmotic velocity is measured by adding to the sample a neutral molecule to which the detector responds.
distance from injector

| Electroosmotic |
| :--- |
| velocity |$=\frac{$|  distance from injector  |
| :---: |
|  to detector  |}{|  migration time of  |
| :---: |
|  neutral molecule  |}

The capillary must be thin enough to dissipate heat rapidly. Temperature gradients disturb the flow and reduce resolution.

Speed $=\frac{\text { distance to detector }}{\text { migration time }}=\frac{L_{\mathrm{d}}}{t}$
Electric field $=\frac{\text { applied voltage }}{\text { capillary length }}=\frac{V}{L_{t}}$

For quantitative analysis, use
Peak area
$\overline{\text { Migration time }}$

The constant of proportionality between electroosmotic velocity, $u_{\mathrm{e} \text { e }}$, and applied field is called electroosmotic mobility, $\mu_{\mathrm{eo}}$.

Electroosmotic mobility:

$$
\begin{gather*}
u_{\mathrm{eo}}=\mu_{\mathrm{eo}} E  \tag{25-10}\\
\uparrow \\
\begin{array}{c}
\text { Electroosmotic mobility } \\
(\text { units }=
\end{array} \mathrm{m}^{2} /[\mathrm{V} \cdot \mathrm{~s}] \text { ) }
\end{gather*}
$$

Electroosmotic mobility is proportional to the surface charge density on the silica and inversely proportional to the square root of ionic strength. Electroosmosis decreases at low pH ( $\mathrm{Si}-\mathrm{O}^{-} \rightarrow \mathrm{Si}-\mathrm{OH}$ decreases surface charge density) and high ionic strength. At pH 9 in 20 mM borate buffer, electroosmotic flow is $\sim 2 \mathrm{~mm} / \mathrm{s}$. At pH 3 , flow is reduced by an order of magnitude.

Uniform electroosmotic flow contributes to the high resolution of capillary electrophoresis. Any effect that decreases uniformity creates band broadening and decreases resolution. The flow of ions in the capillary generates heat (called Joule heating) at a rate of $I^{2} R$ joules per second, where $I$ is current (A) and $R$ is the resistance of the solution (ohms) (Section 13-1). Most of the capillary in Figure 25-22 is in a water-thermostated compartment necessary for temperature control inside the capillary. ${ }^{29}$ Typically, the centerline of the capillary channel is 0.02 to 0.3 K hotter than the edge of the channel. Lower viscosity in the warmer region disturbs the flat electroosmotic profile of the fluid. Joule heating is not a serious problem in a capillary tube with a diameter of $50 \mu \mathrm{~m}$, but the temperature gradient would be prohibitive if the diameter were $\geq 1 \mathrm{~mm}$. Some instruments cool the capillary to reduce the electrical conductivity of solution inside the capillary and prevent runaway Joule heating.

## Mobility

The apparent (or observed) mobility, $\mu_{\text {app }}$, of an ion is the sum of the electrophoretic mobility of the ion plus the electroosmotic mobility of the solution.

## Apparent mobility:

$$
\begin{equation*}
\mu_{\mathrm{app}}=\mu_{\mathrm{ep}}+\mu_{\mathrm{eo}} \tag{25-11}
\end{equation*}
$$

For an analyte cation moving in the same direction as the electroosmotic flow, $\mu_{\mathrm{ep}}$ and $\mu_{\mathrm{eo}}$ have the same sign, so $\mu_{\text {app }}$ is greater than $\mu_{\mathrm{ep}}$. Electrophoresis transports anions in the opposite direction from electroosmosis (Figure 25-24b), so for anions the two terms in Equation 25-11 have opposite signs. At neutral or high pH , brisk electroosmosis transports anions to the cathode because electroosmosis is usually faster than electrophoresis. At low pH , electroosmosis is weak and anions may never reach the detector. If you want to separate anions at low pH , you can reverse the polarity to make the sample end negative and the detector end positive.

The apparent mobility, $\mu_{\text {app }}$, of a particular species is the net speed, $u_{\text {net }}$, of the species divided by the electric field, $E$ :

Apparent mobility:

$$
\begin{equation*}
\mu_{\mathrm{app}}=\frac{u_{\mathrm{net}}}{E}=\frac{L_{\mathrm{d}} / t}{V / L_{\mathrm{t}}} \tag{25-12}
\end{equation*}
$$

where $L_{\mathrm{d}}$ is the length of column from injection to the detector, $L_{\mathrm{t}}$ is the total length of the column from end to end, $V$ is the voltage applied between the two ends, and $t$ is the time required for solute to migrate from the injection end to the detector. Electroosmotic flow is measured by adding an ultraviolet-absorbing neutral solute to the sample and measuring its migration time, $t_{\text {neutral }}$, to the detector.

For quantitative analysis by electrophoresis, normalized peak areas are required. The normalized peak area is the measured peak area divided by the migration time. In chromatography, each analyte passes through the detector at the same rate, so peak area is proportional to the quantity of analyte. In electrophoresis, analytes with different apparent mobilities pass through the detector at different rates. The higher the apparent mobility, the shorter the migration time and the less time the analyte spends in the detector. To correct for time spent in the detector, divide the peak area for each analyte by its migration time.

Electroosmotic mobility is the speed of the neutral species, $u_{\text {neutral }}$, divided by the electric field:

Electroosmotic mobility:

$$
\begin{equation*}
\mu_{\mathrm{eo}}=\frac{u_{\text {neutral }}}{E}=\frac{L_{\mathrm{d}} / t_{\text {neutral }}}{V / L_{\mathrm{t}}} \tag{25-13}
\end{equation*}
$$

The electrophoretic mobility of an analyte is the difference $\mu_{\mathrm{app}}-\mu_{\mathrm{eo}}$.
For maximum precision, mobilities are measured relative to an internal standard. Absolute variation from run to run should not affect relative mobilities, unless there are timedependent (nonequilibrium) interactions of the solute with the wall.

For molecules of similar size, the magnitude of the electrophoretic mobility increases with charge. A protein "charge ladder" is a synthetic mixture made from a single protein with many different charges. ${ }^{30}$ For example, we can obtain such a mixture by acetylating variable numbers of lysine amino acid side chains (Table 9-1) to reduce their charge from $+1\left(\mathrm{R}-\mathrm{NH}_{3}^{+}\right)$to $0\left(\mathrm{R}-\mathrm{NHC}(=\mathrm{O}) \mathrm{CH}_{3}\right)$.

Lysine $-\mathrm{NH}_{2}$ groups have $\mathrm{p} K_{\mathrm{a}} \approx 10.3$. At $\mathrm{pH} 8.3,99 \%$ of these groups are protonated $\left(-\mathrm{NH}_{3}^{+}\right)$. Acetylation gives a mixture with every possible number of modified amino groups from 0 to the total number of lysine residues. This mixture gives the electropherogram in Figure 25-26 with a series of nearly evenly spaced peaks. Each molecule has approximately the same size and shape (and therefore nearly the same friction coefficient) but a different charge.

## EXAMPLE Mobilities in a Protein Charge Ladder

Bovine carbonic anhydrase is a protein with 18 lysine residues. The 19 peaks in Figure 25-26 arise from unmodified protein $\left(\mathrm{P}^{n-}\right)$ plus protein with every possible degree of acetylation: $\mathrm{P}^{(n+1)-}, \mathrm{P}^{(n+2)-}, \mathrm{P}^{(n+3)-}, \ldots, \mathrm{P}^{(n+18)^{-}}$. The voltage applied to the $0.840-\mathrm{m}-$ long capillary is $2.50 \times 10^{4} \mathrm{~V}$. A neutral marker molecule, carried by electroosmotic flow, requires 308 s to travel 0.640 m from the inlet to the detector. Migration times of $\mathrm{P}^{n-}$ and $\mathrm{P}^{(n+1)-}$ are 343 s and 355 s , respectively. Find the electroosmotic velocity and electroosmotic mobility. Find the apparent and electrophoretic mobilities of $\mathrm{P}^{n-}$ and $\mathrm{P}^{(n+1)-}$.

Solution Electroosmotic velocity, $u_{\mathrm{eo}}$, is found from the migration time of the neutral marker:

$$
\text { Electroosmotic velocity }=\frac{\text { distance to detector }\left(L_{\mathrm{d}}\right)}{\text { migration time }}=\frac{0.640 \mathrm{~m}}{308 \mathrm{~s}}=2.08 \mathrm{~mm} / \mathrm{s}
$$

Problem 25-41 shows how to find the charge of unmodified protein from the charge ladder.

FIGURE 25-26 Protein charge ladder. Bovine carbonic anhydrase was acetylated to give species with charges of $n-$ (unacetylated), $(n+1)-,(n+2)-, \ldots,(n+18)-$ (fully acetylated). Electrophoresis was carried out at pH 8.3 at $2.50 \times 10^{4} \mathrm{~V}$ in a capillary with a length of 0.840 m and a distance to the detector of 0.640 m . The neutral, ultraviolet-absorbing marker used to measure electroosmotic flow was mesityl oxide, $\left(\mathrm{CH}_{3}\right)_{2} \mathrm{C}=\mathrm{CHC}(=\mathrm{O}) \mathrm{CH}_{3}$. [From M. K. Menon and A. L. Zydney, "Determination of Effective Protein Charge by Capillary Electrophoresis," Anal. Chem. 2000, 72, 5714.]

Electric field is the voltage divided by the total length, $L_{\mathrm{t}}$, of the column: $E=25000 \mathrm{~V} /$ $0.840 \mathrm{~m}=2.98 \times 10^{4} \mathrm{~V} / \mathrm{m}$. Mobility is the constant of proportionality between velocity and electric field:

$$
u_{\mathrm{eo}}=\mu_{\mathrm{eo}} E \Rightarrow \mu_{\mathrm{eo}}=\frac{u_{\mathrm{eo}}}{E}=\frac{0.00208 \mathrm{~m} / \mathrm{s}}{2.98 \times 10^{4} \mathrm{~V} / \mathrm{m}}=6.98 \times 10^{-8} \frac{\mathrm{~m}^{2}}{\mathrm{~V} \cdot \mathrm{~s}}
$$

The mobility of the neutral marker, which we just calculated, is the electroosmotic mobility for the entire solution.

The apparent mobility of $\mathrm{P}^{n-}$ is obtained from its migration time:

$$
\mu_{\mathrm{app}}=\frac{u_{\mathrm{net}}}{E}=\frac{0.640 \mathrm{~m} / 343 \mathrm{~s}}{2.98 \times 10^{4} \mathrm{~V} / \mathrm{m}}=6.26 \times 10^{-8} \frac{\mathrm{~m}^{2}}{\mathrm{~V} \cdot \mathrm{~s}}
$$

Electrophoretic mobility describes the response of the ion to the electric field. Subtract electroosmotic mobility from apparent mobility to find electrophoretic mobility:

$$
\begin{aligned}
\mu_{\mathrm{app}} & =\mu_{\mathrm{ep}}+\mu_{\mathrm{eo}} \Rightarrow \mu_{\mathrm{ep}}=\mu_{\mathrm{app}}-\mu_{\mathrm{eo}}=(6.26-6.98) \times 10^{-8} \frac{\mathrm{~m}^{2}}{\mathrm{~V} \cdot \mathrm{~s}} \\
& =-0.72 \times 10^{-8} \frac{\mathrm{~m}^{2}}{\mathrm{~V} \cdot \mathrm{~s}}
\end{aligned}
$$

The electrophoretic mobility is negative because the protein has a negative charge and migrates in the opposite direction from electroosmotic flow. Electroosmotic flow at pH 8.3 is faster than electromigration, so the protein does get carried to the detector. Similar calculations for the modified protein $\mathrm{P}^{(n+1)-}$ give $\mu_{\text {app }}=6.05 \times 10^{-8} \mathrm{~m}^{2} /(\mathrm{V} \cdot \mathrm{s})$ and $\mu_{\mathrm{ep}}=-0.93 \times$ $10^{-8} \mathrm{~m}^{2} /(\mathrm{V} \cdot \mathrm{s})$. The electrophoretic mobility of $\mathrm{P}^{(n+1)-}$ is more negative than that of $\mathrm{P}^{n-}$ because the charge is more negative.

Test Yourself If electroosmotic mobility were $5.00 \times 10^{-8} \mathrm{~m}^{2} /(\mathrm{V} \cdot \mathrm{s})$, what would be the migration times of neutral marker and $\mathrm{P}^{n-}$ ? (Answer: $430 \mathrm{~s}, 502 \mathrm{~s}$ )

## Theoretical Plates and Resolution

Consider a capillary of length $L_{\mathrm{d}}$ from the inlet to the detector. In Section 22-4, we defined the number of theoretical plates as $N=L_{\mathrm{d}}^{2} / \sigma^{2}$, where $\sigma$ is the standard deviation of the band. If the only mechanism of zone broadening is longitudinal diffusion, the standard deviation was given by Equation 22-26: $\sigma=\sqrt{2 D t}$, where $D$ is the diffusion coefficient and $t$ is the migration time ( $\left.=L_{\mathrm{d}} / u_{\text {net }}=L_{\mathrm{d}} /\left[\mu_{\mathrm{app}} E\right]\right)$. Combining these equations with the definition of electric field ( $E=V / L_{\mathrm{t}}$, where $V$ is the applied voltage) gives an expression for the number of plates:

$$
\begin{equation*}
\text { Number of plates: } \quad N=\frac{\mu_{\text {app }} V}{2 D} \frac{L_{\mathrm{d}}}{L_{\mathrm{t}}} \tag{25-14}
\end{equation*}
$$

How many theoretical plates might we hope to attain? Using a typical value of $\mu_{\text {app }}=$ $2 \times 10^{-8} \mathrm{~m}^{2} /(\mathrm{V} \cdot \mathrm{s})$ (derived for a 10-min migration time in a capillary with $L_{\mathrm{t}}=60 \mathrm{~cm}$, $L_{\mathrm{d}}=50 \mathrm{~cm}$, and 25 kV ) and using diffusion coefficients from Table 22-1, we find

For $\mathrm{K}^{+}: \quad N=\frac{\left[2 \times 10^{-8} \mathrm{~m}^{2} /(\mathrm{V} \cdot \mathrm{s})\right][25000 \mathrm{~V}]}{2\left(2 \times 10^{-9} \mathrm{~m}^{2} / \mathrm{s}\right)} \frac{0.50 \mathrm{~m}}{0.60 \mathrm{~m}}=1.0 \times 10^{5}$ plates
For serum albumin: $\quad N=\frac{\left[2 \times 10^{-8} \mathrm{~m}^{2} /(\mathrm{V} \cdot \mathrm{s})\right][25000 \mathrm{~V}]}{2\left(0.059 \times 10^{-9} \mathrm{~m}^{2} / \mathrm{s}\right)} \frac{0.50 \mathrm{~m}}{0.60 \mathrm{~m}}=3.5 \times 10^{6}$ plates
For the small, rapidly diffusing $\mathrm{K}^{+}$ion, we expect 100000 plates. For the slowly diffusing protein serum albumin (FM 66000 ), we expect more than 3 million plates. High plate count means that bands are very narrow and resolution between adjacent bands is excellent.

In reality, additional sources of zone broadening include the finite width of the injected band (Equation 22-32), a parabolic flow profile from heating inside the capillary, adsorption of solute on the capillary wall (which acts as a stationary phase), the finite length of the detection zone, and mobility mismatch of solute and buffer ions that leads to nonideal electrophoretic behavior. If these factors are properly controlled, $\sim 10^{5}$ plates are routinely achieved.

Under special conditions in which a reverse hydrodynamic flow was imposed to slow the passage of analytes through the capillary, up to 17 million plates were observed in the separation of small molecules! ${ }^{31}$

Number of plates: $N=\frac{L_{d}^{2}}{\sigma^{2}}$
$L_{\mathrm{d}}=$ distance to detector
$\sigma=$ standard deviation of Gaussian band
$L_{t}=$ total length of column

FIGURE 25-27 Small region from the electropherogram of a complex mixture shows that increasing voltage increases resolution. All conditions are the same in both runs except voltage, which is ordinarily limited to $\sim 30 \mathrm{kV}$. Special precautions were required to prevent electric arcing and overheating at 120 kV . [From K. M. Hutterer and J. W. Jorgenson, "Ultrahigh-Voltage Capillary Zone Electrophoresis," Anal. Chem. 1999, 71, 1293.]

Equation 25-14 says that, for constant $L_{\mathrm{d}} / L_{\mathrm{t}}$, plate count is independent of capillary length. In contrast with chromatography, longer capillaries in electrophoresis do not give higher resolution.

Equation 25-14 also tells us that, the higher the voltage, the greater the number of plates (Figure 25-27). Voltage is ultimately limited by capillary heating, which produces a parabolic temperature profile that gives band broadening. The optimum voltage is found by making an Ohm's law plot of current versus voltage with background electrolyte (also called run buffer) in the capillary. In the absence of overheating, this curve should be a straight line. The maximum allowable voltage is the value at which the curve deviates from linearity (by, say, 5\%). Buffer concentration and composition, thermostat temperature, and active cooling all play roles in how much voltage can be tolerated. Up to a point, higher voltage gives better resolution and faster separations.

As in chromatography, resolution between closely spaced peaks A and B in an electropherogram is related to plate count, $N$, and separation factor, $\gamma$, by Equation 22-30: resolution $=(\sqrt{N} / 4)(\gamma-1)$. The separation factor $\left(\gamma=u_{\text {net }, \mathrm{A}} / u_{\text {net, } \mathrm{B}}\right)$ is the quotient of migration times $t_{\mathrm{B}} / t_{\mathrm{A}}$. Increasing $\gamma$ increases separation of peaks, and increasing $N$ decreases their width.

## 25-7 Conducting Capillary Electrophoresis

Clever variations of electrophoresis allow us to separate neutral molecules as well as ions, to separate optical isomers, and to lower detection limits by up to $10^{6}$.

## Controlling the Environment Inside the Capillary

The inside capillary wall controls electroosmotic velocity and provides undesired adsorption sites for multiply charged molecules, such as proteins. A fused-silica capillary should be prepared for its first use by washing for 1 h with 1 M NaOH at a flow rate of $\sim 4$ column volumes $/ \mathrm{min}$, followed by 1 h with water, followed by 1 h with 6 M HCl , followed by 1 h with run buffer. ${ }^{32} \mathrm{NaOH}$ is thought to generate $\mathrm{Si}-\mathrm{OH}$ groups on the silica surface and HCl removes metal ions from the surface. For subsequent use at high pH , wash for $\sim 10 \mathrm{~s}$ with 0.1 M NaOH , followed by deionized water, and then by at least 5 min with run buffer. ${ }^{33}$ If the capillary is being run with pH 2.5 phosphate buffer, wash between runs with 1 M phosphoric acid, deionized water, and run buffer. ${ }^{34}$ When changing buffers, allow at least 5 min of flow for equilibration. For the pH range 4-6, at which equilibration of the wall with buffer is slow, the capillary needs frequent regeneration with 0.1 M NaOH if migration times become erratic. Buffer in both reservoirs should be replaced periodically because ions become depleted and because electrolysis raises the pH at the cathode and lowers the pH at the anode. The capillary inlet should be $\sim 2 \mathrm{~mm}$ away from and below the electrode to minimize entry of electrolytically generated acid or base into the column. ${ }^{35}$ Stored capillaries should be filled with distilled water.

Background electrolyte (the solution in the capillary and the electrode reservoirs) controls pH and electrolyte composition in the capillary.

Covalent coating helps prevent protein from sticking to capillary and provides reproducible migration times:

FIGURE 25-29 Charge reversal created by a cationic surfactant bilayer coated on the capillary wall. The diffuse part of the double layer contains excess anions, and electroosmotic flow is opposite that shown in Figure 25-24. The surfactant is the didodecyldimethylammonium ion, $\left(n-\mathrm{C}_{12} \mathrm{H}_{25}\right) \mathrm{N}\left(\mathrm{CH}_{3}\right)_{2}^{+}$, represented as $\sim(1$ in the illustration.

For quantitative analysis, it is critical to use an internal standard because the amount of sample injected into the capillary is not reproducible.

FIGURE 25-28 Effect of wall coating on electroosmotic mobility. Bare silica has little charge below pH 3 and high negative charge above pH 8 . Polybrene cation embedded in silicate (lower structure) gives nearly constant positive charge to the wall. Anionic dextran sulfate adsorbed on polybrene (upper structure) gives constant negative charge to the wall. The bare silica wall goes from having little charge at pH 3 to full negative charge at pH 8 . The wall behaves as if it has two populations of $\mathrm{Si}-\mathrm{OH}$ groups with a total surface density of $\sim 4.3 \times 10^{-7} \mathrm{~mol} / \mathrm{m}^{2}$. One-fourth of the silanols have $\mathrm{p} K_{\mathrm{a}}=4.0$ and three-fourths have $\mathrm{p} K_{\mathrm{a}}=5.5 .{ }^{36}$ [From M. R. N. Monton, M. Tomita, T. Soga, and Y. Ishihama, "Polymer Entrapment in Polymerized Silicate for Preparing Highly Stable Capillary Coatings for CE and CE-MS," Anal. Chem. 2007, 79, 7838.]

Different separations require more or less electroosmotic flow. Small anions with high mobility and highly negatively charged proteins require brisk electroosmotic flow or they will not travel toward the cathode. At pH 3 , there is little charge on the silanol groups and little electroosmotic flow. At pH 8, the wall is highly charged and electroosmotic flow is strong. The graph in Figure 25-28 shows that electroosmotic mobility in a bare silica capillary is small and positive below pH 3 . Mobility increases and reaches a high, steady value above pH 8 .

Proteins with many positively charged substituents can bind tightly to negatively charged silica. To control this, $30-60 \mathrm{mM}$ diaminopropane (which gives ${ }^{+} \mathrm{H}_{3} \mathrm{NCH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{NH}_{3}^{+}$) may be added to the run buffer to neutralize charge on the wall. The wall charge can be reduced to near 0 by covalent attachment of silanes with neutral, hydrophilic substituents. However, many coatings are unstable under alkaline conditions.

You can reverse the direction of electroosmotic flow by adding a cationic surfactant, such as didodecyldimethylammonium bromide, to the run buffer. ${ }^{37}$ This molecule has a positive charge at one end and two long hydrocarbon tails. The surfactant coats the negatively charged silica, with the tails pointing away from the surface (Figure 25-29). A second layer of surfactant orients itself in the opposite direction so that the tails form a nonpolar hydrocarbon layer. This bilayer adheres tightly to the wall of the capillary and effectively reverses the wall charge from negative to positive. Buffer anions create electroosmotic flow from cathode to anode when voltage is applied. Electroosmotic flow is in the direction opposite that shown in Figure 25-24. Best results are obtained when the capillary is freshly regenerated for each run.

Figure 25-28 shows a more stable cationic coating formed by embedding the cationic polymer polybrene in a silicate layer formed in situ on the capillary wall. The graph shows that electroosmotic flow is nearly constant in the pH range $2-11$ and opposite that of bare silica. A stable, pH -independent negative surface can be made by adsorption of the anionic polymer dextran sulfate on the cationic polybrene surface.

## Sample Injection and Composition

Hydrodynamic injection uses pressure to force sample into the capillary (Figure 25-22). Electrokinetic injection uses the electric field to drive sample into the capillary. For hydrodynamic injection, the injected volume is

$$
\begin{equation*}
\text { Hydrodynamic injection: } \quad \text { Volume }=\frac{\Delta P \pi d^{4} t}{128 \eta L_{\mathrm{t}}} \tag{25-15}
\end{equation*}
$$

where $\Delta P$ is the pressure difference between the ends of the capillary, $d$ is the capillary inner diameter, $t$ is injection time, $\eta$ is sample viscosity, and $L_{\mathrm{t}}$ is the total length of the capillary.

## EXAMPLE Hydrodynamic Injection Time

How much time is required to inject a sample equal to $2.0 \%$ of the length of a $50-\mathrm{cm}$ capillary if the diameter is $50 \mu \mathrm{~m}$ and the pressure difference is $2.0 \times 10^{4} \mathrm{~Pa}(0.20 \mathrm{bar})$ ? Assume that the viscosity is $0.0010 \mathrm{~kg} /(\mathrm{m} \cdot \mathrm{s})$, which is close to the viscosity of water.

Solution The injection plug will be 1.0 cm long and occupy a volume of $\pi r^{2} \times$ length $=$ $\pi\left(25 \times 10^{-6} \mathrm{~m}\right)^{2}\left(1.0 \times 10^{-2} \mathrm{~m}\right)=1.9_{6} \times 10^{-11} \mathrm{~m}^{3}$. The required time is

$$
t=\frac{128 \eta L_{\mathrm{t}}(\text { volume })}{\Delta P \pi d^{4}}=\frac{128[0.0010 \mathrm{~kg} /(\mathrm{m} \cdot \mathrm{~s})](0.50 \mathrm{~m})\left(1.9_{6} \times 10^{-11} \mathrm{~m}^{3}\right)}{\left(2.0 \times 10^{4} \mathrm{~Pa}\right) \pi\left(50 \times 10^{-6} \mathrm{~m}\right)^{4}}=3.2 \mathrm{~s}
$$

The units work out when we realize that $\mathrm{Pa}=$ force/area $=\left(\mathrm{kg} \cdot \mathrm{m} / \mathrm{s}^{2}\right) / \mathrm{m}^{2}=\mathrm{kg} /\left(\mathrm{m} \cdot \mathrm{s}^{2}\right)$.
Test Yourself How much time would be required to inject a $1.0-\mathrm{cm}$-long sample with twice the viscosity of water into a $40-\mathrm{cm}-l o n g$ column at the same $\Delta P$ ? (Answer: 5.1 s )

For electrokinetic injection, the capillary is dipped in the sample and a voltage is applied between the ends of the capillary. The moles of each ion taken into the capillary in $t$ seconds are

$$
\begin{equation*}
\text { Electrokinetic injection: Moles injected }=\mu_{\mathrm{app}} \underbrace{\left(E \frac{\kappa_{\mathrm{b}}}{\kappa_{\mathrm{s}}}\right)}_{\text {Effective electric field } \equiv E_{\mathrm{eff}}} t \pi r^{2} C \tag{25-16}
\end{equation*}
$$

where $\mu_{\text {app }}$ is the apparent mobility of analyte ( $=\mu_{\text {ep }}+\mu_{\mathrm{eo}}$ ), $E$ is the applied electric field $(\mathrm{V} / \mathrm{m}), r$ is capillary radius, $C$ is sample concentration $\left(\mathrm{mol} / \mathrm{m}^{3}\right)$, and $\kappa_{\mathrm{b}} / \kappa_{\mathrm{s}}$ is the ratio of conductivities of buffer and sample. Each analyte has a different mobility, so the injected sample does not have the same composition as the original sample. Electrokinetic injection is most useful for capillary gel electrophoresis (described later), in which liquid in the capillary is too viscous for hydrodynamic injection.

## EXAMPLE Electrokinetic Injection Time

How much time is required to inject a sample equal to $2.0 \%$ of the length of a $50-\mathrm{cm}$ capillary if the diameter is $50 \mu \mathrm{~m}$ and the injection electric field is $10 \mathrm{kV} / \mathrm{m}$ ? Assume that the sample has $1 / 10$ of the conductivity of background electrolyte and $\mu_{\text {app }}=2.0 \times 10^{-8}$ $\mathrm{m}^{2} /(\mathrm{V} \cdot \mathrm{s})$.

Solution The factor $\kappa_{\mathrm{b}} / \kappa_{\mathrm{s}}$ in Equation $25-16$ is 10 in this case. The length of sample plug injected onto the column is (sample speed) $\times($ time $)=\mu_{\text {app }} E_{\text {eff }}$. The desired injection plug will be 1.0 cm long. The required time is
$t=\frac{\text { plug length }}{\text { speed }}=\frac{\text { plug length }}{\mu_{\text {app }}\left(E \frac{\kappa_{\mathrm{b}}}{\kappa_{\mathrm{s}}}\right)}=\frac{0.010 \mathrm{~m}}{\left[2.0 \times 10^{-8} \mathrm{~m}^{2} /(\mathrm{V} \cdot \mathrm{s})\right](10000 \mathrm{~V} / \mathrm{m})(10)}=5.0 \mathrm{~s}$
Equation 25-16 multiplies the plug length times its cross-sectional area to find its volume and then multiplies by concentration to find the moles in that volume.

Test Yourself What is the effect on injection time if you decrease the applied voltage by a factor of 2 ? (Answer: injection time is doubled)

## Conductivity Effects: Stacking and Skewed Bands

We choose conditions so that analyte is focused into narrow bands at the start of the capillary by a process called stacking. Without stacking, if you inject a zone with a length of 10 mm , no analyte band can be narrower than 10 mm when it reaches the detector.

Stacking depends on the relation between the electric field in the zone of injected sample and that in the background electrolyte on either side of the sample. Optimal buffer concentration in the sample solution is $1 / 10$ of the background electrolyte concentration, and the sample concentration should be $1 / 500$ of the background electrolyte concentration. If sample has a much lower ionic strength than the run buffer, the sample's conductivity is lower and its

FIGURE 25-30 Stacking of anions and cations at opposite ends of low-conductivity sample plug occurs because the electric field in the sample plug is much higher than the field in background electrolyte. Time increases from panels $a$ to $d$. Electroneutrality is maintained by migration of background electrolyte ions, which are not shown.

FIGURE 25-31 Lower trace: Sample injected electrokinetically for 2 s without stacking is limited in volume to prevent band broadening. Upper trace: With stacking, 15 times more sample could be injected (for 30 s), so the signal is 15 times stronger with no increase in bandwidth. [From Y. Zhao and C. E. Lunte, "pH-Mediated Field Amplification On-Column Preconcentration of Anions in Physiological Samples for Capillary Electrophoresis," Anal. Chem. 1999, 71, 3985.]

resistance is much greater. Electric field is inversely proportional to conductivity: the lower the conductivity, the greater the electric field. The electric field across the sample plug inside the capillary is higher than the electric field in the background electrolyte. Figure 25-30 shows ions in the sample plug migrating very fast, because the electric field is very high. When ions reach the zone boundary, they slow down because the field is lower outside the sample plug. This process of stacking continues until analyte cations are concentrated at one end of the sample plug and analyte anions are at the other end. The broad injection becomes concentrated into narrow bands of analyte cations or anions. Figure 25-31 shows signal enhancement by stacking.

If the conductivity of an analyte band is significantly different from the conductivity of the background electrolyte, peak distortion occurs. Figure 25-32 shows a band containing one analyte (as opposed to the sample plug in Figure 25-30, which contains all analytes in the entire injection). If background conductivity is greater than analyte conductivity ( $\kappa_{\mathrm{b}}>\kappa_{\mathrm{a}}$ ), the electric field is lower outside the analyte band than inside the band. The band migrates to the right in Figure 25-32. An analyte molecule that diffuses past the front on the right suddenly encounters a lower electric field and it slows down. Soon, the analyte zone catches up

FIGURE 25-32 Irregular peak shapes arise when conductivity of analyte band, $\kappa_{a}$, is not the same as background conductivity, $\kappa_{b}$. Electropherogram shows cations extracted from the surface of a silicon semiconductor wafer. Background electrolyte contains imidazolium ion for indirect spectrophotometric detection, whose principle is shown in Figure 25-35. [From T. Ehmann, L. Fabry, L. Kotz, and S. Pahlke, "Monitoring of lonic Contaminants on Silicon Wafer Surfaces using Capillary Electrophoresis," Am. Lab., June 2002, p. 18.]

with the molecule and it is back in the zone. A molecule that diffuses out of the zone on the left encounters a lower electric field and it also slows down. The analyte zone is moving faster than the wayward molecule and pulls away. This condition leads to a sharp front and a broad tail, as shown in the lower right electropherogram in Figure 25-32. When $\kappa_{b}<\kappa_{a}$, we observe the opposite electropherogram.

To minimize band distortion, sample concentration must be much less than the background electrolyte concentration. Otherwise, it is necessary to choose a buffer co-ion that has the same mobility as the analyte ion. (The co-ion is the buffer ion with the same charge as analyte. The counterion has the opposite charge.)

## Detectors

Water is so transparent that ultraviolet detectors can operate at wavelengths as short as 185 nm , where most solutes have strong absorption. To take advantage of short-wavelength ultraviolet detection, background electrolyte must have very low absorption. Borate buffers are commonly used in electrophoresis because of their transparency. ${ }^{38}$ Sensitivity is poor because the optical pathlength is only as wide as the capillary, which is $25-75 \mu \mathrm{~m}$. Figure $25-33$ shows a "bubble cell" that increases the absorbance signal-to-noise ratio by a factor of 3 to 5 and a right-angle bend that increases signal-to-noise by a factor of 10 . However, the greater pathlength in the right-angle bend design leads to some band broadening. Successive peaks must be separated by 3 mm or they will overlap in the detector.

Fluorescence detection (shown later in Figure 25-42) is sensitive to naturally fluorescent analytes or to fluorescent derivatives. Amperometric detection is sensitive to analytes that can be oxidized or reduced at an electrode (Figure 25-34). Conductivity detection with ion-exchange

FIGURE 25-33 Capillary designs to increase pathlength for measuring ultraviolet absorption. (a) Bubble cell. "Plug" of solute zone is maintained as it passes through the bubble. (b) Right-angle bend. Light path is made of black fused silica to reduce stray light. Reflective interior serves as "light pipe" to maximize transmission. Detector response is linear up to 1.4 absorbance units. (b) Electropherogram of sugars separated in 0.1 M NaOH , in which OH groups are partially ionized, thereby turning the molecules into anions. [From J. Ye and R. P. Baldwin, "Amperometric Detection in Capillary Electrophoresis with Normal Size Electrodes," Anal. Chem. 1993, 65, 3525.]

FIGURE 25-35 Principle of indirect detection. When analyte emerges from the capillary, the strong background signal decreases.
suppression of the background electrolyte (as in Figure 25-6) can detect small analyte ions at $1-10 \mathrm{ng} / \mathrm{mL}$. Electrospray mass spectrometry (Figure 21-22) provides low detection limits and gives qualitative information about analytes.

Figure 25-35 shows the principle of indirect detection, which applies to fluorescence, absorbance, amperometry, conductivity, and other forms of detection. A substance with a steady background signal is added to the background electrolyte. In the analyte band, analyte molecules displace the chromophoric substance, so the detector signal decreases when analyte passes by. Figure 25-36 shows an impressive separation of $\mathrm{Cl}^{-}$isotopes with indirect detection in the presence of the ultraviolet-absorbing anion chromate. Electroneutrality dictates that an analyte band containing $\mathrm{Cl}^{-}$must have a lower concentration of $\mathrm{CrO}_{4}^{2-}$ than is found in the background electrolyte. With less $\mathrm{CrO}_{4}^{2-}$ to absorb ultraviolet radiation, a negative peak appears when $\mathrm{Cl}^{-}$reaches the detector. Benzoate and phthalate are other anions useful for this purpose. Detection limits in capillary electrophoresis are generally about an order of magnitude higher than detection limits in ion chromatography but one to two orders of magnitude lower than detection limits for ion-selective electrodes.

FIGURE 25-36 Separation of natural isotopes of $0.56 \mathrm{mM} \mathrm{Cl}^{-}$by capillary electrophoresis with indirect spectrophotometric detection at 254 nm . Background electrolyte contains 5 mM CrO 4 2- to provide absorbance at 254 nm and 2 mM borate buffer, pH 9.2. The capillary had a diameter of $75 \mu \mathrm{~m}$, a total length of 47 cm (length to detector $=40 \mathrm{~cm}$ ), and an applied voltage of 20 kV . The difference in electrophoretic mobility of ${ }^{35} \mathrm{Cl}^{-}$and ${ }^{37} \mathrm{Cl}^{-}$is just $0.12 \%$. Conditions were adjusted so that electroosmotic flow was nearly equal to and opposite electrophoretic flow. The resulting near-zero net velocity gave the two isotopes maximum time to be separated by their slightly different mobilities. [From C. A. Lucy and T. L. McDonald, "Separation of Chloride Isotopes by Capillary Electrophoresis Based on the Isotope Effect on Ion Mobility," Anal. Chem. 1995, 67, 1074.]

## Micellar Electrokinetic Chromatography ${ }^{39}$

The type of electrophoresis we have been discussing so far is called capillary zone electrophoresis. Separation is based on differences in electrophoretic mobility. If the capillary wall is negative, electroosmotic flow is toward the cathode (Figure 25-24) and the order of elution is cations before neutrals before anions. If the capillary wall charge is reversed by coating it with a cationic surfactant (Figure 25-29) and instrument polarity is reversed, then the order of elution is anions before neutrals before cations. Neither scheme separates neutral molecules from one another.

Micellar electrokinetic chromatography separates neutral molecules and ions. We illustrate a case in which the anionic surfactant sodium dodecyl sulfate is present above its critical micelle concentration (Box 25-1), so negatively charged micelles are formed. ${ }^{41}$ In Figure 25-37, electroosmotic flow is to the right. Electrophoretic migration of the negatively charged micelles is to the left, but net motion is to the right because the electroosmotic flow dominates.

In the absence of micelles, all neutral molecules reach the detector in time $t_{0}$. Micelles injected with the sample reach the detector in time $t_{\mathrm{mc}}$, which is longer than $t_{0}$ because the micelles migrate upstream. If a neutral molecule equilibrates between free solution and the

inside of the micelles, its migration time is increased, because it migrates at the slower rate of the micelle part of the time. The neutral molecule reaches the detector at a time between $t_{0}$ and $t_{\mathrm{mc}}$. The more time the neutral molecule spends inside the micelle, the longer is its migration time. Migration times of cations and anions also are affected by micelles, because ions partition between the solution and the micelles and interact electrostatically with the micelles.

Micellar electrokinetic chromatography is a form of chromatography because the micelles behave as a pseudostationary phase. Separation of neutral molecules is based on partitioning between the solution and the pseudostationary phase. The mass transfer term $C u_{\mathrm{x}}$ is no longer 0 in the van Deemter equation 25-7, but mass transfer into the micelles is fairly fast and band broadening is modest.

Imagination runs wild with the variables in micellar electrokinetic chromatography. We can add anionic, cationic, zwitterionic, and neutral surfactants to change partition coefficients of analytes. (Cationic surfactants also change the charge on the wall and the direction of electroosmotic flow.) We can add solvents such as acetonitrile or $N$-methylformamide to increase the solubility of organic analytes and to change the partition coefficient between the solution and the micelles. ${ }^{42}$ We can add cyclodextrins (Box 23-1) to separate optical isomers that spend different fractions of the time associated with the cyclodextrins. ${ }^{43}$ In Figure 25-38, chiral micelles were used to separate enantiomers of chiral drugs.

A method called sweeping, which we will not describe in detail, concentrates analyte by a factor of $10^{3}-10^{5}$ for trace analysis. In sweeping, a migrating ionic reagent such as sodium dodecyl sulfate micelles or a chelator binds analyte and concentrates it into a narrow band. Procedures have been described for sweeping neutral analytes, ${ }^{44}$ anions, ${ }^{45}$ and cations. ${ }^{46}$ Another method to concentrate analyte utilizes dynamic changes in pH inside the capillary. ${ }^{47}$ A method called isotachophoresis stacks analytes to concentrate them by factors up to $10^{5}-10^{6} .{ }^{48}$

Capillary electrochromatography, described at the opening of this chapter, differs from micellar electrokinetic chromatography by using a true stationary phase. ${ }^{49}$ Solvent is driven by electroosmosis. Capillary electrochromatography provides about twice as many plates as HPLC for the same particle size and column length. Pressure is not used

FIGURE 25-37 Negatively charged sodium dodecyl sulfate micelles migrate against electroosmotic flow. Neutral molecules (solid color) are in dynamic equilibrium between free solution and the inside of the micelle. The more time spent in the micelle, the more the neutral molecule lags behind electroosmotic flow.

## Confusing terms:

Micellar electrokinetic chromatography: electrophoresis with micelles acting as pseudostationary phase
Capillary electrochromatography: similar to HPLC, except mobile phase is driven by electroosmosis instead of pressure

The structure of one compound is shown. Micelles were formed by a polymer surfactant containing s-leucinate substituents for chiral recognition. [From C. Akbay, S. A. A. Rizvi, and S. A. Shamsi, "Simultaneous Enantioseparation and Tandem UV-MS Detection of Eight $\beta$-Blockers in Micellar Electrokinetic Chromatography Using a Chiral Molecular Micelle," Anal. Chem. 2005, 77, 1672.]

FIGURE 25-39 (a) A chemical gel contains covalent cross-links between different polymer chains. (b) A physical gel is not cross-linked but derives its properties from physical entanglement of the polymers.

FIGURE 25-40 Calibration curve for protein molecular mass in sodium dodecyl sulfate-capillary gel electrophoresis. On the abscissa, $t_{\text {rel }}$, is the migration time of each protein divided by the migration time of a small dye molecule. [Data from J. K. Grady, J. Zang, T. M. Laue, P. Arosio, and N. D. Chasteen, "Characterization of the H - and L-Subunit Ratios in Ferritins by Sodium Dodecyl Sulfate-Capillary Gel Electrophoresis," Anal. Biochem. 2002, 302, 263.]
to drive the mobile phase, so there is no pressure drop associated with the small particles. Capillary electrochromatography has a full range of applications, such as separation of enantiomers, ${ }^{50}$ ion exchange, ${ }^{51}$ and trace analysis. ${ }^{52}$

## Capillary Gel Electrophoresis

Capillary gel electrophoresis is a variant of gel electrophoresis, which has been a primary tool in biochemistry for four decades. Slabs of polymer gel used to separate macromolecules according to size have customarily been chemical gels, in which chains are cross-linked by chemical bonds (Figure 25-39a). Chemical gels cannot be flushed from a capillary, so physical gels (Figure 25-39b) in which polymers are simply entangled are used. Physical gels can be flushed and reloaded to generate a fresh capillary for each separation.

Macromolecules are separated in a gel by sieving, in which smaller molecules migrate faster than large molecules through the entangled polymer network. Color Plate 31 shows part of a deoxyribonucleic acid (DNA) sequence analysis in which a mixture of fluorescencelabeled fragments with up to 400 nucleotides was separated in 32 minutes in a capillary containing $38 \mathrm{~g} / \mathrm{L}$ of linear polyacrylamide (Figure 25-15, with no cross-links) and 6 M urea to stabilize single strands of DNA. Each strand, terminating in one of the four bases A, T, C, or G, is tagged with one of four different fluorescent labels that identify the terminal bases as they pass through a fluorescence detector. Capillary electrophoresis was an enabling technology for determining the sequence of nucleic acids in the human genome. ${ }^{53}$

Biochemists measure molecular mass of proteins by sodium dodecyl sulfate (SDS)-gel electrophoresis. Proteins are first denatured (unfolded to random coils) by reducing their disulfide bonds (-S-S-) with excess 2-mercaptoethanol $\left(\mathrm{HSCH}_{2} \mathrm{CH}_{2} \mathrm{OH}\right)$ and adding sodium dodecyl sulfate $\left(\mathrm{C}_{12} \mathrm{H}_{25} \mathrm{OSO}_{3}^{-} \mathrm{Na}^{+}\right)$. Dodecyl sulfate anion coats hydrophobic regions and gives the protein a large negative charge that is approximately proportional to the length of the protein. Denatured proteins are then separated by electrophoresis through a sieving gel. Large molecules are retarded more than small molecules, which is the opposite behavior from size exclusion chromatography. In Figure 25-40, the logarithm of molecular mass of the SDScoated protein is proportional to $1 /($ migration time). Absolute migration times vary from run to run, so relative migration times are measured. The relative migration time is the migration time of a protein divided by the migration time of a fast-moving small dye molecule.

## Method Development

Capillary electrophoresis is not used as much as liquid chromatography. Advantages of electrophoresis relative to chromatography include (1) higher resolution, (2) low waste production, and (3) generally simpler equipment. Drawbacks of electrophoresis include (1) higher limits of detection, (2) run-to-run irreproducibility of migration times, (3) insolubility of some analytes in common electrolyte solutions, and (4) inability to scale up to a preparative separation.

Liquid chromatography is two decades more mature than capillary electrophoresis. As trained "electropherographers" become more common, more separations will be handled

by electrophoresis. For example, electrophoresis displaced liquid chromatography as the preferred method for forensic analysis of alkaloids in opium and heroin. ${ }^{54}$ The enabling technology for this application was dynamic coating of the capillary between runs to eliminate adsorption of analytes on the silica surface and decrease variations in migration times to less than $0.5 \%$.

Method development for capillary electrophoresis addresses the following points. ${ }^{55}$

1. Select a detection method that provides the required limit of detection. For ultraviolet absorption, select the optimum wavelength. If necessary, use indirect detection or derivatization.
2. If there is a choice, separate analytes as anions, which do not stick to the negatively charged wall. If separating polycations, such as proteins at low pH , select additives to coat the walls or to reverse the wall charge.
3. Dissolve the entire sample. If the sample is not soluble in dilute aqueous buffer, try adding 6 M urea or surfactants. Acetate buffer tends to dissolve more organic solutes than does phosphate buffer. (If it is necessary to dissolve the sample, nonaqueous solvents can be used. ${ }^{56}$ However, the nonaqueous solvent must be compatible with plastic parts in the system. Acetonitrile and methanol are recommended, but electric current should be kept low to minimize outgassing and evaporation. Aqueous micelles or cyclodextrin solve some solubility problems that would otherwise require organic solvent.)
4. Determine how many peaks are present. Assign each peak by using authentic samples of analytes and diode array ultraviolet detection or mass spectrometry.
5. For complex mixtures, use computerized experimental design to help optimize separation conditions. ${ }^{57}$
6. Use the short end of the capillary in Figure 25-22 for quick scouting runs to determine the direction of migration and whether broad peaks are present. Broad peaks indicate that wall effects are occurring and a coating could be required.
7. See if pH alone provides adequate separation. For acids, begin with 50 mM borate buffer, pH 9.3 . For bases, try 50 mM phosphate, pH 2.5 . If the separation is not adequate, try adjusting buffer pH close to the average $\mathrm{p} K_{\mathrm{a}}$ of the solutes.
8. If pH does not provide adequate separation or if analytes are neutral, use surfactants for micellar electrokinetic capillary chromatography. For chiral solutes, try adding cyclodextrins.
9. Select a capillary wash procedure. If migration times are reproducible from run to run with no wash, then no wash is required. If migration times increase, wash for 5 to 10 s with 0.1 M NaOH , followed by 5 min with buffer. If migration times still drift, try increasing or decreasing the NaOH wash time by a few seconds. If migration times decrease, wash with $0.1 \mathrm{M}_{3} \mathrm{PO}_{4}$. If proteins or other cations stick to the walls, try washing with 0.1 M sodium dodecyl sulfate or use a commercial dynamic coating.
10. If necessary, select a sample cleanup method. Cleanup could be required if resolution is poor, if the salt content is high, or if the capillary fouls. Cleanup might involve solidphase extraction (Section 27-3), protein precipitation, or dialysis (Demonstration 26-1).
11. If the detection limit is not sufficient, select a stacking or sweeping method to concentrate analyte in the capillary.
12. For quantitative analysis, determine the linear range required to measure the least concentrated and most concentrated analytes. If desired, select an internal standard. If the migration time or peak area of the standard changes, then you have an indication that some condition has drifted out of control.

## 25-8 Lab-on-a-Chip: Probing Brain Chemistry

One of the most exciting and rapidly developing areas of analytical chemistry is the "lab-on-a-chip." ${ }^{59}$ Liquids can be moved by electroosmosis or by pressure through micron-size channels etched into glass or plastic chips that are about the size of a microscope slide. Chemical reactions can be conducted by moving picoliters of fluid from different reservoirs, mixing them, and subjecting the products to chemical analysis on the chip. Microreactors consuming micrograms of reactants can be used to optimize conditions for synthesis, exploring dozens of conditions in a short time. Chips that manipulate small volumes of liquid are called microfluidic devices. We describe one that is coupled to a microdialysis probe to monitor chemicals in the brain. ${ }^{60}$

Dialysis is the process in which small molecules diffuse across a semipermeable membrane with pores large enough to pass small molecules but not large molecules. The

The European Space Agency ExoMars mission will search for signs of life on Mars with a lab-on-a-chip to measure amines, amino acids, and enantiomers of amino acids. ${ }^{58}$ Sub-part-per-trillion detection limits are 1000 times lower than that of the Viking gas chromatography-mass spectrometer, which did not detect organic compounds on Mars in 1976.

FIGURE 25-41 (a) Diagram and (b) photo of microdialysis probe. Small molecules pass through the semipermeable membrane, but large molecules cannot. (c) Probe inserted into rat to sample chemicals in brain. [Courtesy R. T. Kennedy and Z. D. Sandlin, University of Michigan.]
microdialysis probe in Figure 25-41 has a rigid semipermeable tube that can be inserted into the brain of an anesthetized rat to collect neurotransmitter molecules. Fluid pumped through the probe at a rate of $3 \mu \mathrm{~L} / \mathrm{min}$ transports small molecules that diffused into the probe. Fluid exiting the probe (dialysate) is routed to the sample introduction channel at the lower left of the microfluidic chip in Figure 25-42a.

Liquid in the chip in Figure 25-42a is connected to electrical ground $(0 \mathrm{~V})$ at the left and to -25 kV through the waste outlet at the right. Electroosmotic flow proceeds from left to right through the channels. Some liquid from the sample introduction channel is drawn toward the reaction channel by electroosmotic flow. Derivatization reagent that reacts with the sample to make it fluorescent is also drawn in and mixes with the sample. The reaction channel provides $\sim 1 \mathrm{~min}$ for derivatization before liquid enters the separation channel. Dimensions of the channels determine the electric potential at different points and direct fluid along the desired path. When the high-voltage switch is in the closed position shown in Figure 25-42a, liquid from the reaction channel flows to the waste channel. When the high-voltage switch is momentarily opened, a small plug of solution from the reaction channel is diverted to the separation channel for electrophoretic analysis. Fluorescent products are observed by the detector in Figure $25-42 \mathrm{~b}$ when they reach the detection zone. The $9-\mathrm{cm}$-long separation channel provides $\sim 10^{5}$ theoretical plates with a detection limit of $0.2 \mu \mathrm{M}$ for the neurotransmitter glutamate. Dialysate analyzed in Figure $25-42 \mathrm{c}$ contained $3.3 \mu \mathrm{M}$ glutamate. The system is capable of measuring changes in glutamate in response to physiologic stimulation with a time resolution of $2-4 \mathrm{~min}$. Changes in glutamate concentration occurring in less than 2-4 min would not be resolved from one another.

The microfluidic chip simplifies the handling of dialysate, making microdialysis sampling accessible to more neuroscience laboratories. The chip could be modified to conduct multiple analyses by directing aliquots of dialysate to different chambers for different derivatizations. Microfluidic chips promise to make complex analyses available to more laboratories at lower cost.

## Summary

Ion-exchange chromatography employs resins and gels with covalently bound charged groups that attract solute counterions (and that exclude ions having the same charge as the resin). Polystyrene resins are useful for small ions. Greater cross-linking of the resin increases the capacity, selectivity, and time needed for equilibration. Ionexchange gels based on cellulose and dextran have large pore sizes and low charge densities, suitable for the separation of macromolecules. Certain inorganic solids have ion-exchange properties and are useful at extremes of temperature or radiation. Ion exchangers operate by the principle of mass action, with a gradient of increasing
ionic strength most commonly used to effect a separation. Zwitterionic hydrophobic interaction chromatography can separate anions and cations on the same column.

In suppressed-ion chromatography, a separator column separates ions of interest, and a suppressor membrane converts eluent into a nonionic form so that analytes can be detected by their conductivity. Eluent and suppressor can be generated continuously by electrolysis. Alternatively, nonsuppressed ion chromatography uses an ion-exchange column and low-concentration eluent. If eluent absorbs light, indirect spectrophotometric detection is convenient
and sensitive. Ion-pair chromatography utilizes an ionic surfactant in the eluent to make a reversed-phase column function as an ion-exchange column.

Molecular exclusion chromatography is used for separations based on size and for molecular mass determinations of macromolecules. Molecular exclusion is based on the inability of large molecules to enter small pores in the stationary phase. Small molecules enter these pores and therefore exhibit longer elution times than large molecules. In affinity chromatography, the stationary phase retains one particular solute in a complex mixture. After all other components have been eluted, the desired species is liberated by a change in conditions. In hydrophobic interaction chromatography, high concentrations of ammonium sulfate induce proteins to adhere to a hydrophobic stationary phase. A gradient of decreasing salt concentration is applied to increase the solubility of proteins in water and elute them from the column.

In capillary zone electrophoresis, ions are separated by differences in mobility in a strong electric field applied between the ends of a silica capillary tube. The greater the charge and the smaller the hydrodynamic radius, the greater the electrophoretic mobility. Normally, the capillary wall is negative, and solution is transported from anode to cathode by electroosmosis of cations in the electric double layer. Solute cations arrive first, followed by neutral species,
followed by solute anions (if electroosmosis is stronger than electrophoresis). Apparent mobility is the sum of electrophoretic mobility and electroosmotic mobility (which is the same for all species). Zone dispersion (broadening) arises mainly from longitudinal diffusion and the finite length of the injected sample. Stacking of solute ions in the capillary occurs when the sample has a low conductivity. Electroosmotic flow is reduced at low pH because surface $\mathrm{Si}-\mathrm{O}^{-}$ groups are protonated. $\mathrm{Si}-\mathrm{O}^{-}$groups can be masked by polyamine cations, and the wall charge can be reversed by a cationic surfactant that forms a bilayer along the wall. Covalent coatings reduce electroosmosis and wall adsorption. Hydrodynamic sample injection uses pressure or siphoning; electrokinetic injection uses an electric field. Ultraviolet absorbance is commonly used for detection. Micellar electrophoretic chromatography uses micelles as a pseudostationary phase to separate neutral molecules and ions, which can be concentrated by stacking. Capillary electrochromatography is essentially the same as HPLC, but the mobile phase is driven by electroosmosis instead of pressure. Capillary gel electrophoresis separates macromolecules by sieving. In contrast with molecular exclusion chromatography, small molecules move fastest in gel electrophoresis. Microfluidic devices ("lab-on-a-chip") use electroosmotic or hydrodynamic flow in lithographically fabricated channels to conduct chemical reactions and chemical analysis.

## Exercises

25-A. Vanadyl sulfate ( $\mathrm{VOSO}_{4}$, FM 163.00), as supplied commercially, is contaminated with $\mathrm{H}_{2} \mathrm{SO}_{4}$ (FM 98.08) and $\mathrm{H}_{2} \mathrm{O}$. A solution was prepared by dissolving 0.2447 g of impure $\mathrm{VOSO}_{4}$ in 50.0 mL of water. Spectrophotometric analysis indicated that the concentration of the blue $\mathrm{VO}^{2+}$ ion was 0.0243 M . A $5.00-\mathrm{mL}$ sample was passed through a cation-exchange column loaded with $\mathrm{H}^{+}$. When $\mathrm{VO}^{2+}$ from the $5.00-\mathrm{mL}$ sample became bound to the column, the $\mathrm{H}^{+}$released required 13.03 mL of 0.02274 M NaOH for titration. Find the weight percent of each component $\left(\mathrm{VOSO}_{4}, \mathrm{H}_{2} \mathrm{SO}_{4}\right.$, and $\mathrm{H}_{2} \mathrm{O}$ ) in the vanadyl sulfate.
25-B. Blue Dextran 2000 was eluted during gel filtration in a volume of 36.4 mL from a $2.0 \times 40 \mathrm{~cm}$ (diameter $\times$ length) column of Sephadex G-50, which fractionates molecules in the molecular mass range 1500 to 30000 .
(a) At what retention volume would hemoglobin (molecular mass $64000)$ be expected?
(b) Suppose that radioactive ${ }^{22} \mathrm{NaCl}$, which is not adsorbed on the column, is eluted in a volume of 109.8 mL . What would be the retention volume of a molecule with $K_{\mathrm{av}}=0.65$ ?

25-C. Consider a capillary electrophoresis experiment conducted near pH 9 , at which the electroosmotic flow is stronger than the electrophoretic flow.
(a) Draw a picture of the capillary, showing the placement of the anode, cathode, injector, and detector. Show the direction of electroosmotic flow and the direction of electrophoretic flow of a cation and an anion. Show the direction of net flow.
(b) Using Table 14-1, explain why $\mathrm{Cl}^{-}$has a shorter migration time than $\mathrm{I}^{-}$. Predict whether $\mathrm{Br}^{-}$will have a shorter migration time than $\mathrm{Cl}^{-}$or a greater migration time than $\mathrm{I}^{-}$.
(c) Why is the mobility of $\mathrm{I}^{-}$greater than that of $\mathrm{Cl}^{-}$?

25-5. Consider a negatively charged protein adsorbed on an anionexchange gel at pH 8 .
(a) How will a gradient of eluent pH (from pH 8 to some lower pH ) be useful for eluting the protein? Assume that the ionic strength of the eluent is kept constant.
(b) How would a gradient of ionic strength (at constant pH ) be useful for eluting the protein?
25-6. What does the designation 200/400 mesh mean on a bottle of chromatography stationary phase? What is the size range of such particles? (See Table 27-2.) Which particles are smaller, 100/200 or 200/400 mesh?

25-7. Propose a scheme for separating trimethylamine, dimethylamine, methylamine, and ammonia from one another by ion-exchange chromatography.

25-8. Suppose that an ion-exchange resin $\left(\mathrm{R}^{-} \mathrm{Na}^{+}\right)$is immersed in a solution of NaCl . Let the concentration of $\mathrm{R}^{-}$in the resin be 3.0 M .
(a) What will the ratio $\left[\mathrm{Cl}^{-}\right]_{\mathrm{o}} /\left[\mathrm{Cl}^{-}\right]_{\mathrm{i}}$ be if $\left[\mathrm{Cl}^{-}\right]_{\mathrm{o}}$ is 0.10 M ?
(b) What will the ratio $\left[\mathrm{Cl}^{-}\right]_{\mathrm{o}} /\left[\mathrm{Cl}^{-}\right]_{\mathrm{i}}$ be if $\left[\mathrm{Cl}^{-}\right]_{\mathrm{o}}$ is 1.0 M ?
(c) Will the fraction of electrolyte inside the resin increase or decrease as the outside concentration of electrolyte increases?

25-9. Material balance. If you intend to measure all the anions and cations in an unknown, one sanity check on your results is that the total positive charge should equal the total negative charge. Concentrations of anions and cations in pond water in Figure 25-7 are expressed in $\mu \mathrm{g} / \mathrm{mL}$. Find the total concentration of negative and positive charge ( $\mathrm{mol} / \mathrm{L}$ ) to assess the quality of the analysis. What do you conclude about this analysis?

25-10. (a) Explain how anions and cations can be separated by hydrophilic interaction chromatography in Figure 25-5, using the zwitterionic stationary phase in Figure 24-14. Why does the gradient go from high $\mathrm{CH}_{3} \mathrm{CN}$ to low $\mathrm{CH}_{3} \mathrm{CN}$ content?
(b) Isocratic elution with $20 \mathrm{vol} \%$ acetonitrile plus $80 \mathrm{vol} \%$ aqueous buffer did not separate $\mathrm{Na}^{+}$from $\mathrm{Cl}^{-}$. Eluent with $40 \mathrm{vol} \%$ acetonitrile plus 60 vol $\%$ aqueous buffer gave a baseline separation. Suggest an explanation.

25-11. In the separation of proteins by hydrophobic interaction chromatograpy, why does eluent strength increase with decreasing salt concentration in the aqueous eluent?
25-12. In ion-exclusion chromatography, ions are separated from nonelectrolytes by an ion-exchange column. Nonelectrolytes penetrate the stationary phase, whereas half of the ions are repelled by the fixed charges. Because electrolytes have access to less of the column volume, they are eluted before nonelectrolytes. The chromatogram here shows the separation of trichloroacetic acid (TCA, $\mathrm{p} K_{\mathrm{a}}=0.5$ ), dichloroacetic acid ( $\mathrm{DCA}, \mathrm{p} K_{\mathrm{a}}=1.1$ ), and monochloroacetic acid (MCA, $\mathrm{p} K_{\mathrm{a}}=2.86$ ) by passage through a cation-exchange resin eluted with 0.01 M HCl . Explain why the three acids are separated and why they emerge in the order shown.

Separation of acids on cation-exchange column. [From V. T. Turkelson and M. Richards, "Separation of the Citric Acid Cycle Acids by Liquid Chromatography," Anal. Chem. 1978, 50, 1420.]

25-13. 垹 Norepinephrine (NE) in human urine can be assayed by ion-pair chromatography by using an octadecylsilane stationary phase and sodium octyl sulfate as the mobile-phase additive. Electrochemical detection (oxidation at 0.65 V versus $\mathrm{Ag} \mid \mathrm{AgCl}$ ) is used, with 2,3-dihydroxybenzylamine (DHBA) as internal standard.

Norepinephrine cation (NE)

2,3-Dihydroxybenzylamine cation (DHBA)
(a) Explain the physical mechanism by which an ion-pair separation works.
(b) A urine sample containing an unknown amount of NE and a fixed, added concentration of DHBA gave a detector peak height ratio NE/DHBA $=0.298$. Then small standard additions of NE were made, with the following results:

| Added concentration of <br> $\mathrm{NE}(\mathrm{ng} / \mathrm{mL})$ | Peak height <br> ratio NE/DHBA |
| :--- | :--- |
| 12 | 0.414 |

Using the graphical treatment shown in Section 5-3, find the original concentration of NE in the specimen.

25-14. Decomposition of dithionite $\left(\mathrm{S}_{2} \mathrm{O}_{4}^{2-}\right)$ was studied by chromatography on an anion-exchange column eluted with 20 mM trisodium 1,3,6-naphthalenetrisulfonate in $90 \mathrm{vol} \% \mathrm{H}_{2} \mathrm{O} / 10 \mathrm{vol} \%$ $\mathrm{CH}_{3} \mathrm{CN}$ with ultraviolet detection at 280 nm . A solution of sodium dithionite stored for 34 days in the absence of air gave five peaks identified as $\mathrm{SO}_{3}^{2-}, \mathrm{SO}_{4}^{2-}, \mathrm{S}_{2} \mathrm{O}_{3}^{2-}, \mathrm{S}_{2} \mathrm{O}_{4}^{2-}$, and $\mathrm{S}_{2} \mathrm{O}_{5}^{2-}$. All the peaks had a negative absorbance. Explain why.
25-15. (a) Suppose that the reservoir in Figure 25-8 contains 1.5 L of $2.0 \mathrm{M} \mathrm{K}_{2} \mathrm{PO}_{4}$. For how many hours can the reservoir provide 20 mM KOH at a flow rate of $1.0 \mathrm{~mL} / \mathrm{min}$ if $75 \%$ consumption of $\mathrm{K}^{+}$in the reservoir is feasible?
(b) What starting and ending current would be required to produce a gradient from 5.0 mM KOH to 0.10 M KOH at $1.0 \mathrm{~mL} / \mathrm{min}$ flow rate?

25-16. The system in Figure 25-8 can be adapted to produce the strong acid eluent methanesulfonic acid $\left(\mathrm{CH}_{3} \mathrm{SO}_{3}^{-} \mathrm{H}^{+}\right)$. For this purpose, the polarity of the electrodes is reversed and the reservoir can contain $\mathrm{NH}_{4}^{+} \mathrm{CH}_{3} \mathrm{SO}_{3}^{-}$. The barrier membrane and the resin bed at the bottom of the figure must both be anion-exchangers loaded with $\mathrm{CH}_{3} \mathrm{SO}_{3}^{-}$. Draw this system and write the chemistry that occurs in each part.

## Molecular Exclusion and Affinity Chromatography

25-17. (a) How can molecular exclusion chromatography be used to measure the molecular mass of a protein?
(b) Which pore size in Figure 25-17 is most suitable for chromatography of molecules with molecular mass near 100000 ?
25-18. A gel-filtration column has a radius, $r$, of 0.80 cm and a length, $l$, of 20.0 cm .
(a) Calculate the volume, $V_{\mathrm{t}}$, of the column, which is equal to $\pi r^{2} l$. (b) The void volume, $V_{\mathrm{o}}$, was 18.1 mL , and the total volume of mobile phase was 35.8 mL . Find $K_{\mathrm{av}}$ for a solute eluted at 27.4 mL .

25-19. Ferritin (molecular mass 450000 ), transferrin (molecular mass 80000 ), and ferric citrate were separated by molecular exclusion chromatography on Bio-Gel P-300. The column had a length of 37 cm and a $1.5-\mathrm{cm}$ diameter. Eluate fractions of 0.65 mL were collected. The maximum of each peak came at the following fractions: ferritin, 22; transferrin, 32 ; and ferric citrate, 84. (That is, the ferritin peak came at an elution volume of $22 \times 0.65=14.3 \mathrm{~mL}$.) Assuming that ferritin is eluted at the void volume and that ferric citrate is eluted at $V_{\mathrm{m}}$, find $K_{\mathrm{av}}$ for transferrin.

25-20. (a) The void volume in Figure 25-17 is the volume at which the curves rise vertically at the left. What is the smallest molecular mass of molecules excluded from the $10-\mathrm{nm}$-pore-size column?
(b) What is the molecular mass of molecules eluted at 6.5 mL from the $10-\mathrm{nm}$ column?

25-21. A polystyrene resin molecular exclusion HPLC column has a diameter of 7.8 mm and a length of 30 cm . The solid portions of the gel particles occupy $20 \%$ of the volume, the pores occupy $40 \%$, and the volume between particles occupies $40 \%$.
(a) At what volume would totally excluded molecules be expected to emerge?
(b) At what volume would the smallest molecules be expected?
(c) A mixture of polyethylene glycols of various molecular masses is eluted between 23 and 27 mL . What does this imply about the retention mechanism for these solutes on the column?

25-22. The following substances were separated on a gel filtration column. Estimate the molecular mass of the unknown.

| Compound | $V_{\mathrm{r}}(\mathrm{mL})$ | Molecular mass (Da) |
| :--- | :--- | :--- |
| Blue Dextran 2000 | 17.7 | $2 \times 10^{6}$ |
| Aldolase | 35.6 | 158000 |
| Catalase | 32.3 | 210000 |
| Ferritin | 28.6 | 440000 |
| Thyroglobulin | 25.1 | 669000 |
| Unknown | 30.3 | $?$ |

## Capillary Electrophoresis

## 25-23. What is electroosmosis?

25-24. Electroosmotic velocities of buffered solutions are shown for a bare silica capillary and one with aminopropyl groups (silica- $\mathrm{Si}-\mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{NH}_{2}$ ) covalently attached to the wall. A positive sign means that flow is toward the cathode. Explain the signs and relative magnitudes of the velocities.

Electroosmotic velocity ( $\mathrm{mm} / \mathrm{s}$ ) for $E=4.0 \times 10^{4} \mathrm{~V} / \mathrm{m}$

| Capillary wall | pH 10 | pH 2.5 |
| :--- | :--- | :---: |
| Bare silica | +3.1 | +0.2 |
| Aminopropyl-modified silica | +1.8 | -1.3 |

Source: K. Emoto, J. M. Harris, and M. Van Alstine, "Grafting Poly(ethylene glycol) Epoxide to Amino-Derivatized Quartz: Effect of Temperature and pH on Grafting Density," Anal. Chem. 1996, 68, 3751.
$\mathbf{2 5 - 2 5}$. Fluorescent derivatives of amino acids separated by capillary zone electrophoresis had migration times with the following order: arginine (fastest) $<$ phenylalanine $<$ asparagine $<$ serine $<$ glycine (slowest). Explain why arginine has the shortest migration time.

$\mathbf{2 5 - 2 6}$. What is the principal source of zone broadening in ideal capillary electrophoresis?

25-27. Consider the electrophoresis of heparin in Figure 25-21.
(a) Electrophoresis was carried out at pH 2.8 , at which sulfate groups are negative. Why was reverse polarity (detector end positive) used?
(b) The ionic strength of $30 \mathrm{mg} / \mathrm{mL}$ heparin samples is higher than that of typical samples for electrophoresis. What is the benefit of high buffer concentration ( 0.6 M phosphate)?
(c) A narrow capillary ( $25 \mu \mathrm{~m}$ diameter) was chosen to be compatible with the high-ionic-strength buffer. What is the advantage of the narrow capillary?
(d) $\mathrm{Li}^{+}$has lower mobility than $\mathrm{Na}^{+}$. Explain why lithium phosphate can be used at higher electric field strength than sodium phosphate to generate the same current. What is the advantage of higher field strength for this separation?

25-28. (a) An electrophoresis channel etched into a glass plate has a rectangular $12 \times 50 \mu \mathrm{~m}$ cross section. How long (mm) is the sample zone for a $100-\mathrm{pL}$ sample?
(b) If sample travels 24 mm in 8 s to reach the detector, what is the standard deviation in bandwidth contributed by the finite length of the injection zone? (Hint: See Equation 22-32.)
(c) If the diffusion coefficient of a solute is $1.0 \times 10^{-8} \mathrm{~m}^{2} / \mathrm{s}$, what is the diffusional contribution (standard deviation) to band broadening?
(d) What is the expected total bandwidth at the baseline $(w=4 \sigma)$ ?

25-29. State three different methods to reduce electroosmotic flow. Why does the direction of electroosmotic flow change when a silica capillary is washed with a cationic surfactant?
25-30. Explain how neutral molecules can be separated by micellar electrokinetic chromatography. Why is this a form of chromatography?

25-31. (a) What pressure difference is required to inject a sample equal to $1.0 \%$ of the length of a $60.0-\mathrm{cm}$ capillary in 4.0 s if the diameter is $50 \mu \mathrm{~m}$ ? Assume that the viscosity of the solution is $0.0010 \mathrm{~kg} /(\mathrm{m} \cdot \mathrm{s})$.
(b) The pressure exerted by a column of water of height $h$ is $h \rho g$, where $\rho$ is the density of water and $g$ is the acceleration of gravity $\left(9.8 \mathrm{~m} / \mathrm{s}^{2}\right)$. To what height would you need to raise the sample vial to create the necessary pressure to load the sample in 4.0 s ? Is it possible to raise the inlet of this column to this height? How could you obtain the desired pressure?
25-32. (a) How many moles of analyte are present in a $10.0-\mu \mathrm{M}$ solution that occupies $1.0 \%$ of the length of a $25-\mu \mathrm{m} \times 60.0-\mathrm{cm}$ capillary?
(b) What voltage is required to inject this many moles into a capillary in 4.0 s if the sample has $1 / 10$ of the conductivity of background electrolyte, $\mu_{\mathrm{app}}=3.0 \times 10^{-8} \mathrm{~m}^{2} /(\mathrm{V} \cdot \mathrm{s})$, and the sample concentration is $10.0 \mu \mathrm{M}$ ?

25-33. Measure the number of plates for the electrophoretic peak in Figure 25-23. Use Equation 22-29 for asymmetric peaks to find the number of plates for the chromatographic peak.

25-34. (a) A long thin molecule has a greater friction coefficient than a short fat molecule. Predict whether fumarate or maleate will have greater electrophoretic mobility.

Fumarate

Maleate
(b) Electrophoresis is run with the injection end positive and the detection end negative. At pH 8.5 , both anions have a charge of -2 . The electroosmotic flow from the positive terminal to the negative terminal is greater than the electrophoretic flow, so these two anions have a net migration from the positive to the negative end of the capillary in electrophoresis. From your answer to part (a), predict the order of elution of these two species.
(c) At pH 4.0 , both anions have a charge close to -1 , and the electroosmotic flow is weak. Therefore, electrophoresis is run with the injection end negative and the detection end positive. The anions migrate from the negative end of the capillary to the positive end. Predict the order of elution.

25-35. (a) A particular solution in a particular capillary has an electroosmotic mobility of $1.3 \times 10^{-8} \mathrm{~m}^{2} /(\mathrm{V} \cdot \mathrm{s})$ at pH 2 and $8.1 \times$ $10^{-8} \mathrm{~m}^{2} /(\mathrm{V} \cdot \mathrm{s})$ at pH 12 . How long will it take a neutral solute to travel 52 cm from the injector to the detector if 27 kV is applied across the 62 - cm -long capillary tube at pH 2 ? At pH 12 ?
(b) An analyte anion has an electrophoretic mobility of $-1.6 \times$ $10^{-8} \mathrm{~m}^{2} /(\mathrm{V} \cdot \mathrm{s})$. How long will it take to reach the detector at pH 2 ? At pH 12 ?

25-36. Figure 25-27 shows the effect on resolution of increasing voltage from 28 to 120 kV .
(a) What is the expected ratio of migration times $\left(t_{120 \mathrm{kV}} / t_{28 \mathrm{kV}}\right)$ in the two experiments? Measure the migration times for peak 1 and find the observed ratio.
(b) What is the expected ratio of plates ( $N_{120 \mathrm{kV}} / N_{28 \mathrm{kV}}$ ) in the two experiments?
(c) What is the expected ratio of bandwidths ( $\sigma_{120 \mathrm{kv}} / \sigma_{28 \mathrm{kV}}$ )?
(d) What is the physical reason why increasing voltage decreases bandwidth and increases resolution?

25-37. The observed behavior of benzyl alcohol $\left(\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{CH}_{2} \mathrm{OH}\right)$ in capillary electrophoresis is given here. Draw a graph showing the number of plates versus the electric field and explain what happens as the field increases.

| Electric field (V/m) | Number of plates |
| :---: | :---: |
| 6400 | 38000 |
| 12700 | 78000 |
| 19000 | 96000 |
| 25500 | 124000 |
| 31700 | 124000 |
| 38000 | 96000 |

25-38. Measure the width of the ${ }^{35} \mathrm{Cl}^{-}$peak at half-height in Figure 25-36 and calculate the plate number. The capillary was 40.0 cm in length. Find the plate height.
25-39. The migration time for $\mathrm{Cl}^{-}$in a capillary zone electrophoresis experiment is 17.12 min and the migration time for $\mathrm{I}^{-}$is 17.78 min . From mobilities in Table 14-1, predict the migration time of $\mathrm{Br}^{-}$. (The observed value is 19.6 min .)
 trophoresis. Ferritin is a hollow iron-storage protein ${ }^{61}$ consisting of 24 subunits that are a variable mixture of heavy (H) or light (L) chains, arranged in octahedral symmetry. The hollow center, with a diameter of 8 nm , can hold up to 4500 iron atoms in the approximate form of the mineral ferrihydrite $\left(5 \mathrm{Fe}_{2} \mathrm{O}_{3} \cdot 9 \mathrm{H}_{2} \mathrm{O}\right)$. Iron(II) enters the protein through eight pores located on the threefold
symmetry axes of the octahedron. Oxidation to Fe (III) occurs at catalytic sites on the H chains. Other sites on the inside of the L chains appear to nucleate the crystallization of ferrihydrite.

Migration times for protein standards and the ferritin subunits are given in the table. Prepare a graph of $\log$ (molecular mass) versus $1 /($ relative migration time), where relative migration time $=$ (migration time)/(migration time of marker dye). Compute the molecular mass of the ferritin light and heavy chains. The masses of the chains, computed from amino acid sequences, are 19766 and 21099 Da .

| Protein | Molecular <br> mass (Da) | Migration <br> time (min) |
| :--- | :--- | :--- |
| Orange G marker dye | small | 13.17 |
| $\alpha$-Lactalbumin | 14200 | 16.46 |
| Carbonic anhydrase | 29000 | 18.66 |
| Ovalbumin | 45000 | 20.16 |
| Bovine serum albumin | 66000 | 22.36 |
| Phosphorylase B | 97000 | 23.56 |
| $\beta$-Galactosidase | 116000 | 24.97 |
| Myosin | 205000 | 28.25 |
| Ferritin light chain |  | 17.07 |
| Ferritin heavy chain |  | 17.97 |

source: J. K. Grady, J. Zang, T. M. Laue, P. Arosio, and N. D. Chasteen,
"Characterization of the H- and L-Subunit Ratios in Ferritins by Sodium Dodecyl Sulfate-Capillary Gel Electrophoresis," Anal. Biochem. 2002, 302, 263.

25-41. proportional to charge. If members of a charge ladder (Figure 25-26) have the same friction coefficient (that is, the same size and shape), then the charge of the unmodified protein divided by its electrophoretic mobility, $z_{0} / \mu_{0}$, is equal to the charge of the $n$th member divided by its electrophoretic mobility $\left(z_{0}+\Delta z_{n}\right) / \mu_{n}$. Setting these two expressions equal to each other and rearranging gives

$$
\Delta z_{n}=z_{0}\left(\frac{\mu_{n}}{\mu_{0}}-1\right)
$$

where $z_{0}$ is the charge of the unmodified protein, $\Delta z_{n}$ is the charge difference between the $n$th modified protein and the unmodified protein, $\mu_{n}$ is the electrophoretic mobility of the $n$th modified protein, and $\mu_{0}$ is the electrophoretic mobility of the unmodified protein. The migration time of the neutral marker molecule in Figure 25-26 is 308.5 s . The migration time of the unmodified protein is 343.0 s . Other members of the charge ladder have migration times of 355.4, 368.2, 382.2, 395.5, 409.1, 424.9, 438.5, 453.0, 467.0, 482.0, 496.4, $510.1,524.1,536.9,551.4,565.1,577.4$, and 588.5 s . Calculate the electrophoretic mobility of each protein and prepare a plot of $\Delta z_{n}$ versus $\left(\mu_{n} / \mu_{0}\right)-1$. If the points lie on a straight line, the slope is the charge of the unmodified protein, $z_{0}$. Prepare such a plot, suggest an explanation for its shape, and find $z_{0}$.

25-42. Resolution. Suppose that the electroosmotic mobility of a solution is $+1.61 \times 10^{-7} \mathrm{~m}^{2} /(\mathrm{V} \cdot \mathrm{s})$. How many plates are required to separate sulfate from bromide with a resolution of 2.0? Use Table 14-1 for mobilities and Equation 22-30 for resolution.
25-43. The water-soluble vitamins niacinamide (a neutral compound), riboflavin (a neutral compound), niacin (an anion), and thiamine (a cation) were separated by micellar electrokinetic chromatography in 15 mM borate buffer ( pH 8.0 ) with 50 mM sodium dodecyl sulfate. The migration times were niacinamide ( 8.1 min ), riboflavin ( 13.0 min ), niacin ( 14.3 min ), and thiamine ( 21.9 min ). What would the order have been in the absence of sodium dodecyl sulfate? Which compound is most soluble in the micelles?

25-44. When the following three compounds are separated by micellar electrokinetic chromatography at pH 9.6 , three peaks are observed. When $10 \mathrm{mM} \alpha$-cyclodextrin is added to the run buffer, two of the three peaks split into two peaks, giving a total of five peaks. Explain this observation and predict which compound does not split.

$\mathbf{2 5 - 4 5}$. A van Deemter plot for the separation of neutral dyes by micellar electrokinetic chromatography is shown below. ${ }^{62}$

(a) Explain why plate height increases at low and high velocities.
(b) The irregular flow path term, $A$, in the van Deemter equation should really be 0 for the ideal case of micellar electrokinetic chromatography. The observed value of $A$ is $2.32 \mu \mathrm{~m}$, which accounts for two-thirds of the band broadening at the optimum velocity. Suggest some reasons why $A$ is not 0 .
25-46. Ti Ho obtain the best separation of two weak acids in capillary electrophoresis, it makes sense to use the pH at which their charge difference is greatest. Prepare a spreadsheet to examine the charges of malonic and phthalic acid as a function of pH . At what pH is the difference greatest?
25-47. Optimizing a separation of acids. Benzoic acid containing ${ }^{16} \mathrm{O}$ can be separated from benzoic acid containing ${ }^{18} \mathrm{O}$ by electrophoresis at a suitable pH because they have slightly different acid dissociation constants. The difference in mobility is caused by the different fraction of each acid in the anionic form, $\mathrm{A}^{-}$. Calling this fraction $\alpha$, we can write

$$
\begin{array}{ll}
\mathrm{H}^{16} \mathrm{~A} \stackrel{{ }^{16} K}{\rightleftharpoons} \mathrm{H}^{+}+{ }^{16} \mathrm{~A}^{-} & \mathrm{H}^{18} \mathrm{~A} \stackrel{{ }^{18} K}{\rightleftharpoons} \mathrm{H}^{+}+{ }^{18} \mathrm{~A}^{-} \\
{ }^{16} \alpha=\frac{{ }^{16} K}{{ }^{16} K+\left[\mathrm{H}^{+}\right]} & { }^{18} \alpha=\frac{{ }^{18} K}{{ }^{18} K+\left[\mathrm{H}^{+}\right]}
\end{array}
$$

where $K$ is the equilibrium constant. The greater the fraction of acid in the form $\mathrm{A}^{-}$, the faster it will migrate in the electric field.

It can be shown that, for electrophoresis, the maximum separation will occur when $\Delta \alpha / \sqrt{\alpha}$ is a maximum. In this expression, $\Delta \alpha={ }^{16} \alpha-{ }^{18} \alpha$, and $\bar{\alpha}$ is the average fraction of dissociation $\left[=\frac{1}{2}\left({ }^{16} \alpha+{ }^{18} \alpha\right)\right]$.
(a) Let us denote the ratio of acid dissociation constants as $R={ }^{16} K /{ }^{18} K$. In general, $R$ will be close to unity. For benzoic acid, $R=1.020$. Abbreviate ${ }^{16} K$ as $K$ and write ${ }^{18} K=K / R$. Derive an expression for $\Delta \alpha / \sqrt{\bar{\alpha}}$ in terms of $K,\left[\mathrm{H}^{+}\right]$, and $R$. Because both equilibrium constants are nearly equal ( $R$ is close to unity), set $\bar{\alpha}$ equal to ${ }^{16} \alpha$ in your expression.
(b) Find the maximum value of $\Delta \alpha / \sqrt{\alpha}$ by taking the derivative with respect to $\left[\mathrm{H}^{+}\right]$and setting it equal to 0 . Show that the maximum difference in mobility of isotopic benzoic acids occurs when $\left[\mathrm{H}^{+}\right]=(K / 2 R)(1+\sqrt{1+8 R})$.
(c) Show that, for $R \approx 1$, this expression simplifies to $\left[\mathrm{H}^{+}\right]=2 K$, or $\mathrm{pH}=\mathrm{p} K-0.30$. That is, the maximum electrophoretic separation should occur when the column buffer has $\mathrm{pH}=\mathrm{p} K-0.30$, regardless of the exact value of $R .{ }^{63}$

25-48. (a) Ion mobility spectrometry (Section 21-3) is gas-phase electrophoresis. Describe how ion mobility spectrometry works and state the analogies between this technique and capillary electrophoresis.
(b) As in electrophoresis, the velocity, $u$, of a gas-phase ion is $u=\mu E$, where $\mu$ is the mobility of the ion and $E$ is the electric field ( $E=V / L$, where $V$ is the voltage difference across distance $L$ ). In ion mobility spectrometry, the time to go from the gate to the detector (Figure 21-20a) is called drift time, $t_{\mathrm{d}}$. Drift time is related to voltage: $t_{\mathrm{d}}=L / u=L /(\mu E)=L /(\mu(V / L))=L^{2} / \mu \mathrm{V}$. Plate number is $N$ $=5.55\left(t_{\mathrm{d}} / w_{1 / 2}\right)^{2}$, where $w_{1 / 2}$ is the width of the peak at half-height. Ideally, peak width depends only on the width of the gate pulse that admits ions to the drift tube and on diffusive broadening of ions while they migrate: ${ }^{64}$

$$
w_{1 / 2}^{2}=t_{g}^{2}+\left(\frac{16 k T \ln 2}{V e z}\right) t_{d}^{2}
$$

where $t_{\mathrm{g}}$ is the time that the ion gate is open, $k$ is Boltzmann's constant, $T$ is temperature, $V$ is the potential difference from the gate to the detector, $e$ is the elementary charge, and $z$ is the charge of the ion. Prepare a graph of $N$ versus $V(0 \leq V \leq 20000)$ for an ion with $\mu=8 \times 10^{-5} \mathrm{~m}^{2} /(\mathrm{s} \cdot \mathrm{V})$, and $t_{\mathrm{g}}=0,0.05$, or 0.2 ms at 300 K . Let the length of the drift region be $L=0.2 \mathrm{~m}$. Explain the shapes of the curves. What is the disadvantage of using short $t_{\mathrm{g}}$ ?
(c) Why does decreasing $T$ increase $N$ ?
(d) In a well-optimized ion mobility spectrometer, protonated arginine ion $(z=1)$ had a drift time of 24.925 ms and $w_{1 / 2}=0.154 \mathrm{~ms}$ at 300 K . Find $N$. For $V=12500 \mathrm{~V}$ and $t_{\mathrm{g}}=0.05 \mathrm{~ms}$, what is the theoretical plate number?
(e) Resolution is given by $R=(\sqrt{N} / 4)(\gamma-1)$, where $\gamma$ is the ratio of drift times for two components. In a well-optimized ion mobility spectrometer, protonated leucine had $t_{\mathrm{d}}=22.5 \mathrm{~ms}$ and protonated isoleucine had $t_{\mathrm{d}}=22.0 \mathrm{~ms}$. Both had $N \approx 80000$. What is the resolution of the two peaks?

# Gravimetric Analysis, Precipitation Titrations, and Combustion Analysis 

THE GEOLOGIC TIME SCALE AND GRAVIMETRIC ANALYSIS

Layers of rock exposed in the Grand Canyon by the erosive action of the Colorado River provide a window on a billion years of Earth's history. [Left: Adapted from F. Press, R. Siever, J. Gratzinger, and T. H. Jordan. Understanding Earth, 4th ed. (New York: W. H. Freeman and Company, 2004). Right: Carol Polich/Lonely Planet Images.]

In the 1800 s , geologists understood that new layers (strata) of rock are deposited on top of older layers. Characteristic fossils in each layer helped geologists to identify strata from the same geologic era all around the world. However, the actual age of each layer was unknown.

Ernest Rutherford, Frederick Soddy, Bertram Boltwood, and Robert Strutt showed in the early 1900s that uranium decays to lead plus eight atoms of helium with a half-life of several billion years. Rutherford estimated the age of a rock from its U and He content. Boltwood obtained more reliable ages of minerals by measuring the U and Pb content.

In 1910, Arthur Holmes, a 20 -year-old student of Strutt at Imperial College in London, became the first person to assign actual ages to minerals formed in specific geologic periods. Holmes conjectured that when certain U-containing minerals crystallized from hot magma, the crystals would be relatively free of impurities such as Pb . Once the mineral solidified, Pb would begin to accumulate. The ratio $\mathrm{Pb} / \mathrm{U}$ would tell how long ago the mineral crystallized. Holmes measured U by the rate of production of radioactive Rn gas. To measure Pb , he dissolved each mineral in molten borax, dissolved the fused mass in acid, and quantitatively precipitated milligrams of $\mathrm{PbSO}_{4}$. The nearly constant ratio $\mathrm{Pb} / \mathrm{U}=0.045 \mathrm{~g} / \mathrm{g}$ in 15 minerals was consistent with the hypotheses that Pb is the end product of U decay and that little Pb had been present when the minerals crystallized. The calculated age of the "Devonian-age" minerals was 370 million years-four times older than the most accepted age of Earth at that time.
Geologic ages deduced by Holmes in 1911

| Geologic period | $\mathrm{Pb} / \mathrm{U}(\mathrm{g} / \mathrm{g})$ | Millions of years | Today's accepted value |
| :--- | :---: | :---: | :---: |
| Carboniferous | 0.041 | 340 | $330-362$ |
| Devonian | 0.045 | 370 | $362-380$ |
| Silurian | 0.053 | 430 | $418-443$ |
| Precambrian | $0.125-0.20$ | $1025-1640$ | $900-2500$ |

[^16]Gravimetry was the main form of chemical analysis in the eighteenth and nineteenth centuries, but it is too tedious to be a method of choice today. However, gravimetry remains one of the most accurate methods. Standards used to calibrate instruments are frequently derived from gravimetric or titrimetric procedures.

Marie and Pierre Curie and Henri Becquerel shared the Nobel Prize in physics in 1903 for pioneering investigations of radioactivity. The Curies needed four years to isolate 100 mg of $\mathrm{RaCl}_{2}$ from several tons of ore. Marie received the Nobel Prize in chemistry in 1911 for her isolation of metallic radium. Linus Pauling, John Bardeen, and Frederick Sanger are the only others who received two Nobel Prizes.
n gravimetric analysis, the mass of a product is used to calculate the quantity of the original analyte (the species being analyzed). Careful gravimetric analysis by T. W. Richards and his colleagues early in the twentieth century determined the atomic masses of $\mathrm{Ag}, \mathrm{Cl}$, and N to six-figure accuracy. ${ }^{1}$ This Nobel Prize-winning work allowed the accurate determination of atomic masses of many elements. In precipitation titrations, the quantity of titrant required for complete precipitation of analyte tells us how much analyte was present. In combustion analysis, a sample is burned in excess oxygen and products are measured. Combustion is typically used to measure $\mathrm{C}, \mathrm{H}, \mathrm{N}, \mathrm{S}$, and halogens in organic matter. To measure other elements, organic matter is burned in a closed system. Products and ash (solid residue) are then dissolved in acid or base and measured by inductively coupled plasma with atomic emission or mass spectrometry.

## 26-1 Examples of Gravimetric Analysis

Chloride can be measured by precipitating the anion with $\mathrm{Ag}^{+}$and finding the mass of AgCl .

$$
\begin{equation*}
\mathrm{Ag}^{+}+\mathrm{Cl}^{-} \rightarrow \mathrm{AgCl}(s) \tag{26-1}
\end{equation*}
$$

## EXAMPLE A Gravimetric Calculation

A $10.00-\mathrm{mL}$ solution containing $\mathrm{Cl}^{-}$was treated with excess $\mathrm{AgNO}_{3}$ to precipitate 0.4368 g of AgCl . What was the molarity of $\mathrm{Cl}^{-}$in the unknown?

Solution The formula mass of AgCl is 143.321 . Precipitate weighing 0.4368 g contains

$$
\frac{0.4368 \mathrm{~g} \mathrm{AgCt}}{143.321 \mathrm{~g} \mathrm{AgCt} / \mathrm{mol} \mathrm{AgCl}}=3.048 \times 10^{-3} \mathrm{~mol} \mathrm{AgCl}
$$

Because 1 mol of AgCl contains 1 mol of $\mathrm{Cl}^{-}$, there must have been $3.048 \times 10^{-3} \mathrm{~mol}$ of $\mathrm{Cl}^{-}$in the unknown.

$$
\left[\mathrm{Cl}^{-}\right]=\frac{3.048 \times 10^{-3} \mathrm{~mol}}{0.01000 \mathrm{~L}}=0.3048 \mathrm{M}
$$

Test Yourself How many grams of $\mathrm{Br}^{-}$were in a sample that produced 1.000 g of AgBr precipitate $(\mathrm{FM}=187.77)$ ? (Answer: 0.4255 g$)$

## EXAMPLE Marie Curie"s Measurement of the Atomic Mass of Radium

In her Ph.D. research (Radioactive Substances, 1903), Marie Curie measured the atomic mass of the element radium, which she discovered. She knew that radium is in the same family as barium, so the formula of radium chloride is $\mathrm{RaCl}_{2}$. When 0.09192 g of pure $\mathrm{RaCl}_{2}$ was dissolved and treated with excess $\mathrm{AgNO}_{3}, 0.08890 \mathrm{~g}$ of AgCl precipitated. How many moles of $\mathrm{Cl}^{-}$were in the $\mathrm{RaCl}_{2}$ ? From this measurement, find the atomic mass of Ra.

Solution AgCl precipitate weighing 0.08890 g contains

$$
\frac{0.08890 \mathrm{~g} \mathrm{AgCt}}{143.321 \mathrm{~g} \mathrm{AgCt} / \mathrm{mol} \mathrm{AgCl}}=6.202_{9} \times 10^{-4} \mathrm{~mol} \mathrm{AgCl}
$$

Because 1 mol of AgCl contains 1 mol of $\mathrm{Cl}^{-}$, there must have been $6.202{ }_{9} \times 10^{-4} \mathrm{~mol}$ of $\mathrm{Cl}^{-}$in the $\mathrm{RaCl}_{2}$. For 2 mol of Cl , there must be 1 mol of Ra , so

$$
\mathrm{mol} \text { radium }=\frac{6.202_{9} \times 10^{-4} \mathrm{motet}}{2 \mathrm{~mol} \mathrm{Ct} / \mathrm{mol} \mathrm{Ra}}=3.101_{4} \times 10^{-4} \mathrm{~mol}
$$

Let the formula mass of $\mathrm{RaCl}_{2}$ be $x$. We found that $0.09192 \mathrm{~g} \mathrm{RaCl}_{2}$ contains $3.101_{4} \times 10^{-4} \mathrm{~mol} \mathrm{RaCl}_{2}$. Therefore,

$$
\begin{gathered}
3.101_{4} \times 10^{-4} \mathrm{~mol} \mathrm{RaCl}_{2}=\frac{0.09192 \mathrm{~g} \mathrm{RaCl}}{x \mathrm{~g} \mathrm{RaCl}_{2} / \mathrm{mol} \mathrm{RaCl}_{2}} \\
x=\frac{0.09192 \mathrm{~g} \mathrm{RaCl}}{3.101_{4} \times 10^{-4} \mathrm{~mol} \mathrm{RaCl}_{2}}=296.3_{8} \mathrm{~g} / \mathrm{mol}
\end{gathered}
$$

The atomic mass of Cl is 35.453 , so the formula mass of $\mathrm{RaCl}_{2}$ is
Formula mass of $\mathrm{RaCl}_{2}=$ atomic mass of $\mathrm{Ra}+2(35.453 \mathrm{~g} / \mathrm{mol})=296.3_{8} \mathrm{~g} / \mathrm{mol}$

$$
\Rightarrow \text { atomic mass of } \mathrm{Ra}=225.5 \mathrm{~g} / \mathrm{mol}
$$

Test Yourself How many grams of AgBr would have been formed from 0.100 g of $\mathrm{RaBr}_{2}$ ? (Answer: 0.097 g )

Representative analytical precipitations are listed in Table 26-1. A few common organic precipitants (agents that cause precipitation) are listed in Table 26-2. Conditions must be controlled to selectively precipitate one species. Potentially interfering substances may need to be removed prior to analysis.

The inside cover of this book lists the atomic number (the integer mass) of the long-lived isotope of Ra, which is 226.

TABLE 26-1 Representative gravimetric analyses

| Species analyzed | Precipitated form | Form weighed | Interfering species |
| :---: | :---: | :---: | :---: |
| $\mathrm{K}^{+}$ | $\mathrm{KB}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{4}$ | $\mathrm{KB}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{4}$ | $\mathrm{NH}_{4}^{+}, \mathrm{Ag}^{+}, \mathrm{Hg}^{2+}, \mathrm{Tl}^{+}, \mathrm{Rb}^{+}, \mathrm{Cs}^{+}$ |
| $\mathrm{Mg}^{2+}$ | $\mathrm{Mg}\left(\mathrm{NH}_{4}\right) \mathrm{PO}_{4} \cdot 6 \mathrm{H}_{2} \mathrm{O}$ | $\mathrm{Mg}_{2} \mathrm{P}_{2} \mathrm{O}_{7}$ | Many metals except $\mathrm{Na}^{+}$and $\mathrm{K}^{+}$ |
| $\mathrm{Ca}^{2+}$ | $\mathrm{CaC}_{2} \mathrm{O}_{4} \cdot \mathrm{H}_{2} \mathrm{O}$ | $\mathrm{CaCO}_{3}$ or CaO | Many metals except $\mathrm{Mg}^{2+}, \mathrm{Na}^{+}, \mathrm{K}^{+}$ |
| $\mathrm{Ba}^{2+}$ | $\mathrm{BaSO}_{4}$ | $\mathrm{BaSO}_{4}$ | $\mathrm{Na}^{+}, \mathrm{K}^{+}, \mathrm{Li}^{+}, \mathrm{Ca}^{2+}, \mathrm{Al}^{3+}, \mathrm{Cr}^{3+}, \mathrm{Fe}^{3+}, \mathrm{Sr}^{2+}, \mathrm{Pb}^{2+}, \mathrm{NO}_{3}^{-}$ |
| $\mathrm{Ti}^{4+}$ | TiO (5,7-dibromo-8hydroxyquinoline) ${ }_{2}$ | Same | $\mathrm{Fe}^{3+}, \mathrm{Zr}^{4+}, \mathrm{Cu}^{2+}, \mathrm{C}_{2} \mathrm{O}_{4}^{2-}$, citrate, HF |
| $\mathrm{VO}_{4}^{3-}$ | $\mathrm{Hg}_{3} \mathrm{VO}_{4}$ | $\mathrm{V}_{2} \mathrm{O}_{5}$ | $\mathrm{Cl}^{-}, \mathrm{Br}^{-}, \mathrm{I}^{-}, \mathrm{SO}_{4}^{2-}, \mathrm{CrO}_{4}^{2-}, \mathrm{AsO}_{4}^{3-}, \mathrm{PO}_{4}^{3-}$ |
| $\mathrm{Cr}^{3+}$ | $\mathrm{PbCrO}_{4}$ | $\mathrm{PbCrO}_{4}$ | $\mathrm{Ag}^{+}$, $\mathrm{NH}_{4}^{+}$ |
| $\mathrm{Mn}^{2+}$ | $\mathrm{Mn}\left(\mathrm{NH}_{4}\right) \mathrm{PO}_{4} \cdot \mathrm{H}_{2} \mathrm{O}$ | $\mathrm{Mn}_{2} \mathrm{P}_{2} \mathrm{O}_{7}$ | Many metals |
| $\mathrm{Fe}^{3+}$ | $\mathrm{Fe}\left(\mathrm{HCO}_{2}\right)_{3}$ | $\mathrm{Fe}_{2} \mathrm{O}_{3}$ | Many metals |
| $\mathrm{Co}^{2+}$ | Co (1-nitroso-2-naphtholate) $2^{2}$ | $\mathrm{CoSO}_{4}$ (by reaction with $\mathrm{H}_{2} \mathrm{SO}_{4}$ ) | $\mathrm{Fe}^{3+}, \mathrm{Pd}^{2+}, \mathrm{Zr}^{4+}$ |
| $\mathrm{Ni}^{2+}$ | $\mathrm{Ni}\left(\right.$ dimethylglyoximate) ${ }_{2}$ | Same | $\mathrm{Pd}^{2+}, \mathrm{Pt}^{2+}, \mathrm{Bi}^{3+}, \mathrm{Au}^{3+}$ |
| $\mathrm{Cu}^{2+}$ | CuSCN (after reduction of $\mathrm{Cu}^{2+}$ to $\mathrm{Cu}^{+}$with $\mathrm{HSO}_{3}^{-}$) | CuSCN | $\mathrm{NH}_{4}^{+}, \mathrm{Pb}^{2+}, \mathrm{Hg}^{2+}, \mathrm{Ag}^{+}$ |
| $\mathrm{Zn}^{2+}$ | $\mathrm{Zn}\left(\mathrm{NH}_{4}\right) \mathrm{PO}_{4} \cdot \mathrm{H}_{2} \mathrm{O}$ | $\mathrm{Zn}_{2} \mathrm{P}_{2} \mathrm{O}_{7}$ | Many metals |
| $\mathrm{Ce}^{4+}$ | $\mathrm{Ce}\left(\mathrm{IO}_{3}\right)_{4}$ | $\mathrm{CeO}_{2}$ | $\mathrm{Th}^{4+}, \mathrm{Ti}^{4+}, \mathrm{Zr}^{4+}$ |
| $\mathrm{Al}^{3+}$ | Al (8-hydroxyquinolate) ${ }_{3}$ | Same | Many metals |
| $\mathrm{Sn}^{4+}$ | $\mathrm{Sn}\left(\right.$ cupferron) ${ }_{4}$ | $\mathrm{SnO}_{2}$ | $\mathrm{Cu}^{2+}, \mathrm{Pb}^{2+}, \mathrm{As}($ III $)$ |
| $\mathrm{Pb}^{2+}$ | $\mathrm{PbSO}_{4}$ | $\mathrm{PbSO}_{4}$ | $\mathrm{Ca}^{2+}, \mathrm{Sr}^{2+}, \mathrm{Ba}^{2+}, \mathrm{Hg}^{2+}, \mathrm{Ag}^{+}, \mathrm{HCl}, \mathrm{HNO}_{3}$ |
| $\mathrm{NH}_{4}^{+}$ | $\mathrm{NH}_{4} \mathrm{~B}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{4}$ | $\mathrm{NH}_{4} \mathrm{~B}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{4}$ | $\mathrm{K}^{+}, \mathrm{Rb}^{+}, \mathrm{Cs}^{+}$ |
| $\mathrm{Cl}^{-}$ | AgCl | AgCl | $\mathrm{Br}^{-}, \mathrm{I}^{-}, \mathrm{SCN}^{-}, \mathrm{S}^{2-}, \mathrm{S}_{2} \mathrm{O}_{3}^{2-}, \mathrm{CN}^{-}$ |
| $\mathrm{Br}^{-}$ | AgBr | AgBr | $\mathrm{Cl}^{-}, \mathrm{I}^{-}, \mathrm{SCN}^{-}, \mathrm{S}^{2-}, \mathrm{S}_{2} \mathrm{O}_{3}^{2-}, \mathrm{CN}^{-}$ |
| $\mathrm{I}^{-}$ | AgI | AgI | $\mathrm{Cl}^{-}, \mathrm{Br}^{-}, \mathrm{SCN}^{-}, \mathrm{S}^{2-}, \mathrm{S}_{2} \mathrm{O}_{3}^{2-}, \mathrm{CN}^{-}$ |
| $\mathrm{SCN}^{-}$ | CuSCN | CuSCN | $\mathrm{NH}_{4}^{+}, \mathrm{Pb}^{2+}, \mathrm{Hg}^{2+}, \mathrm{Ag}^{+}$ |
| $\mathrm{CN}^{-}$ | AgCN | AgCN | $\mathrm{Cl}^{-}, \mathrm{Br}^{-}, \mathrm{I}^{-}, \mathrm{SCN}^{-}, \mathrm{S}^{2-}, \mathrm{S}_{2} \mathrm{O}_{3}^{2-}$ |
| $\mathrm{F}^{-}$ | $\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3} \mathrm{SnF}$ | $\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3} \mathrm{SnF}$ | Many metals (except alkali metals), $\mathrm{SiO}_{4}^{4-}, \mathrm{CO}_{3}^{2-}$ |

| $\mathrm{CO}_{3}^{2-}$ | $\mathrm{CO}_{2}$ (by acidification) | $\mathrm{CO}_{2}$ | (The liberated $\mathrm{CO}_{2}$ is trapped with Ascarite and weighed.) |

TABLE 26-2 Common organic precipitating agents
Name

FIGURE 26-1 Particle-size distribution of colloids formed when $\mathrm{FeSO}_{4}$ was oxidized to $\mathrm{Fe}^{3+}$ in $10^{-4} \mathrm{M} \mathrm{OH}^{-}$in the presence of phosphate $\left(\mathrm{PO}_{4}^{3-}\right)$, silicate $\left(\mathrm{SiO}_{4}^{4-}\right)$, or no added anions. [From M. L. Magnuson, D. A. Lytle, C. M. Frietch, and C. A. Kelty, "Characterization of Submicron Aqueous Iron(III) Colloids by Sedimentation Field Flow Fractionation," Anal. Chem. 2001, 73, 4815.]

Supersaturation tends to decrease the particle size of a precipitate.

## 26-2 Precipitation

The ideal product of a gravimetric analysis should be pure, insoluble, and easily filterable, and should possess a known composition. Few substances meet these requirements, but appropriate techniques can help optimize properties of gravimetric precipitates.

Precipitated particles should not be so small that they clog or pass through the filter. Larger crystals have less surface area to which impurities can become attached. At the other extreme is a colloidal suspension of particles that have diameters in the approximate range $1-500 \mathrm{~nm}$ and pass through most filters (Figure 26-1 and Demonstration 26-1). Precipitation conditions determine the particle size.

## Crystal Growth

Crystallization occurs in two phases: nucleation and particle growth. In nucleation, solutes are thought to form a disorganized cluster of sufficient size, which then reorganizes into an ordered structure capable of growing into larger particles. ${ }^{5}$ Nucleation can occur on suspended impurity particles or scratches on a glass surface. When Fe (III) reacts with 0.1 M tetramethylammonium hydroxide at $25^{\circ} \mathrm{C}$, nuclei of hydrated $\mathrm{Fe}(\mathrm{OH})_{3}$ are 4 nm in diameter and contain $\sim 50 \mathrm{Fe}$ atoms. ${ }^{6}$ In particle growth, molecules or ions condense onto the nucleus to form a larger crystal. $\mathrm{Fe}(\mathrm{OH})_{3}$ nuclei grow into plates with lateral dimensions of $\sim 30 \times 7 \mathrm{~nm}$ after 15 min at $60^{\circ} \mathrm{C}$.

A supersaturated solution contains more solute than should be present at equilibrium. Nucleation proceeds faster than particle growth in a highly supersaturated solution to produce tiny particles or, worse, a colloid. In a less supersaturated solution, nucleation is slower, and nuclei have a chance to grow into larger, more tractable particles.

Techniques that promote particle growth include

1. Raising the temperature to increase solubility and thereby decrease supersaturation
2. Adding precipitant slowly with vigorous mixing, to prevent a local, highly supersaturated condition where the stream of precipitant first enters the analyte
3. Using a large volume of solution so that concentrations of analyte and precipitant are low

## DEMONSTRATION 26-1 Colloids and Dialysis

Colloids are particles with diameters of $\sim 1-100 \mathrm{~nm}$. They are larger than most molecules but too small to precipitate. They remain in solution, suspended by the Brownian motion (random movement) of solvent molecules. ${ }^{2}$

To prepare colloidal iron(III) hydroxide, heat 200 mL of distilled water in a beaker to $70^{\circ}-90^{\circ} \mathrm{C}$ and leave an identical beaker of water at room temperature. Add 1 mL of $1 \mathrm{M} \mathrm{FeCl}_{3}$ to each beaker and stir. The warm solution turns brown-red in a few seconds, whereas the cold solution remains yellow (Color Plate 32). The yellow color is characteristic of low-molecular-mass $\mathrm{Fe}^{3+}$ compounds. The red color results from colloidal aggregates of $\mathrm{Fe}^{3+}$ ions held together by hydroxide, oxide, and some chloride ions. Each particle contains $\sim 10^{3}$ atoms of Fe with a molecular mass of $10^{5}$ and a diameter of 10 nm .

You can demonstrate the size of colloidal particles by dialysis, a process in which two solutions are separated by a semipermeable membrane that has pores with diameters of $1-5 \mathrm{~nm} .^{3}$ Small molecules diffuse through these pores, but large molecules (such as proteins or colloids) cannot. (Microdialysis in biology is shown in Figure 25-41.)

Pour some brown-red colloid into a dialysis tube knotted at one end; then tie off the other end. Drop the tube into a flask of distilled water to show that the color remains inside the bag after several days (Color Plate 32). For comparison, leave an identical bag containing dark blue $1 \mathrm{M} \mathrm{CuSO}_{4} \cdot 5 \mathrm{H}_{2} \mathrm{O}$ in another flask of water. $\mathrm{Cu}^{2+}$ diffuses out and the internal and external solution will be light blue in 24 h . The yellow food coloring, tartrazine, can be used in place of $\mathrm{Cu}^{2+}$. If dialysis is conducted in hot water, it is completed during one class period. ${ }^{4}$

Large molecules remain trapped inside a dialysis bag, whereas small molecules diffuse through the membrane in both directions.

Dialysis is used to treat patients suffering from kidney failure. Blood is passed over a membrane through which metabolic waste products diffuse and are diluted into a large volume of liquid that is discarded. Protein molecules, which are a necessary part of the blood plasma, are too large to cross the membrane and are retained in the blood.

## Homogeneous Precipitation

In homogeneous precipitation, the precipitant is generated slowly by a chemical reaction (Table 26-3). For example, urea decomposes slowly in boiling water to produce $\mathrm{OH}^{-}$:

Gradual $\mathrm{OH}^{-}$production enhances the particle size of $\mathrm{Fe}(\mathrm{III})$ formate precipitate:

## Precipitation in the Presence of Electrolyte

Ionic compounds are usually precipitated in the presence of an electrolyte. To understand why, we must discuss how tiny colloidal crystallites coagulate (come together) into larger crystals. We illustrate the case of AgCl , which is commonly formed in $0.1 \mathrm{M} \mathrm{HNO}_{3}$.

Figure 26-2 shows a colloidal particle of AgCl growing in a solution containing excess $\mathrm{Ag}^{+}, \mathrm{H}^{+}$, and $\mathrm{NO}_{3}^{-}$. The surface of the particle has excess positive charge due to the adsorption of extra silver ions on exposed chloride ions. (To be adsorbed means to be attached to the surface. In contrast, absorption means penetration beyond the surface, to the inside.) The

An electrolyte is a compound that dissociates into ions when it dissolves.

Although it is common to find the excess common ion adsorbed on the crystal surface, other ions can be selectively adsorbed. Citrate is bound in preference to sulfate on the surface of $\mathrm{BaSO}_{4}$.

TABLE 26-3 Common reagents used for homogeneous precipitation

| Precipitant | Reagent | Reaction | Some elements precipitated |
| :---: | :---: | :---: | :---: |
| $\mathrm{OH}^{-}$ | Urea | $\left(\mathrm{H}_{2} \mathrm{~N}\right)_{2} \mathrm{CO}+3 \mathrm{H}_{2} \mathrm{O} \rightarrow \mathrm{CO}_{2}+2 \mathrm{NH}_{4}^{+}+2 \mathrm{OH}^{-}$ | $\mathrm{Al}, \mathrm{Ga}, \mathrm{Th}, \mathrm{Bi}$, $\mathrm{Fe}, \mathrm{Sn}$ |
| $\mathrm{OH}^{-}$ | Potassium cyanate | $\mathrm{HOCN}+2 \mathrm{H}_{2} \mathrm{O} \rightarrow \mathrm{NH}_{4}^{+}+\mathrm{CO}_{2}+\mathrm{OH}$ <br> Hydrogen cyanate | $\mathrm{Cr}, \mathrm{Fe}$ |
| $\mathrm{S}^{2-}$ | Thioacetamide ${ }^{a}$ |  | $\begin{aligned} & \mathrm{Sb}, \mathrm{Mo}, \mathrm{Cu}, \\ & \mathrm{Cd} \end{aligned}$ |
| $\mathrm{SO}_{4}^{2-}$ | Sulfamic acid | $\mathrm{H}_{3} \stackrel{+}{\mathrm{NSO}} \mathrm{SO}_{3}^{-}+\mathrm{H}_{2} \mathrm{O} \rightarrow \mathrm{NH}_{4}^{+}+\mathrm{SO}_{4}^{2-}+\mathrm{H}^{+}$ | $\begin{aligned} & \mathrm{Ba}, \mathrm{Ca}, \mathrm{Sr}, \\ & \mathrm{~Pb} \end{aligned}$ |
| $\mathrm{C}_{2} \mathrm{O}_{4}^{2-}$ | Dimethyl oxalate |  | $\mathrm{Ca}, \mathrm{Mg}, \mathrm{Zn}$ |
| $\mathrm{PO}_{4}^{3-}$ | Trimethyl phosphate | $\left(\mathrm{CH}_{3} \mathrm{O}\right)_{3} \mathrm{P}=\mathrm{O}+3 \mathrm{H}_{2} \mathrm{O} \rightarrow 3 \mathrm{CH}_{3} \mathrm{OH}+\mathrm{PO}_{4}^{3-}+3 \mathrm{H}^{+}$ | Zr, Hf |
| $\mathrm{CrO}_{4}^{2-}$ | Chromic ion plus bromate | $2 \mathrm{Cr}^{3+}+\mathrm{BrO}_{3}^{-}+5 \mathrm{H}_{2} \mathrm{O} \rightarrow 2 \mathrm{CrO}_{4}^{2-}+\mathrm{Br}^{-}+10 \mathrm{H}^{+}$ | Pb |
| 8-Hydroxyquinoline | 8-Acetoxyquinoline |  | $\begin{aligned} & \mathrm{Al}, \mathrm{U}, \mathrm{Mg}, \\ & \mathrm{Zn} \end{aligned}$ |

a. Hydrogen sulfide is volatile and toxic; it should be handled only in a well-vented hood. Thioacetamide is a carcinogen that should be handled with gloves. If thioacetamide contacts your skin, wash yourself thoroughly immediately. Leftover reagent is destroyed by heating at $50^{\circ} \mathrm{C}$ with
5 mol of NaOCl per mole of thioacetamide. [H. Elo, J. Chem. Ed. 1987, 64, A144.]

FIGURE 26-2 Colloidal particle of AgCl growing in a solution containing excess $\mathrm{Ag}^{+}, \mathrm{H}^{+}$, and $\mathrm{NO}_{3}^{-}$. The particle has a net positive charge because of adsorbed $\mathrm{Ag}^{+}$ions. The region of solution surrounding the particle is called the ionic atmosphere. It has a net negative charge because the particle attracts anions and repels cations.
positively charged surface attracts anions and repels cations from the ionic atmosphere (Figure 26-2) surrounding the particle. The positively charged particle and the negatively charged ionic atmosphere together are called the electric double layer.

Colloidal particles must collide with one another to coalesce. However, the negatively charged ionic atmospheres of the particles repel one another. Particles must have enough kinetic energy to overcome electrostatic repulsion before they can coalesce.

Heating promotes coalescence by increasing the kinetic energy. Increasing electrolyte concentration $\left(\mathrm{HNO}_{3}\right.$ for AgCl$)$ decreases the volume of the ionic atmosphere and allows particles to come closer together before electrostatic repulsion becomes significant. For this reason, most gravimetric precipitations are done in the presence of an electrolyte.

## Digestion

Liquid from which a substance precipitates or crystallizes is called the mother liquor. After precipitation, most procedures call for a period of standing in the presence of the hot mother liquor. This treatment, called digestion, promotes slow recrystallization of the precipitate. Particle size increases and impurities tend to be expelled from the crystal.

## Purity

Adsorbed impurities are bound to the surface of a crystal. Absorbed impurities (within the crystal) are classified as inclusions or occlusions. Inclusions are impurity ions that randomly occupy sites in the crystal lattice normally occupied by ions that belong in the crystal. Inclusions are more likely when the impurity ion has a size and charge similar to those of one of the ions that belongs to the product. Occlusions are pockets of impurity that are literally trapped inside the growing crystal.

Adsorbed, occluded, and included impurities are said to be coprecipitated. That is, the impurity is precipitated along with the desired product, even though the solubility of the impurity has not been exceeded (Figure 26-3).

Coprecipitation tends to be worst in colloidal precipitates such as $\mathrm{BaSO}_{4}, \mathrm{Al}(\mathrm{OH})_{3}$, and $\mathrm{Fe}(\mathrm{OH})_{3}$, which all have a large surface area. Many procedures call for washing away the mother liquor, redissolving the precipitate, and reprecipitating the product. During the second precipitation, the concentration of impurities in solution is lower than during the first precipitation, and the degree of coprecipitation therefore tends to be lower.

Occasionally, a trace component is intentionally isolated by coprecipitation with a major component of the solution. The precipitate used to collect the trace component is said to be a gathering agent, and the process is called gathering. Natural arsenic in drinking water in Bangladesh is a significant health hazard. One way to remove arsenic is by coprecipitation with $\mathrm{Fe}(\mathrm{OH})_{3} .{ }^{7} \mathrm{Fe}(\mathrm{II})$ or $\mathrm{Fe}(s)$ is added to the water and oxidized in air for several hours to precipitate $\mathrm{Fe}(\mathrm{OH})_{3}$. After filtration through sand to remove solids, the water is drinkable.

Some impurities can be treated with a masking agent to prevent them from reacting with the precipitant. In the gravimetric analysis of $\mathrm{Be}^{2+}, \mathrm{Mg}^{2+}, \mathrm{Ca}^{2+}$, or $\mathrm{Ba}^{2+}$ with the reagent $N-p$-chlorophenylcinnamohydroxamic acid, impurities such as $\mathrm{Ag}^{+}, \mathrm{Mn}^{2+}, \mathrm{Zn}^{2+}, \mathrm{Cd}^{2+}$, $\mathrm{Hg}^{2+}, \mathrm{Fe}^{2+}$, and $\mathrm{Ga}^{3+}$ are kept in solution by excess $\mathrm{KCN} . \mathrm{Pb}^{2+}, \mathrm{Pd}^{2+}, \mathrm{Sb}^{3+}, \mathrm{Sn}^{2+}, \mathrm{Bi}^{3+}$, $\mathrm{Zr}^{4+}, \mathrm{Ti}^{4+}, \mathrm{V}^{5+}$, and $\mathrm{Mo}^{6+}$ are masked with a mixture of citrate and oxalate.

$$
\begin{aligned}
& \underset{\text { Analyte }}{\mathrm{Ca}^{2+}}+\underset{\substack{N-p \text {-Chlorophenyl- } \\
\text { cinnamohydroxamic acid }}}{\rightarrow} \quad \underset{\text { Precipitate }}{ } \mathrm{CaR}_{2}(s) \downarrow+2 \mathrm{H}^{+} \\
& \underset{\text { Impurity }}{\mathrm{Mn}^{2+}}+\underset{\text { Masking agent }}{6 \mathrm{CN}^{-}} \rightarrow \underset{\text { Stays in solution }}{\mathrm{Mn}(\mathrm{CN})_{6}^{4-}}
\end{aligned}
$$

Even when a precipitate forms in a pure state, impurities might collect on the product while it is standing in the mother liquor. This is called postprecipitation and usually involves a supersaturated impurity that does not readily crystallize. An example is the crystallization of $\mathrm{MgC}_{2} \mathrm{O}_{4}$ on $\mathrm{CaC}_{2} \mathrm{O}_{4}$.

Washing a precipitate on a filter helps remove droplets of liquid containing excess solute. Some precipitates can be washed with water, but many require electrolyte to maintain coherence. For these precipitates, the ionic atmosphere is required to neutralize the surface charge of the tiny particles. If electrolyte is washed away with water, the charged solid particles repel one another and the product breaks up. This breaking up, called peptization, results in loss of product through the filter. AgCl will peptize if washed with water, so it is washed with dilute $\mathrm{HNO}_{3}$ instead. Electrolyte used for washing must be volatile so that it will be lost during drying. Volatile electrolytes include $\mathrm{HNO}_{3}, \mathrm{HCl}, \mathrm{NH}_{4} \mathrm{NO}_{3}, \mathrm{NH}_{4} \mathrm{Cl}$, and $\left(\mathrm{NH}_{4}\right)_{2} \mathrm{CO}_{3}$.

## Product Composition

The final product must have a known, stable composition. A hygroscopic substance is one that picks up water from the air and is therefore difficult to weigh accurately. Many precipitates contain a variable quantity of water and must be dried under conditions that give a known (possibly zero) stoichiometry of $\mathrm{H}_{2} \mathrm{O}$.

Ignition (strong heating) is used to change the chemical form of some precipitates. For example, igniting $\mathrm{Fe}\left(\mathrm{HCO}_{2}\right)_{3} \cdot n \mathrm{H}_{2} \mathrm{O}$ at $850^{\circ} \mathrm{C}$ for 1 h gives $\mathrm{Fe}_{2} \mathrm{O}_{3}$, and igniting $\mathrm{Mg}\left(\mathrm{NH}_{4}\right) \mathrm{PO}_{4} \cdot 6 \mathrm{H}_{2} \mathrm{O}$ at $1100^{\circ} \mathrm{C}$ gives $\mathrm{Mg}_{2} \mathrm{P}_{2} \mathrm{O}_{7}$.

FIGURE 26-3 Coprecipitation of phosphate with calcium carbonate in coral. Coprecipitated phosphate is proportional to phosphate concentration in seawater. By measuring P/Ca in ancient coral, we can infer that phosphate concentration in the western Mediterranean Sea 11200 years ago was twice as high as current values. [Data from P. Montagna, M. McCulloch, M. Taviani, C. Mazzoli, and B. Vendrell, "Phosphorus in Cold-Water Corals as a Proxy for Seawater Nutrient Chemistry," Science 2006, 312, 1788.]

Removal of occluded $\mathrm{NO}_{3}^{-}$from $\mathrm{BaSO}_{4}$ by reprecipitation
$\left.\begin{array}{ll} & {\left[\mathrm{NO}_{3}^{-}\right] /\left[\mathrm{SO}_{4}^{-}\right]} \\ \text {in precipitate }\end{array}\right]$

Data from H. Bao, "Purifying Barite for Oxygen Isotope Measurement by Dissolution and Reprecipitation in a Chelating Solution," Anal. Chem. 2006, 78, 304.

(ligand atoms are bold)

Ammonium chloride decomposes when heated:

$$
\mathrm{NH}_{4} \mathrm{Cl}(s) \rightarrow \mathrm{NH}_{3}(g)+\mathrm{HCl}(g)
$$

FIGURE 26-4 Thermogravimetric curve for calcium salicylate. [From G. Liptay, ed., Atlas of Thermoanalytical Curves (London: Heyden and Son, 1976).]

If you were performing this analysis, it would be important to determine that the impurities in the piperazine do not precipitate-otherwise the result will be high.

The gravimetric factor relates mass of product to mass of analyte.

In thermogravimetric analysis, a substance is heated, and its mass is measured as a function of temperature. Figure 26-4 shows how the composition of calcium salicylate changes in four stages:

The composition of the product depends on the temperature and duration of heating.

## 26-3 Examples of Gravimetric Calculations

We now examine some examples that illustrate how to relate the mass of a gravimetric precipitate to the quantity of the original analyte. The general approach is to relate the moles of product to the moles of reactant.

## EXAMPLE Relating Mass of Product to Mass of Reactant

The piperazine content of an impure commercial material can be determined by precipitating and weighing the diacetate: ${ }^{8}$

In one experiment, 0.3126 g of sample was dissolved in 25 mL of acetone, and 1 mL of acetic acid was added. After 5 min , the precipitate was filtered, washed with acetone, dried at $110^{\circ} \mathrm{C}$, and found to weigh 0.7121 g . Find the wt $\%$ of piperazine in the sample.

Solution For each mole of piperazine in the impure material, 1 mol of product is formed.

$$
\text { Moles of product }=\frac{0.7121 \mathrm{~g}}{206.240 \mathrm{~g} / \mathrm{mol}}=3.453 \times 10^{-3} \mathrm{~mol}
$$

This many moles of piperazine corresponds to

$$
\text { Grams of piperazine }=\left(3.453 \times 10^{-3} \mathrm{mot}\right)\left(86.136 \frac{\mathrm{~g}}{\mathrm{mot}}\right)=0.2974 \mathrm{~g}
$$

which gives

$$
\text { Percentage of piperazine in analyte }=\frac{0.2974 g}{0.3126 g} \times 100=95.14 \%
$$

An alternative (but equivalent) way to work this problem is to realize that 206.240 g $(1 \mathrm{~mol})$ of product will be formed for every $86.136 \mathrm{~g}(1 \mathrm{~mol})$ of piperazine analyzed. Because 0.7121 g of product was formed, the amount of reactant is given by

$$
\begin{gathered}
\frac{x \mathrm{~g} \text { piperazine }}{0.7121 \mathrm{~g} \text { product }}=\frac{86.136 \mathrm{~g} \text { piperazine }}{206.243 \mathrm{~g} \text { product }} \\
\Rightarrow x=\left(\frac{86.136 \mathrm{~g} \text { piperazine }}{206.240 \text { g protuct }}\right) 0.7121 \mathrm{~g} \text { product }=0.2974 \mathrm{~g} \text { piperazine }
\end{gathered}
$$

The quantity $86.136 / 206.240$ is the gravimetric factor relating the mass of starting material to the mass of product.

Test Yourself A 0.3854 g sample gave 0.8000 g of product. Find the $\mathrm{wt} \%$ of piperazine in the sample. (Answer: 86.69\%)

For a reaction in which the stoichiometric relation between analyte and product is not 1:1, we must use the correct stoichiometry in formulating the gravimetric factor. For example, an unknown containing $\mathrm{Mg}^{2+}$ (atomic mass $=24.3050$ ) can be analyzed gravimetrically to produce magnesium pyrophosphate $\left(\mathrm{Mg}_{2} \mathrm{P}_{2} \mathrm{O}_{7}, \mathrm{FM} 222.553\right)$. The gravimetric factor would be

$$
\frac{\text { Grams of } \mathrm{Mg} \text { in analyte }}{\text { Grams of } \mathrm{Mg}_{2} \mathrm{P}_{2} \mathrm{O}_{7} \text { formed }}=\frac{2 \times(24.3050)}{222.553}
$$

because it takes two $\mathrm{Mg}^{2+}$ to make one $\mathrm{Mg}_{2} \mathrm{P}_{2} \mathrm{O}_{7}$.

## EXAMPLE Calculating How Much Precipitant to Use

(a) To measure the nickel content in steel, the alloy is dissolved in 12 M HCl and neutralized in the presence of citrate ion, which maintains iron in solution. The slightly basic solution is warmed, and dimethylglyoxime (DMG) is added to precipitate the red DMG-nickel complex quantitatively. The product is filtered, washed with cold water, and dried at $110^{\circ} \mathrm{C}$.

If the nickel content is known to be near $3 \mathrm{wt} \%$ and you wish to analyze 1.0 g of steel, what volume of $1.0 \mathrm{wt} \%$ alcoholic DMG solution should be used to give a $50 \%$ excess of DMG for the analysis? Assume that the density of the alcohol solution is $0.79 \mathrm{~g} / \mathrm{mL}$.

Solution Because the Ni content is about $3 \%, 1.0 \mathrm{~g}$ of steel will contain about 0.03 g of Ni , which corresponds to

$$
\frac{0.03 \mathrm{gAi}}{58.69 \mathrm{gAi} / \mathrm{mol} \mathrm{Ni}}=5.11 \times 10^{-4} \mathrm{~mol} \mathrm{Ni}
$$

This amount of metal requires

$$
2\left(5.11 \times 10^{-4} \mathrm{~mol} \mathrm{Ni}\right)(116.12 \mathrm{~g} \mathrm{DMG} / \mathrm{mol} \mathrm{Ni})=0.119 \mathrm{~g} \mathrm{DMG}
$$

because 1 mol of $\mathrm{Ni}^{2+}$ requires 2 mol of DMG. A $50 \%$ excess of DMG would be $(1.5)(0.119 \mathrm{~g})=0.178 \mathrm{~g}$. This much DMG is contained in

$$
\frac{0.178 \mathrm{~g} \text { DAG }}{0.010 \mathrm{gDMG} / \mathrm{g} \text { solution }}=17.8 \mathrm{~g} \text { solution }
$$

which occupies a volume of

$$
\frac{17.8 \mathrm{~g} \text { solution }}{0.79 \mathrm{~g} \text { solution } / \mathrm{mL}}=23 \mathrm{~mL}
$$

(b) If 1.1634 g of steel gives 0.1795 g of precipitate, what is the percentage of Ni in the steel?

Solution For each mole of Ni in the steel, 1 mol of precipitate will be formed. Therefore, 0.1795 g of precipitate corresponds to

$$
\frac{0.1795 \mathrm{~g} \mathrm{Ni}(\mathrm{DMG})_{2}}{288.91 \mathrm{~g} \mathrm{Ni}(\mathrm{DMG})_{2} / \mathrm{mol} \mathrm{Ni}(\mathrm{DMG})_{2}}=6.213 \times 10^{-4} \mathrm{~mol} \mathrm{Ni}(\mathrm{DMG})_{2}
$$

The mass of Ni in the steel is $\left(6.213 \times 10^{-4} \mathrm{molNi}\right)(58.69 \mathrm{~g} / \mathrm{mol} \mathrm{Ni})=0.03646 \mathrm{~g}$, and the $\mathrm{wt} \% \mathrm{Ni}$ in steel is

$$
\frac{0.03646 \mathrm{~g} \mathrm{Ni}}{1.1634 \mathrm{~g} \text { steel }} \times 100=3.134 \%
$$

Please appreciate the huge uncertainty: A $0.5-\mathrm{mg}$ difference in mass of product gives a $9 \%$ difference in calculated composition of the mixture.

A slightly simpler way to approach this problem comes from realizing that 58.69 g of $\mathrm{Ni}(1 \mathrm{~mol})$ would give $288.91 \mathrm{~g}(1 \mathrm{~mol})$ of product. Calling the mass of Ni in the sample $x$, we can write

$$
\frac{\text { Grams of Ni analyzed }}{\text { Grams of product formed }}=\frac{x}{0.1795}=\frac{58.69}{288.91} \Rightarrow \mathrm{Ni}=0.03646 \mathrm{~g}
$$

Test Yourse/f An alloy contains $\sim 2.0 \mathrm{wt} \% \mathrm{Ni}$. What volume of $0.83 \mathrm{wt} \% \mathrm{DMG}$ should be used to provide a $50 \%$ excess of DMG for the analysis of 1.8 g of steel? What mass of $\mathrm{Ni}(\mathrm{DMG})_{2}$ precipitate is expected? (Answer: $33 \mathrm{~mL}, 0.18 \mathrm{~g}$ )

## EXAMPLE A Problem with Two Components

A mixture of the 8 -hydroxyquinoline complexes of Al and Mg weighed 1.0843 g . When ignited in a furnace open to the air, the mixture decomposed, leaving a residue of $\mathrm{Al}_{2} \mathrm{O}_{3}$ and MgO weighing 0.1344 g . Find the weight percent of $\mathrm{Al}\left(\mathrm{C}_{9} \mathrm{H}_{6} \mathrm{NO}\right)_{3}$ in the original mixture.

Solution We will abbreviate the 8-hydroxyquinoline anion as Q . Letting the mass of $\mathrm{AlQ}_{3}$ be $x$ and the mass of $\mathrm{MgQ}_{2}$ be $y$, we can write

$$
\underset{\substack{\text { Mass of } \\ \mathrm{AlQ}_{3}}}{x}+\underset{\substack{\text { Mass of }^{M g Q_{2}}} \underset{y}{y}=1.0843 \mathrm{~g}}{\substack{\text { and }}}
$$

The moles of Al are $x / 459.43$, and the moles of Mg are $y / 312.61$. The moles of $\mathrm{Al}_{2} \mathrm{O}_{3}$ are one-half of the total moles of Al , because it takes 2 mol of Al to make 1 mol of $\mathrm{Al}_{2} \mathrm{O}_{3}$.

$$
\text { Moles of } \mathrm{Al}_{2} \mathrm{O}_{3}=\left(\frac{1}{2}\right) \frac{x}{459.43}
$$

The moles of MgO will equal the moles of $\mathrm{Mg}=y / 312.61$. Now we can write

$$
\overbrace{\underbrace{2}_{\text {mol Al}} \mathrm{O}_{3}}^{\left.\frac{1}{2}\right) \frac{x}{459.43} \underbrace{(101.96)}_{\frac{\mathrm{g} \mathrm{Al}_{2} \mathrm{O}_{3}}{\mathrm{~mol} \mathrm{Al}_{2} \mathrm{O}_{3}}}} \mathrm{M}_{\mathrm{mol} \mathrm{MgO}}^{\frac{\mathrm{g} \mathrm{MgO}}{\mathrm{~mol} \mathrm{MgO}}} \underbrace{\text { Mass of } \mathrm{Al}_{2} \mathrm{O}_{3}}_{\underbrace{\frac{y}{312.61}} \underbrace{(40.304)}}=0.1344 \mathrm{~g}
$$

Substituting $y=1.0843-x$ into the preceding equation gives

$$
\left(\frac{1}{2}\right)\left(\frac{x}{459.43}\right)(101.96)+\left(\frac{1.0843-x}{312.61}\right)(40.304)=0.1344 \mathrm{~g}
$$

from which we find $x=0.3003 \mathrm{~g}$, which is $27.70 \%$ of the original mixture.
Test Yourself If reproducibility is $\pm 0.5 \mathrm{mg}$, product mass might have been 0.1339 to 0.1349 g. Find wt $\% \mathrm{Al}\left(\mathrm{C}_{9} \mathrm{H}_{6} \mathrm{NO}\right)_{3}$ if the product weighed 0.1339 g. (Answer: $30.27 \%$ )

## 26-4 Combustion Analysis

A historically important form of gravimetric analysis was combustion analysis to determine C and H in organic compounds burned in excess $\mathrm{O}_{2}$ (Figure 26-5). Instead of weighing combustion products, modern instruments use thermal conductivity, infrared absorption, flame photometry (for S), and coulometry (for halogens) to measure products.

## Gravimetric Combustion Analysis

In gravimetric combustion analysis, partially combusted product is passed through catalysts such as Pt gauze, $\mathrm{CuO}, \mathrm{PbO}_{2}$, or $\mathrm{MnO}_{2}$ at elevated temperature to complete the oxidation to

FIGURE 26-5 Gravimetric combustion analysis for carbon and hydrogen.
$\mathrm{CO}_{2}$ and $\mathrm{H}_{2} \mathrm{O}$. The combustion products are flushed through a chamber containing $\mathrm{P}_{4} \mathrm{O}_{10}$ ("phosphorus pentoxide"), which absorbs water, and then through a chamber of Ascarite ( NaOH on asbestos), which absorbs $\mathrm{CO}_{2}$. The increase in mass of each chamber tells how much H and C were initially present. A guard tube prevents atmospheric $\mathrm{H}_{2} \mathrm{O}$ or $\mathrm{CO}_{2}$ from entering the chambers.

## EXAMPLE Combustion Analysis Calculations

A compound weighing 5.714 mg produced 14.414 mg of $\mathrm{CO}_{2}$ and 2.529 mg of $\mathrm{H}_{2} \mathrm{O}$ upon combustion. Find the wt \% of C and H in the sample.

Solution One mole of $\mathrm{CO}_{2}$ contains 1 mol of carbon. Therefore,

$$
\begin{aligned}
& \text { Moles of } \mathrm{C} \text { in sample }=\text { moles of } \mathrm{CO}_{2} \text { produced } \\
& \qquad=\frac{14.414 \times 10^{-3} \mathrm{~g} \mathrm{CO}_{2}}{44.010 \mathrm{~g} / \mathrm{mol} \mathrm{CO}_{2}}=3.275 \times 10^{-4} \mathrm{~mol} \\
& \text { Mass of } \mathrm{C} \text { in sample }=\left(3.275 \times 10^{-4} \mathrm{~mol} \mathrm{C}\right)(12.0107 \mathrm{~g} / \mathrm{mol} \mathrm{C})=3.934 \mathrm{mg} \\
& \mathrm{wt} \% \mathrm{C}=\frac{3.934 \mathrm{mg} \mathrm{C}}{5.714 \mathrm{mg} \text { sample }} \times 100=68.84 \%
\end{aligned}
$$

One mole of $\mathrm{H}_{2} \mathrm{O}$ contains 2 mol of H . Therefore,
Moles of H in sample $=2\left(\right.$ moles of $\mathrm{H}_{2} \mathrm{O}$ produced $)$

$$
=2\left(\frac{2.529 \times 10^{-3} \mathrm{~g} \mathrm{H}_{2} \mathrm{O}}{18.015 \mathrm{~g} / \mathrm{mol} \mathrm{H}_{2} \mathrm{O}}\right)=2.808 \times 10^{-4} \mathrm{~mol}
$$

Mass of H in sample $=\left(2.808 \times 10^{-4} \mathrm{~mol} \mathrm{H}\right)(1.0079 \mathrm{~g} / \mathrm{mol} \mathrm{H})=2.830 \times 10^{-4} \mathrm{~g}$

$$
\mathrm{wt} \% \mathrm{H}=\frac{0.2830 \mathrm{mg} \mathrm{H}}{5.714 \mathrm{mg} \mathrm{sample}} \times 100=4.95 \%
$$

Test Yourself A 6.234-mg sample produced $12.123 \mathrm{mg} \mathrm{CO}_{2}$ and 2.529 mg of $\mathrm{H}_{2} \mathrm{O}$. Find the $\mathrm{wt} \%$ of C and H in the sample. (Answer: 53.07, 4.54\%)

## Combustion Analysis Today ${ }^{9}$

Figure 26-6 shows an instrument that measures C, H, N, and S in a single operation. First, a $\sim 2-\mathrm{mg}$ sample is accurately weighed and sealed in a tin or silver capsule. The analyzer is swept with He gas that has been treated to remove traces of $\mathrm{O}_{2}, \mathrm{H}_{2} \mathrm{O}$, and $\mathrm{CO}_{2}$. At the start of a run, a measured excess of $\mathrm{O}_{2}$ is added to the He stream. Then the capsule is dropped into a preheated ceramic crucible, where the capsule melts and sample is rapidly oxidized.

$$
\mathrm{C}, \mathrm{H}, \mathrm{~N}, \mathrm{~S} \xrightarrow{1050^{\circ} \mathrm{C} / \mathrm{O}_{2}} \mathrm{CO}_{2}(g)+\mathrm{H}_{2} \mathrm{O}(g)+\mathrm{N}_{2}(g)+\underbrace{\mathrm{SO}_{2}(g)+\mathrm{SO}_{3}(g)}_{95 \% \mathrm{SO}_{2}}
$$

An oxidation catalyst completes the oxidation of sample, and a reduction catalyst carries out any required reduction and removes excess $\mathrm{O}_{2}$.

The Sn capsule is oxidized to $\mathrm{SnO}_{2}$, which

1. Liberates heat to vaporize and crack (decompose) sample
2. Uses available oxygen immediately
3. Ensures that sample oxidation occurs in gas phase
4. Acts as an oxidation catalyst

FIGURE 26-7 Sequence of events in dynamic flash combustion. [From E. Pella, "Elemental Organic Analysis. 1. Historical Developments," Am. Lab., February 1990, p. 116.]

FIGURE 26-6 $\mathrm{C}, \mathrm{H}, \mathrm{N}, \mathrm{S}$ elemental analyzer uses gas chromatography with thermal conductivity detection to measure $\mathrm{N}_{2}, \mathrm{CO}_{2}, \mathrm{H}_{2} \mathrm{O}$, and $\mathrm{SO}_{2}$ combustion products. [Adapted from E. Pella, "Elemental Organic Analysis. 2. State of the Art," Am. Lab., August 1990, p. 28.]

Products pass through hot $\mathrm{WO}_{3}$ oxidation catalyst to complete the combustion of C to $\mathrm{CO}_{2}$. In the next zone, metallic Cu at $850^{\circ} \mathrm{C}$ reduces $\mathrm{SO}_{3}$ to $\mathrm{SO}_{2}$ and removes excess $\mathrm{O}_{2}$ :

$$
\begin{gathered}
\mathrm{Cu}+\mathrm{SO}_{3} \xrightarrow{850^{\circ} \mathrm{C}} \mathrm{SO}_{2}+\mathrm{CuO}(s) \\
\mathrm{Cu}+\frac{1}{2} \mathrm{O}_{2} \xrightarrow{850^{\circ} \mathrm{C}} \mathrm{CuO}(s)
\end{gathered}
$$

The mixture of $\mathrm{CO}_{2}, \mathrm{H}_{2} \mathrm{O}, \mathrm{N}_{2}$, and $\mathrm{SO}_{2}$ is separated by gas chromatography, and each component is measured with a thermal conductivity detector (Figure 23-17). Alternatively, $\mathrm{CO}_{2}$, $\mathrm{H}_{2} \mathrm{O}$, and $\mathrm{SO}_{2}$ can be measured by infrared absorbance.

A key to elemental analysis is dynamic flash combustion, which creates a short burst of gaseous products, instead of slowly bleeding products out over several minutes. Chromatographic analysis requires that the whole sample be injected at once. Otherwise, the injection zone is so broad that the products cannot be separated.

In dynamic flash combustion, the tin-encapsulated sample is dropped into the preheated furnace shortly after the flow of a $50 \mathrm{vol} \% \mathrm{O}_{2} / 50 \mathrm{vol} \% \mathrm{He}$ mixture is started (Figure 26-7). The Sn capsule melts at $235^{\circ} \mathrm{C}$ and is instantly oxidized to $\mathrm{SnO}_{2}$, thereby liberating $594 \mathrm{~kJ} / \mathrm{mol}$, and heating the sample to $1700^{\circ}-1800^{\circ} \mathrm{C}$. By dropping the sample in before much $\mathrm{O}_{2}$ is present, decomposition (cracking) occurs prior to oxidation, which minimizes the formation of nitrogen oxides. (Flammable liquid samples would be admitted prior to any $\mathrm{O}_{2}$ to prevent explosions.)

Analyzers that measure C, H, and N, but not S, use better optimized catalysts. The oxidation catalyst is $\mathrm{Cr}_{2} \mathrm{O}_{3}$. The gas then passes through hot $\mathrm{Co}_{3} \mathrm{O}_{4}$ coated with Ag to absorb halogens and sulfur. A hot Cu column scavenges excess $\mathrm{O}_{2}$.

Oxygen analysis requires a different strategy. The sample is thermally decomposed (a process called pyrolysis) in the absence of added $\mathrm{O}_{2}$. Gaseous products are passed through nickelized carbon at $1075^{\circ} \mathrm{C}$ to convert oxygen from the compound into $\mathrm{CO}\left(\right.$ not $\left.\mathrm{CO}_{2}\right)$. Other products include $\mathrm{N}_{2}, \mathrm{H}_{2}, \mathrm{CH}_{4}$, and hydrogen halides. Acidic products are absorbed by NaOH , and the remaining gases are separated and measured by gas chromatography with a thermal conductivity detector.

For halogenated compounds, combustion gives $\mathrm{CO}_{2}, \mathrm{H}_{2} \mathrm{O}, \mathrm{N}_{2}$, and $\mathrm{HX}(\mathrm{X}=$ halogen $)$. The HX is trapped in aqueous solution and titrated with $\mathrm{Ag}^{+}$ions in a coulometer (Section 16-3). This instrument counts the electrons produced (one $\mathrm{e}^{-}$for each $\mathrm{Ag}^{+}$) during complete reaction with HX.

Table 26-4 shows representative results for two of seven compounds sent to more than 35 laboratories to compare their performance in combustion analysis. The accuracy for all seven compounds is excellent: Mean values of wt \% C, H, N, and S for $\sim 150$ measurements of each

TABLE 26-4 Accuracy and precision of combustion analysis of pure compounds ${ }^{\text {a }}$

| Substance | C | H | N | S |
| :---: | :---: | :---: | :---: | :---: |
| $\mathrm{C}_{7} \mathrm{H}_{9} \mathrm{NO}_{2} \mathrm{~S}$ theoretical wt\% | 49.10 | 5.30 | 8.18 | 18.73 |
| Toluene-4-sulfonamide | $49.1 \pm 0.63$ | $5.3 \pm 0.31$ | $8.2 \pm 0.38$ | $18.7 \pm 0.89$ |
| $\mathrm{C}_{4} \mathrm{H}_{7} \mathrm{NO}_{2} \mathrm{~S}$ theoretical wt\% | 36.07 | 5.30 | 10.52 | 24.08 |
| 4-Thiazolidinecarboxylic acid | $36.0 \pm 0.33$ | $5.3 \pm 0.16$ | $10.5 \pm 0.16$ | $24.0 \pm 0.53$ |

a. Results for two of seven pure compounds that were analyzed by 33-45 laboratories each year over six years. Each lab analyzed each compound at least five times during at least two days. For each substance, first row gives theoretical wt\% and second row gives measured wt\%. Uncertainties are $95 \%$ confidence intervals computed for all results after rejecting outliers at the $1 \%$ significance level.
source: R. Companyó, R. Rubio, A. Sahuquillo, R. Boqué, A. Maroto, and J. Riu, "Uncertainty Estimation in Organic Elemental Analysis Using Information from Proficiency Tests," Anal. Bioanal. Chem. 2008, 392, 1497.
compound are almost always within $0.1 \mathrm{wt} \%$ of theoretical values. Precision for all seven compounds is summarized at the bottom of the table. The mean $95 \%$ confidence interval for C is $\pm 0.47 \mathrm{wt} \%$. For H, N, and S, the $95 \%$ confidence intervals are $\pm 0.24, \pm 0.31$, and $\pm 0.76 \mathrm{wt} \%$, respectively. Chemists consider a result within $\pm 0.3$ of the theoretical wt $\%$ to be good evidence that the compound has the expected formula. This criterion can be difficult to meet for C and S with a single analysis because the $95 \%$ confidence intervals are larger than $\pm 0.3 \mathrm{wt} \%$.

Silicon compounds, such as $\mathrm{SiC}, \mathrm{Si}_{3} \mathrm{~N}_{4}$, and silicates (rocks) can be analyzed by reaction with elemental fluorine $\left(\mathrm{F}_{2}\right)$ in a Ni vessel to produce $\mathrm{SiF}_{4}$ and fluorinated products of every element in the periodic table except $\mathrm{O}, \mathrm{N}, \mathrm{He}, \mathrm{Ne}, \mathrm{Ar}$, and $\mathrm{Kr} .{ }^{10}$ Products can be measured by mass spectrometry. Nitrogen in $\mathrm{Si}_{3} \mathrm{~N}_{4}$ and some other metal nitrides can be analyzed by heating to $3000^{\circ} \mathrm{C}$ in an inert atmosphere to liberate nitrogen as $\mathrm{N}_{2}$, which is measured by thermal conductivity.

## 26-5 Precipitation Tittration Curves

In gravimetric analysis, we could measure an unknown concentration of $I^{-}$by adding excess $\mathrm{Ag}^{+}$and weighing the AgI precipitate. In a precipitation titration, we monitor the course of the reaction between analyte $\left(\mathrm{I}^{-}\right)$and titrant $\left(\mathrm{Ag}^{+}\right)$to locate the equivalence point at which there is exactly enough titrant for stoichiometric reaction with the analyte. Knowing how much titrant was added tells us how much analyte was present. We seek the equivalence point in a titration, but we observe the end point at which there is an abrupt change in a physical property (such as an electrode potential) that is being measured. The physical property is chosen to make the end point as close as possible to the equivalence point.

The titration curve is a graph showing how the concentration of a reactant varies as titrant is added. We will derive equations that can be used to predict precipitation titration curves. One reason to calculate titration curves is to understand the chemistry that occurs during titrations. A second reason is to learn how experimental control can be exerted to influence the quality of an analytical titration. Concentrations of analyte and titrant and the size of the solubility product ( $K_{\mathrm{sp}}$ ) influence the sharpness of the end point.

Concentration varies over orders of magnitude, so it is useful to plot the p function:
p Function:

$$
\begin{equation*}
\mathrm{pX}=-\log _{10}[\mathrm{X}] \tag{26-8}
\end{equation*}
$$

where $[\mathrm{X}]$ is the concentration of X .
Consider the titration of 25.00 mL of $0.1000 \mathrm{M} \mathrm{I}^{-}$with $0.05000 \mathrm{M} \mathrm{Ag}^{+}$,

Titration reaction:

$$
\begin{equation*}
\mathrm{I}^{-}+\mathrm{Ag}^{+} \rightarrow \mathrm{AgI}(s) \tag{26-9}
\end{equation*}
$$

and suppose that we are monitoring $\left[\mathrm{Ag}^{+}\right]$with an electrode. Reaction $26-9$ is the reverse of the dissolution of $\operatorname{AgI}(s)$, whose solubility product is rather small:

$$
\begin{equation*}
\operatorname{AgI}(s) \rightleftharpoons \mathrm{Ag}^{+}+\mathrm{I}^{-} \quad K_{\mathrm{sp}}=\left[\mathrm{Ag}^{+}\right]\left[\mathrm{I}^{-}\right]=8.3 \times 10^{-17} \tag{26-10}
\end{equation*}
$$

The equilibrium constant for the titration reaction 26-9 is large ( $K=1 / K_{\text {sp }}=1.2 \times 10^{16}$ ), so the equilibrium lies far to the right. Each aliquot of $\mathrm{Ag}^{+}$reacts nearly completely with $\mathrm{I}^{-}$,
$F_{2}$ is exceedingly reactive and dangerous. It must be handled only in systems designed for its use.

The introduction to titrations in Section 1-5 and solubility products in Section 6-3 are prerequisites for studying precipitation titration curves.

The $p$ function should really be written in terms of activity: $\mathrm{pX}=-\log \mathcal{A}_{\mathrm{x}}$. For simplicity, we use $\mathrm{pX}=-\log [\mathrm{X}]$ in this chapter.
$V_{\mathrm{e}}=$ volume of titrant at equivalence point

Eventually, we will derive a single, unified equation for a spreadsheet that treats all regions of the titration curve. To understand the chemistry, we break the curve into three regions described by approximate equations that are easy to use.

When $V<V_{\mathrm{e}}$, the concentration of unreacted $\mathrm{I}^{-}$regulates the solubility of AgI.
\(\log (\underbrace{}_{\begin{array}{c}1.4_{5} <br>
Two significant <br>

figures\end{array}} \times 10^{-15})=\underbrace{14.84}_{\)|  Two digits  |
| :---: |
|  in mantissa  |$}$

Significant figures in logarithms were discussed in Section 3-2.

## Streamlined calculation well worth using.

leaving only a tiny amount of $\mathrm{Ag}^{+}$in solution. At the equivalence point, there will be a sudden increase in $\left[\mathrm{Ag}^{+}\right]$because there is no $\mathrm{I}^{-}$left to consume the added $\mathrm{Ag}^{+}$.

What volume of $\mathrm{Ag}^{+}$titrant is needed to reach the equivalence point? We calculate this volume, designated $V_{\mathrm{e}}$, with the fact that 1 mol of $\mathrm{Ag}^{+}$reacts with 1 mol of $\mathrm{I}^{-}$.

$$
\begin{gathered}
\underbrace{(0.02500 \mathrm{~L})\left(0.1000 \mathrm{~mol} \mathrm{I}^{-} / \mathrm{L}\right)}_{\mathrm{mol} \mathrm{I}^{-}}=\underbrace{\left(V_{\mathrm{e}}\right)\left(0.05000 \mathrm{~mol} \mathrm{Ag}^{+} / \mathrm{L}\right)}_{\mathrm{mol} \mathrm{Ag}^{+}} \\
\Rightarrow V_{\mathrm{e}}=0.05000 \mathrm{~L}=50.00 \mathrm{~mL}
\end{gathered}
$$

The titration curve has three distinct regions, depending on whether we are before, at, or after the equivalence point. Let's consider each region separately.

## Before the Equivalence Point

Suppose that 10.00 mL of $\mathrm{Ag}^{+}$have been added. There are more moles of $\mathrm{I}^{-}$than $\mathrm{Ag}^{+}$at this point, so virtually all $\mathrm{Ag}^{+}$is "used up" to make $\mathrm{AgI}(s)$. We want to find the small concentration of $\mathrm{Ag}^{+}$remaining in solution after reaction with $\mathrm{I}^{-}$. Imagine that Reaction 26-9 has gone to completion and that some AgI redissolves (Reaction 26-10). The solubility of $\mathrm{Ag}^{+}$is determined by the concentration of free $\mathrm{I}^{-}$remaining in the solution:

$$
\begin{equation*}
\left[\mathrm{Ag}^{+}\right]=\frac{K_{\mathrm{sp}}}{\left[\mathrm{I}^{-}\right]} \tag{26-11}
\end{equation*}
$$

Free $\mathrm{I}^{-}$is overwhelmingly from the $\mathrm{I}^{-}$that has not been precipitated by 10.00 mL of $\mathrm{Ag}^{+}$. By comparison, $\mathrm{I}^{-}$from dissolution of $\mathrm{AgI}(s)$ is negligible.

So let's find the concentration of unprecipitated $\mathrm{I}^{-}$:

$$
\begin{aligned}
\text { Moles of } \mathrm{I}^{-} & =\text {original mols of } \mathrm{I}^{-}-\text {moles of } \mathrm{Ag}^{+} \text {added } \\
& =(0.02500 \mathrm{~L})(0.100 \mathrm{~mol} / \mathrm{L})-(0.01000 \mathrm{~L})(0.05000 \mathrm{~mol} / \mathrm{L}) \\
& =0.002000 \mathrm{~mol} \mathrm{I}^{-}
\end{aligned}
$$

The volume is $0.03500 \mathrm{~L}(25.00 \mathrm{~mL}+10.00 \mathrm{~mL})$, so the concentration is

$$
\begin{equation*}
\left[\mathrm{I}^{-}\right]=\frac{0.002000 \mathrm{~mol} \mathrm{I}^{-}}{0.03500 \mathrm{~L}}=0.05714 \mathrm{M} \tag{26-12}
\end{equation*}
$$

The concentration of $\mathrm{Ag}^{+}$in equilibrium with this much $\mathrm{I}^{-}$is

$$
\begin{equation*}
\left[\mathrm{Ag}^{+}\right]=\frac{K_{\mathrm{sp}}}{\left[\mathrm{I}^{-}\right]}=\frac{8.3 \times 10^{-17}}{0.05714}=1.4_{5} \times 10^{-15} \mathrm{M} \tag{26-13}
\end{equation*}
$$

Finally, the p function we seek is

$$
\begin{equation*}
\mathrm{pAg}{ }^{+}=-\log \left[\mathrm{Ag}^{+}\right]=-\log \left(1.4_{5} \times 10^{-15}\right)=14.84 \tag{26-14}
\end{equation*}
$$

Two significant figures in $K_{\text {sp }}$ provide two significant figures in $\left[\mathrm{Ag}^{+}\right]$. The two figures in $\left[\mathrm{Ag}^{+}\right]$translate into two figures in the mantissa of the p function, which is written as 14.84.

The preceding step-by-step calculation is a tedious way to find the concentration of $\mathrm{I}^{-}$. Here is a streamlined procedure that is well worth learning. Bear in mind that $V_{\mathrm{e}}=50.00 \mathrm{~mL}$. When 10.00 mL of $\mathrm{Ag}^{+}$have been added, the reaction is one-fifth complete because 10.00 mL out of the 50.00 mL of $\mathrm{Ag}^{+}$needed for complete reaction have been added. Therefore, fourfifths of the $I^{-}$is unreacted. If there were no dilution, $\left[I^{-}\right]$would be four-fifths of its original value. However, the original volume of 25.00 mL has been increased to 35.00 mL . If no $\mathrm{I}^{-}$had been consumed, the concentration would be the original value of $\left[\mathrm{I}^{-}\right.$] times (25.00/35.00). Accounting for both the reaction and the dilution, we can write

$$
\left[\mathrm{I}^{-}\right]=\underbrace{\left(\frac{4.000}{5.000}\right)}_{\begin{array}{c}
\text { Fraction } \\
\text { remaining }
\end{array}} \underbrace{(0.1000 \mathrm{M})}_{\begin{array}{c}
\text { Original } \\
\text { concentration }
\end{array}} \underbrace{\left(\frac{25.00}{35.00}\right)^{K}}_{\begin{array}{c}
\text { Dilution } \\
\text { factor }
\end{array}}=0.05714 \mathrm{M}
$$

This is the same result found in Equation 26-12.

## EXAMPLE Using the Streamlined Calculation

Let's calculate $\mathrm{pAg}^{+}$when $V_{\mathrm{Ag}^{+}}$(the volume added from the buret) is 49.00 mL .
Solution Because $V_{\mathrm{e}}=50.00 \mathrm{~mL}$, the fraction of $\mathrm{I}^{-}$reacted is 49.00/50.00, and the fraction remaining is $1.00 / 50.00$. The total volume is $25.00+49.00=74.00 \mathrm{~mL}$.

$$
\begin{aligned}
{\left[\mathrm{I}^{-}\right] } & =\underbrace{\left(\frac{1.00}{50.00}\right)}_{\begin{array}{c}
\text { Fraction } \\
\text { remaining }
\end{array}} \underbrace{0.1000 \mathrm{M})}_{\begin{array}{c}
\text { Original } \\
\text { concentration }
\end{array}} \underbrace{\left(\frac{25.00}{74.00}\right)}_{\begin{array}{c}
\text { Dilution } \\
\text { factor }
\end{array}}=6.76 \times 10^{-4} \mathrm{M} \\
{\left[\mathrm{Ag}^{+}\right] } & =K_{\text {sp }} /\left[\mathrm{I}^{-}\right]=\left(8.3 \times 10^{-17}\right) /\left(6.76 \times 10^{-4}\right)=1.23 \times 10^{-13} \mathrm{M} \\
\mathrm{pAg}^{+} & =-\log \left[\mathrm{Ag}^{+}\right]=12.91
\end{aligned}
$$

The concentration of $\mathrm{Ag}^{+}$is negligible compared with the concentration of unreacted $\mathrm{I}^{-}$, even though the titration is $98 \%$ complete.

Test Yourself Find $\mathrm{pAg}^{+}$at 49.1 mL . (Answer: 12.86 )

## At the Equivalence Point

Now we have added exactly enough $\mathrm{Ag}^{+}$to react with all the $\mathrm{I}^{-}$. We can imagine that all AgI precipitates and some redissolves to give equal concentrations of $\mathrm{Ag}^{+}$and $\mathrm{I}^{-}$. The value of $\mathrm{pAg}^{+}$is found by setting $\left[\mathrm{Ag}^{+}\right]=\left[\mathrm{I}^{-}\right]=x$ in the solubility product:

$$
\begin{aligned}
{\left[\mathrm{Ag}^{+}\right]\left[\mathrm{I}^{-}\right] } & =K_{\text {sp }} \\
(x)(x) & =8.3 \times 10^{-17} \Rightarrow x=9.1 \times 10^{-9} \Rightarrow \mathrm{pAg}^{+}=-\log x=8.04
\end{aligned}
$$

This value of $\mathrm{pAg}^{+}$is independent of the original concentrations or volumes.

## After the Equivalence Point

Virtually all $\mathrm{Ag}^{+}$added before the equivalence point has precipitated. The solution contains all of the $\mathrm{Ag}^{+}$added after the equivalence point. Suppose that $V_{\mathrm{Ag}^{+}}=52.00 \mathrm{~mL}$. The volume past the equivalence point is 2.00 mL . The calculation proceeds as follows:

$$
\begin{aligned}
& \text { Moles of } \mathrm{Ag}^{+}=(0.00200 \mathrm{~L})(0.05000 \mathrm{~mol} \mathrm{Ag} \\
& {\left[\mathrm{Ag}^{+}\right] }=(0.000100 \mathrm{Lol}) /(0.07700 \mathrm{~L})=0.000100 \mathrm{~mol} \\
& 1.30 \times 10^{-3} \mathrm{M} \Rightarrow \mathrm{pAg}^{+}=2.89 \\
& \text { Total volume }=77.00 \mathrm{~mL}
\end{aligned}
$$

We could justify three significant figures for the mantissa of $\mathrm{pAg}^{+}$because there are three significant figures in $\left[\mathrm{Ag}^{+}\right]$. For consistency with earlier results, we retain only two figures.

For a streamlined calculation, the concentration of $\mathrm{Ag}^{+}$in the buret is 0.05000 M , and 2.00 mL of titrant are being diluted to $(25.00+52.00)=77.00 \mathrm{~mL}$. Hence, $\left[\mathrm{Ag}^{+}\right]$is

$$
\left[\mathrm{Ag}^{+}\right]=\underbrace{(0.05000 \mathrm{M})}_{\begin{array}{c}
\text { Original } \\
\text { concentration } \\
\text { of } \mathrm{Ag}^{+}
\end{array}} \underbrace{\left(\frac{2.00}{77.00}\right)}_{\begin{array}{c}
\text { Dilution } \\
\text { factor }
\end{array}}=1.30 \times 10^{-3} \mathrm{M}
$$

## The Shape of the Titration Curve

Titration curves in Figure 26-8 illustrate the effect of reactant concentration. The equivalence point is the steepest point of the curve. It is the point of maximum slope (a negative slope in this case) and is therefore an inflection point (at which the second derivative is 0 ):

Steepest slope:

$$
\frac{d y}{d x} \text { reaches its greatest value }
$$

Inflection point:

$$
\frac{d^{2} y}{d x^{2}}=0
$$

In titrations involving $1: 1$ stoichiometry of reactants, the equivalence point is the steepest point of the titration curve. For stoichiometries other than $1: 1$, such as $2 \mathrm{Ag}^{+}+\mathrm{CrO}_{4}^{2-} \rightarrow$ $\mathrm{Ag}_{2} \mathrm{CrO}_{4}(s)$, the curve is not symmetric. The equivalence point is not at the center of the

When $v=V_{\mathrm{e},}\left[\mathrm{Ag}^{+}\right]$is determined by the solubility of pure Agl. This problem is the same as if we had just added Agl(s) to water.

When $V>V_{\mathrm{e},}\left[\mathrm{Ag}^{+}\right]$is determined by the excess $\mathrm{Ag}^{+}$added from the buret.

FIGURE 26-8 Titration curves showing the effect of diluting the reactants.
Outer curve: 25.00 mL of $0.1000 \mathrm{M} \mathrm{I}^{-}$titrated with $0.05000 \mathrm{M} \mathrm{Ag}^{+}$
Middle curve: 25.00 mL of $0.01000 \mathrm{M} \mathrm{I}^{-}$titrated with $0.005000 \mathrm{M} \mathrm{Ag}^{+}$
Inner curve: 25.00 mL of $0.001000 \mathrm{M} \mathrm{I}^{-}$titrated with $0.0005000 \mathrm{M} \mathrm{Ag}^{+}$

At the equivalence point, the titration curve is steepest for the least soluble precipitate.

FIGURE 26-9 Titration curves showing the effect of $K_{\text {sp }}$. Each curve is calculated for 25.00 mL of 0.1000 M halide titrated with $0.05000 \mathrm{M} \mathrm{Ag}^{+}$. Equivalence points are marked by arrows.

steepest section of the curve, and it is not an inflection point. In practice, conditions are chosen such that titration curves are steep enough for the steepest point to be a good estimate of the equivalence point, regardless of the stoichiometry.

Figure 26-9 illustrates how $K_{\mathrm{sp}}$ affects the titration of halide ions. The least soluble product, AgI, gives the sharpest change at the equivalence point. However, even for AgCl , the curve is steep enough to locate the equivalence point accurately. The larger the equilibrium constant for a titration reaction, the more pronounced will be the change in concentration near the equivalence point.

## EXAMPLE Calculating Concentrations During a Precipitation Titration

25.00 mL of $0.04132 \mathrm{M} \mathrm{Hg}_{2}\left(\mathrm{NO}_{3}\right)_{2}$ were titrated with $0.05789 \mathrm{M} \mathrm{KIO}_{3}$.

$$
\mathrm{Hg}_{2}^{2+}+\underset{\text { Iodate }}{2 \mathrm{IO}_{3}^{-}} \rightarrow \mathrm{Hg}_{2}\left(\mathrm{IO}_{3}\right)_{2}(s)
$$

For $\mathrm{Hg}_{2}\left(\mathrm{IO}_{3}\right)_{2}, K_{\text {sp }}=1.3 \times 10^{-18}$. Find $\left[\mathrm{Hg}_{2}^{2+}\right]$ in the solution after addition of (a) 34.00 mL of $\mathrm{KIO}_{3}$; (b) 36.00 mL of $\mathrm{KIO}_{3}$; and (c) at the equivalence point.

Solution The volume of iodate needed to reach the equivalence point is found as follows:

$$
\begin{gathered}
\text { Moles of } \mathrm{IO}_{3}^{-}=\left(\frac{2 \mathrm{~mol} \mathrm{IO}_{3}^{-}}{1 \mathrm{~mol} \mathrm{Hg}_{2}^{2+}}\right)\left(\text { moles of } \mathrm{Hg}_{2}^{2+}\right) \\
\underbrace{\left(V_{\mathrm{e}}\right)(0.05789 \mathrm{M})}_{\text {Moles of } \mathrm{IO}_{3}^{-}}=2 \underbrace{25.00 \mathrm{~mL})(0.04132 \mathrm{M})}_{\text {Moles of } \mathrm{Hg}_{2}^{2+}} \Rightarrow V_{\mathrm{e}}=35.69 \mathrm{~mL}
\end{gathered}
$$

(a) When $V=34.00 \mathrm{~mL}$, the precipitation of $\mathrm{Hg}_{2}^{2+}$ is not yet complete.

$$
\left[\mathrm{Hg}_{2}^{2+}\right]=\underbrace{\left(\frac{35.69-34.00}{35.69}\right)}_{\begin{array}{c}
\text { Fraction } \\
\text { remaining }
\end{array}} \underbrace{(0.04132 \mathrm{M})}_{\begin{array}{c}
\text { Original } \\
\text { oncentration } \\
\text { of } \mathrm{Hg}_{2}^{2+}
\end{array}} \underbrace{\left(\frac{25.00}{25.00+34.00}\right)}_{\begin{array}{c}
\text { Dilution } \\
\text { factor }
\end{array}}=8.29 \times 10^{-4} \mathrm{M}
$$

(b) When $V=36.00 \mathrm{~mL}$, the precipitation is complete. We have gone $(36.00-35.69)=$ 0.31 mL past the equivalence point. The concentration of excess $\mathrm{IO}_{3}^{-}$is

$$
\left[\mathrm{IO}_{3}^{-}\right]=(\underbrace{(0.05789 \mathrm{M})}_{\begin{array}{c}
\text { Original } \\
\text { concentration } \\
\text { of } \mathrm{IO}_{3}^{-}
\end{array}} \underbrace{\left(\frac{0.31}{25.00+36.00}\right)}_{\begin{array}{c}
\text { Dilution } \\
\text { factor }
\end{array}}=2.9_{4} \times 10^{-4} \mathrm{M}
$$

The concentration of $\mathrm{Hg}_{2}^{2+}$ in equilibrium with solid $\mathrm{Hg}_{2}\left(\mathrm{IO}_{3}\right)_{2}$ plus this much $\mathrm{IO}_{3}^{-}$is

$$
\left[\mathrm{Hg}_{2}^{2+}\right]=\frac{K_{\mathrm{sp}}}{\left[\mathrm{IO}_{3}^{-}\right]^{2}}=\frac{1.3 \times 10^{-18}}{\left(2.9_{4} \times 10^{-4}\right)^{2}}=1.5 \times 10^{-11} \mathrm{M}
$$

(c) At the equivalence point, there is exactly enough $\mathrm{IO}_{3}^{-}$to react with all $\mathrm{Hg}_{2}^{2+}$. We can imagine that all of the ions precipitate and then some $\mathrm{Hg}_{2}\left(\mathrm{IO}_{3}\right)_{2}(s)$ redissolves, giving two moles of iodate for each mole of mercurous ion:

$$
\begin{gathered}
\mathrm{Hg}_{2}\left(\mathrm{IO}_{3}\right)_{2}(s) \rightleftharpoons \underset{x}{\rightleftharpoons \mathrm{Hg}_{2}^{2+}}+\underset{2 x}{2 \mathrm{IO}_{3}^{-}} \\
(x)(2 x)^{2}=K_{\text {sp }} \Rightarrow x=\left[\mathrm{Hg}_{2}^{2+}\right]=6.9 \times 10^{-7} \mathrm{M}
\end{gathered}
$$

Test Yourself Find $\left[\mathrm{Hg}_{2}^{2+}\right]$ at 34.50 and 36.5 mL . (Answer: $5.79 \times 10^{-4} \mathrm{M}$, $2.2 \times 10^{-12} \mathrm{M}$ )

Our calculations presume that the only chemistry that occurs is the reaction of anion with cation to precipitate solid salt. If other reactions occur, such as complex formation or ion-pair formation, we would have to modify the calculations.

## 26-6 Titration of a Mixture

If a mixture of two ions is titrated, the less soluble precipitate forms first. If the solubilities are sufficiently different, the first precipitation is nearly complete before the second commences.

Consider the addition of $\mathrm{AgNO}_{3}$ to a solution containing KI and KCl . Because $K_{\text {sp }}(\mathrm{AgI}) \ll K_{\text {sp }}(\mathrm{AgCl})$, AgI precipitates first. When precipitation of $\mathrm{I}^{-}$is almost complete, the concentration of $\mathrm{Ag}^{+}$abruptly increases and AgCl begins to precipitate. When $\mathrm{Cl}^{-}$is consumed, another abrupt increase in $\left[\mathrm{Ag}^{+}\right]$occurs. We expect two breaks in the titration curve, first at $V_{\mathrm{e}}$ for AgI and then at $V_{\mathrm{e}}$ for AgCl .

Figure 26-10 shows an experimental curve for this titration. The apparatus used to measure the curve is shown in Figure 26-11, and the theory of how this system measures $\mathrm{Ag}^{+}$concentration is discussed in Section 14-2.

A liquid containing suspended particles is said to be turbid because the particles scatter light.

The product with the smaller $K_{\text {sp }}$ precipitates first, if the stoichiometry of the precipitates is the same. Precipitation of $\mathrm{I}^{-}$and $\mathrm{Cl}^{-}$with $\mathrm{Ag}^{+}$ produces two breaks in the titration curve, first for $\mathrm{I}^{-}$and then for $\mathrm{Cl}^{-}$.

FIGURE 26-10 Experimental titration curves. (a) 40.00 mL of 0.0502 M KI plus 0.0500 M KCl titrated with 0.0845 M AgNO 3 . Inset expands the region near the first equivalence point. (b) 20.00 mL of $0.1004 \mathrm{M} \mathrm{I}^{-}$titrated with $0.0845 \mathrm{M} \mathrm{Ag}^{+}$.

FIGURE 26-11 Apparatus for measuring the titration curves in Figure 26-10. The silver electrode responds to changes in $\mathrm{Ag}^{+}$ concentration, and the glass electrode provides a constant reference potential in this experiment. The measured voltage changes by approximately 59 mV for each factor-of-10 change in $\left[\mathrm{Ag}^{+}\right]$. All solutions, including $\mathrm{AgNO}_{3}$, were maintained at pH 2.0 by using 0.010 M sulfate buffer prepared from $\mathrm{H}_{2} \mathrm{SO}_{4}$ and KOH .

The $\mathrm{I}^{-}$end point is taken as the intersection of the steep and nearly horizontal curves shown in the inset of Figure 26-10. Precipitation of $\mathrm{I}^{-}$is not quite complete when $\mathrm{Cl}^{-}$begins to precipitate. (The way we know that $\mathrm{I}^{-}$precipitation is not complete is by a calculation. That's what these obnoxious calculations are for!) Therefore, the end of the steep portion (the intersection) is a better approximation of the equivalence point than is the middle of the steep section. The $\mathrm{Cl}^{-}$end point is taken as the midpoint of the second steep section, at 47.41 mL . The moles of $\mathrm{Cl}^{-}$in the sample equal the moles of $\mathrm{Ag}^{+}$delivered between the first and second end points. That is, it requires $23.85 \mathrm{~mL}^{\text {of }} \mathrm{Ag}^{+}$to precipitate $\mathrm{I}^{-}$, and $(47.41-23.85)=$ 23.56 mL of $\mathrm{Ag}^{+}$to precipitate $\mathrm{Cl}^{-}$.

Comparison of the $\mathrm{I}^{-} / \mathrm{Cl}^{-}$and pure $\mathrm{I}^{-}$titration curves in Figure 26-10 shows that the $\mathrm{I}^{-}$end point is $0.38 \%$ too high in the $\mathrm{I}^{-} / \mathrm{Cl}^{-}$titration. We expect the first end point at 23.76 mL , but it is observed at 23.85 mL . Two factors contribute to this high value. One is experimental error, which is always present. This discrepancy is as likely to be positive as negative. However, the end point in some titrations, especially $\mathrm{Br}^{-} / \mathrm{Cl}^{-}$titrations, is systematically 0 to $3 \%$ high, depending on conditions. This error is attributed to coprecipitation of AgCl with AgBr . Even though the solubility of AgCl has not been exceeded, some $\mathrm{Cl}^{-}$becomes attached to AgBr as it precipitates and carries down an equivalent amount of $\mathrm{Ag}^{+}$. A high concentration of nitrate reduces coprecipitation, perhaps because $\mathrm{NO}_{3}^{-}$competes with $\mathrm{Cl}^{-}$for binding sites.

The second end point in Figure 26-10 corresponds to complete precipitation of both halides. It is observed at the expected value of $V_{\mathrm{Ag}^{+}}$. The concentration of $\mathrm{Cl}^{-}$, found from the difference between the two end points, will be slightly low in Figure 26-10, because the first end point is slightly high.

## 26-7 Calculating Titration Curves with a Spreadsheet

Now you understand the chemistry that occurs at different stages of a precipitation titration, and you should know how to calculate the shape of a titration curve. We now introduce spreadsheet calculations that are more powerful than hand calculations and less prone to error. If you are not interested in spreadsheets at this time, you can skip this section.

Consider the addition of $V_{\mathrm{M}}$ liters of cation $\mathrm{M}^{+}$(whose initial concentration is $C_{\mathrm{M}}^{0}$ ) to $V_{\mathrm{X}}^{0}$ liters of solution containing anion $\mathrm{X}^{-}$with a concentration $C_{\mathrm{X}}^{0}$.

$$
\begin{equation*}
\underset{\substack{\text { Titrant } \\ C_{\mathrm{M}}^{0}, V_{\mathrm{M}}}}{\mathrm{M}^{+}}+\underset{\substack{\text { Analyte } \\ C_{\mathrm{X}}^{0}, V_{\mathrm{X}}^{0}}}{\mathrm{X}^{-} \stackrel{K_{\mathrm{sp}}}{\rightleftharpoons}} \mathrm{MX}(s) \tag{26-15}
\end{equation*}
$$

The total moles of added $\mathrm{M}\left(=C_{\mathrm{M}}^{0} \cdot V_{\mathrm{M}}\right)$ must equal the moles of $\mathrm{M}^{+}$in solution $\left(=\left[\mathrm{M}^{+}\right] \cdot\right.$ $\left(V_{\mathrm{M}}+V_{\mathrm{X}}^{0}\right)$ ) plus the moles of precipitated $\mathrm{MX}(s)$. (This equality is called a mass balance,

|  | A | B | C | D | E |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 1 | Titration of I- with $\mathrm{Ag}+$ |  |  |  |  |
| 2 |  |  |  |  |  |
| 3 | Ksp(Agl) = | pAg | [Ag+] | [1-] | Vm |
| 4 | 8.30E-17 | 15.08 | 8.32E-16 | $9.98 \mathrm{E}-02$ | 0.035 |
| 5 | Vo = | 15 | $1.00 \mathrm{E}-15$ | $8.30 \mathrm{E}-02$ | 3.195 |
| 6 | 25 | 14 | $1.00 \mathrm{E}-14$ | $8.30 \mathrm{E}-03$ | 39.322 |
| 7 | $\mathrm{Co}(\mathrm{I})=$ | 12 | $1.00 \mathrm{E}-12$ | $8.30 \mathrm{E}-05$ | 49.876 |
| 8 | 0.1 | 10 | $1.00 \mathrm{E}-10$ | $8.30 \mathrm{E}-07$ | 49.999 |
| 9 | $\mathrm{Co}(\mathrm{Ag})=$ | 8 | $1.00 \mathrm{E}-08$ | $8.30 \mathrm{E}-09$ | 50.000 |
| 10 | 0.05 | 6 | 1.00E-06 | $8.30 \mathrm{E}-11$ | 50.001 |
| 11 |  | 4 | $1.00 \mathrm{E}-04$ | $8.30 \mathrm{E}-13$ | 50.150 |
| 12 |  | 3 | $1.00 \mathrm{E}-03$ | $8.30 \mathrm{E}-14$ | 51.531 |
| 13 |  | 2 | $1.00 \mathrm{E}-02$ | $8.30 \mathrm{E}-15$ | 68.750 |
| 14 | $\mathrm{C} 4=10 \wedge$ - $\mathrm{B}^{\text {4 }}$ |  |  |  |  |
| 15 | D4 = \$A\$4/C4 |  |  |  |  |
| 16 | $\mathrm{E} 4=\$ \mathrm{~A}$ \$6*(\$A\$8+C4-D4)/(\$A\$10-C4+D4) |  |  |  |  |

FIGURE 26-12 Spreadsheet for titration of 25 mL of $0.1 \mathrm{M} \mathrm{I}^{-}$with $0.05 \mathrm{M} \mathrm{Ag}^{+}$.
even though it is really a mole balance.) In a similar manner, we can write a mass balance for X .

| Mass balance for M: | $C_{\mathrm{M}}^{0} \cdot V_{\mathrm{M}}=\left[\mathrm{M}^{+}\right]\left(V_{\mathrm{M}}+V_{\mathrm{X}}^{0}\right)+\operatorname{mol~MX}(s)$ |  |  |
| :---: | :---: | :---: | :---: |
| Mass balance for $X$ : | Total moles of added M | Moles of M in solution | Moles of M in precipitate |
|  | $C_{\mathrm{X}}^{0} \cdot V_{\mathrm{X}}^{0}$ | ${ }^{-1}\left(V_{\mathrm{M}}+\right.$ | $\operatorname{mol~MX(s)~}$ |
|  | Total moles of added X | Moles of X in solution | Moles of X in precipitate |

Now equate mol MX(s) from Equation 26-16 with mol MX(s) from Equation 26-17:

$$
C_{\mathrm{M}}^{0} \cdot V_{\mathrm{M}}-\left[\mathrm{M}^{+}\right]\left(V_{\mathrm{M}}+V_{\mathrm{X}}^{0}\right)=C_{\mathrm{X}}^{0} \cdot V_{\mathrm{X}}^{0}-\left[\mathrm{X}^{-}\right]\left(V_{\mathrm{M}}+V_{\mathrm{X}}^{0}\right)
$$

which can be rearranged to

$$
\begin{equation*}
\text { Precipitation of } X^{-} \text {with } M^{+}: \quad V_{\mathrm{M}}=V_{\mathrm{X}}^{0}\left(\frac{C_{\mathrm{X}}^{0}+\left[\mathrm{M}^{+}\right]-\left[\mathrm{X}^{-}\right]}{C_{\mathrm{M}}^{0}-\left[\mathrm{M}^{+}\right]+\left[\mathrm{X}^{-}\right]}\right) \tag{26-18}
\end{equation*}
$$

Equation 26-18 relates the volume of added $\mathrm{M}^{+}$to $\left[\mathrm{M}^{+}\right],\left[\mathrm{X}^{-}\right]$, and the constants $V_{\mathrm{X}}^{0}, C_{\mathrm{X}}^{0}$, and $C_{\mathrm{M}}^{0}$. To use Equation 26-18 in a spreadsheet, enter values of $p M$ and compute corresponding values of $V_{M}$, as shown in Figure 26-12 for the iodide titration of Figure 26-9. This is the reverse of the way you normally calculate a titration curve in which $V_{\mathrm{M}}$ would be input and pM would be output. Column C of Figure 26-12 is calculated with the formula $\left[\mathrm{M}^{+}\right]=10^{-\mathrm{pM}}$, and column D is given by $\left[\mathrm{X}^{-}\right]=K_{\text {sp }} /\left[\mathrm{M}^{+}\right]$. Column E is calculated from Equation 26-18. The first input value of $\mathrm{pM}(15.08)$ was selected by trial and error to produce a small $V_{\mathrm{M}}$. You can start wherever you like. If your initial value of pM is before the true starting point, then $V_{\mathrm{M}}$ in column E will be negative. In practice, you will want more points than we have shown so that you can plot an accurate titration curve.

## 26-8 End-Point Detection

Precipitation titration end points are commonly found with electrodes (Figure 26-11) or indicators. We now describe two indicator methods for the titration of $\mathrm{Cl}^{-}$with $\mathrm{Ag}^{+}$:
Volhard titration: formation of a soluble, colored complex at the end point
Fajans titration: adsorption of a colored indicator on the precipitate at the end point

The mass balance states that the moles of an element in all species in a mixture equals the total moles of that element delivered to the solution.

A supplementary section at www.whfreeman.com/qca8e derives a spreadsheet equation for the titration of a mixture, such as that in Figure 26-10.

FIGURE 26-13 lons from solution are adsorbed on the surface of a growing crystallite. (a) A crystal growing in the presence of excess lattice anions (anions that belong in the crystal) will have a slight negative charge because anions are predominantly adsorbed. (b) A crystal growing in the presence of excess lattice cations will have a slight positive charge and can therefore adsorb a negative indicator ion. Anions and cations in the solution that do not belong in the crystal lattice are less likely to be adsorbed than are ions belonging to the lattice. These diagrams omit other ions in solution. Overall, each solution plus its growing crystallites must have zero total charge.

## Volhard Titration

The Volhard titration is a titration of $\mathrm{Ag}^{+}$in $\mathrm{HNO}_{3}$ solution. $\mathrm{For}_{\mathrm{Cl}}{ }^{-}$, a back titration is necessary. First, $\mathrm{Cl}^{-}$is precipitated by a known, excess quantity of standard $\mathrm{AgNO}_{3}$.

$$
\mathrm{Ag}^{+}+\mathrm{Cl}^{-} \rightarrow \mathrm{AgCl}(s)
$$

The AgCl is filtered and washed, and excess $\mathrm{Ag}^{+}$in the combined filtrate is titrated with standard KSCN (potassium thiocyanate) in the presence of $\mathrm{Fe}^{3+}$.

$$
\mathrm{Ag}^{+}+\mathrm{SCN}^{-} \rightarrow \operatorname{AgSCN}(s)
$$

When all $\mathrm{Ag}^{+}$has been consumed, $\mathrm{SCN}^{-}$reacts with $\mathrm{Fe}^{3+}$ to form a red complex.

$$
\mathrm{Fe}^{3+}+\mathrm{SCN}^{-} \rightarrow \underset{\mathrm{Red}}{\mathrm{FeSCN}^{2+}}
$$

The appearance of red color is the end point. Knowing how much $\mathrm{SCN}^{-}$was required for the back titration tells us how much $\mathrm{Ag}^{+}$was left over from the reaction with $\mathrm{Cl}^{-}$. The total amount of $\mathrm{Ag}^{+}$is known, so the amount consumed by $\mathrm{Cl}^{-}$can be calculated.

In the analysis of $\mathrm{Cl}^{-}$by the Volhard method, the end point would slowly fade if the AgCl were not filtered off, because AgCl is more soluble than AgSCN . The AgCl slowly dissolves and is replaced by AgSCN . To eliminate this secondary reaction, we filter the AgCl and titrate only the $\mathrm{Ag}^{+}$in the filtrate. $\mathrm{Br}^{-}$and $\mathrm{I}^{-}$, whose silver salts are less soluble than AgSCN , can be titrated by the Volhard method without isolating the silver halide precipitate.

## Fajans Titration

The Fajans titration uses an adsorption indicator. To see how this works, consider the electric charge at the surface of a precipitate. When $\mathrm{Ag}^{+}$is added to $\mathrm{Cl}^{-}$, there is excess $\mathrm{Cl}^{-}$in solution prior to the equivalence point. Some $\mathrm{Cl}^{-}$is adsorbed onto the AgCl surface, imparting a negative charge to the crystal (Figure 26-13a). After the equivalence point, there is excess $\mathrm{Ag}^{+}$in solution. Adsorption of $\mathrm{Ag}^{+}$onto the AgCl surface places positive charge on the precipitate (Figure 26-13b). The abrupt change from negative to positive occurs at the equivalence point.

Common adsorption indicators are anionic dyes, which are attracted to positively charged particles produced immediately after the equivalence point. Adsorption of the negatively charged dye onto the positively charged surface changes the color of the dye. The color change is the end point in the titration. Because the indicator reacts with the precipitate surface, we want as much surface area as possible. To attain maximum surface area, we use conditions that keep the particles as small as possible, because small particles have more surface area than an equal volume of large particles. Low electrolyte concentration helps prevent coagulation of the precipitate and maintains small particle size.

The most common indicator for AgCl is dichlorofluorescein. This dye is greenish yellow in solution but turns pink when adsorbed onto AgCl (Demonstration 26-2 and Color Plate 33). The pH of the reaction must be controlled because the indicator is a weak acid and must be present in its anionic form. The dye eosin is useful in the titration of $\mathrm{Br}^{-}, \mathrm{I}^{-}$, and $\mathrm{SCN}^{-}$. It gives a sharper end point than dichlorofluorescein and is more sensitive (that is, less halide can be titrated). It cannot be used for AgCl , because eosin is more strongly bound than $\mathrm{Cl}^{-}$to AgCl . Eosin binds to AgCl crystallites even before the particles become positively charged.

In all argentometric titrations, but especially with adsorption indicators, strong light (such as daylight through a window) should be avoided. Light decomposes silver salts, and adsorbed indicators are especially light sensitive.

## DEMONSTRATION 26-2 Fajans Titration

The Fajans titration of $\mathrm{Cl}^{-}$with $\mathrm{Ag}^{+}$demonstrates indicator end points in precipitation titrations. Dissolve 0.5 g of NaCl plus 0.15 g of dextrin in 400 mL of water. Dextrin retards coagulation of the AgCl precipitate. Add 1 mL of dichlorofluorescein indicator solution containing either $1 \mathrm{mg} / \mathrm{mL}$ of dichlorofluorescein in $95 \%$ aqueous ethanol or $1 \mathrm{mg} / \mathrm{mL}$ of the sodium salt in water.

Titrate the NaCl solution with a solution containing 2 g of $\mathrm{AgNO}_{3}$ in $30 \mathrm{~mL} \mathrm{H} \mathrm{H}_{2} \mathrm{O}$. About 20 mL are required. Color Plate 33 shows yellow indicator prior to titration, milky white AgCl suspension during the titration, and pink suspension at the end point, when the anionic indicator becomes adsorbed on the cationic precipitate.

| Species analyzed | Notes |
| :---: | :---: |
|  | Volhard Method |
| $\begin{aligned} & \mathrm{Br}^{-}, \mathrm{I}^{-}, \mathrm{SCN}^{-}, \mathrm{CNO}^{-}, \\ & \mathrm{AsO}_{4}^{3-}, \end{aligned}$ | Precipitate removal is unnecessary. |
| $\begin{gathered} \mathrm{Cl}^{-}, \mathrm{PO}_{4}^{3-}, \mathrm{CN}^{-}, \mathrm{C}_{2} \mathrm{O}_{4}^{2-}, \\ \mathrm{CO}_{3}^{2-}, \mathrm{S}^{\mathrm{S}^{2-}}, \mathrm{CrO}_{4}^{2-} \end{gathered}$ | Precipitate removal required. |
| $\mathrm{BH}_{4}^{-}$ | Back titration of $\mathrm{Ag}^{+}$left after reaction with $\mathrm{BH}_{4}^{-}$: $\mathrm{BH}_{4}^{-}+8 \mathrm{Ag}^{+}+8 \mathrm{OH}^{-} \rightarrow 8 \mathrm{Ag}(s)+\mathrm{H}_{2} \mathrm{BO}_{3}^{-}+5 \mathrm{H}_{2} \mathrm{O}$ |
| $\mathrm{K}^{+}$ | $\mathrm{K}^{+}$is first precipitated with a known excess of $\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{4} \mathrm{~B}^{-}$ Remaining $\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{4} \mathrm{~B}^{-}$is precipitated with a known exces of $\mathrm{Ag}^{+}$. Unreacted $\mathrm{Ag}^{+}$is then titrated with $\mathrm{SCN}^{-}$. |
|  | Fajans Method |
| $\begin{aligned} & \mathrm{Cl}^{-}, \mathrm{Br}^{-}, \mathrm{I}^{-}, \mathrm{SCN}^{-} \\ & \mathrm{Fe}(\mathrm{CN})_{6}^{4-} \end{aligned}$ | Titration with $\mathrm{Ag}^{+}$. Detection with dyes such as fluorescein, dichlorofluorescein, eosin, bromophenol blue. |
| $\mathrm{Zn}^{2+}$ | Titration with $\mathrm{K}_{4} \mathrm{Fe}(\mathrm{CN})_{6}$ to produce $\mathrm{K}_{2} \mathrm{Zn}_{3}\left[\mathrm{Fe}(\mathrm{CN})_{6}\right]_{2}$. End-point detection with diphenylamine. |
| $\mathrm{SO}_{4}^{2-}$ | Titration with $\mathrm{Ba}(\mathrm{OH})_{2}$ in $50 \mathrm{vol} \%$ aqueous methanol using alizarin red S as indicator. |
| $\mathrm{Hg}_{2}^{2+}$ | Titration with NaCl to produce $\mathrm{Hg}_{2} \mathrm{Cl}_{2}$. End point detected with bromophenol blue. |
| $\mathrm{PO}_{4}^{3-}, \mathrm{C}_{2} \mathrm{O}_{4}^{2-}$ | Titration with $\mathrm{Pb}\left(\mathrm{CH}_{3} \mathrm{CO}_{2}\right)_{2}$ to give $\mathrm{Pb}_{3}\left(\mathrm{PO}_{4}\right)_{2}$ or $\mathrm{PbC}_{2} \mathrm{O}_{4}$. End point detected with dibromofluorescein $\left(\mathrm{PO}_{4}^{3-}\right)$ or fluorescein $\left(\mathrm{C}_{2} \mathrm{O}_{4}^{2-}\right)$. |

Applications of precipitation titrations are listed in Table 26-5. Whereas the Volhard method is an argentometric titration, the Fajans method has wider applications. Because the Volhard titration is carried out in acidic solution (typically $0.2 \mathrm{M} \mathrm{HNO}_{3}$ ), it avoids certain interferences that affect other titrations. Silver salts of $\mathrm{CO}_{3}^{2-}, \mathrm{C}_{2} \mathrm{O}_{4}^{2-}$, and $\mathrm{AsO}_{4}^{3-}$ are soluble in acidic solution, so these anions do not interfere.

Dichlorofluorescein

Tetrabromofluorescein (eosin)

Because the Volhard method is a titration of $\mathrm{Ag}^{+}$, it can be adapted for the determination of any anion that forms an insoluble silver salt.

## Summary

In gravimetric analysis, we relate the mass of a known product to the mass of analyte. Most commonly, analyte ion is precipitated by a suitable counterion. Measures taken to reduce supersaturation and promote the formation of large, easily filtered particles (as opposed to colloids) include (1) raising the temperature during precipitation, (2) slowly adding and vigorously mixing reagents, (3) maintaining a large sample volume, and (4) using homogeneous precipitation. Precipitates are usually digested in hot mother liquor to promote particle growth and recrystallization. Precipitates are then filtered and washed; some must be washed with a volatile electrolyte to prevent peptization. The product is heated to dryness or ignited to achieve a reproducible, stable composition. Gravimetric calculations relate moles of product to moles of analyte.

In combustion analysis for $\mathrm{C}, \mathrm{H}, \mathrm{N}, \mathrm{S}$, and halogens, an organic compound in a tin capsule is rapidly heated with excess $\mathrm{O}_{2}$ to give
predominantly $\mathrm{CO}_{2}, \mathrm{H}_{2} \mathrm{O}, \mathrm{N}_{2}, \mathrm{SO}_{2}$, and HX (hydrogen halides). A hot oxidation catalyst completes the process, and hot Cu scavenges excess $\mathrm{O}_{2}$. For sulfur analysis, hot copper also converts $\mathrm{SO}_{3}$ into $\mathrm{SO}_{2}$. Products may be separated by gas chromatography and measured by their thermal conductivity. Some instruments use infrared absorption to measure $\mathrm{CO}_{2}, \mathrm{H}_{2} \mathrm{O}$, and $\mathrm{SO}_{2}$. HX is trapped in aqueous solution and measured by coulometric titration (counting electrons) with electrolytically generated $\mathrm{Ag}^{+}$. Oxygen in organic compounds can be measured by pyrolysis in the absence of added $\mathrm{O}_{2}$ to convert oxygen from the compound into CO.

Concentrations of reactants and products during a precipitation titration are calculated in three regions. Before the equivalence point, there is excess analyte. Its concentration is the product (fraction remaining) $\times$ (original concentration) $\times$ (dilution factor). The concentration of titrant can be found from the solubility product of the
precipitate and the known concentration of excess analyte. At the equivalence point, concentrations of both reactants are governed by the solubility product. After the equivalence point, the concentration of analyte can be determined from the solubility product of precipitate and the known concentration of excess titrant.

The Volhard titration measures $\mathrm{Ag}^{+}$by the reaction of $\mathrm{Fe}^{3+}$ with $\mathrm{SCN}^{-}$after the precipitation of AgSCN is complete. Anions
that precipitate with $\mathrm{Ag}^{+}$are measured by treating them with a known excess of $\mathrm{Ag}^{+}$and then back-titrating the excess $\mathrm{Ag}^{+}$by the Volhard titration. The Fajans titration applies to many precipitations that do not necessarily involve $\mathrm{Ag}^{+}$. The end point is a color change that occurs when a charged indicator is adsorbed onto the charged surface of the precipitate after the equivalence point.

## Exercises

26-A. An organic compound with a formula mass of $417 \mathrm{~g} / \mathrm{mol}$ was analyzed for ethoxyl $\left(\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{O}-\right)$ groups by the reactions

$$
\begin{gathered}
\mathrm{ROCH}_{2} \mathrm{CH}_{3}+\mathrm{HI} \rightarrow \mathrm{ROH}+\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{I} \\
\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{I}+\mathrm{Ag}^{+}+\mathrm{OH}^{-} \rightarrow \mathrm{AgI}(s)+\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{OH}
\end{gathered}
$$

A $25.42-\mathrm{mg}$ sample of compound produced 29.03 mg of AgI. How many ethoxyl groups are there in each molecule?
26-B. A $0.649-\mathrm{g}$ sample containing only $\mathrm{K}_{2} \mathrm{SO}_{4}$ (FM 174.27) and $\left(\mathrm{NH}_{4}\right)_{2} \mathrm{SO}_{4}$ (FM 132.14) was dissolved in water and treated with $\mathrm{Ba}\left(\mathrm{NO}_{3}\right)_{2}$ to precipitate all $\mathrm{SO}_{4}^{2-}$ as $\mathrm{BaSO}_{4}$ (FM 233.39). Find the weight percent of $\mathrm{K}_{2} \mathrm{SO}_{4}$ in the sample if 0.977 g of precipitate was formed.

26-C. Consider a mixture of the two solids, $\mathrm{BaCl}_{2} \cdot 2 \mathrm{H}_{2} \mathrm{O}$ ( FM 244.26 ) and KCl ( FM 74.551 ), in an unknown ratio. (The notation $\mathrm{BaCl}_{2} \cdot 2 \mathrm{H}_{2} \mathrm{O}$ means that a crystal is formed with two water molecules for each $\mathrm{BaCl}_{2}$.) When the unknown is heated to $160^{\circ} \mathrm{C}$ for 1 h , the water of crystallization is driven off:

$$
\mathrm{BaCl}_{2} \cdot 2 \mathrm{H}_{2} \mathrm{O}(\mathrm{~s}) \xrightarrow{160^{\circ} \mathrm{C}} \mathrm{BaCl}_{2}(\mathrm{~s})+2 \mathrm{H}_{2} \mathrm{O}(\mathrm{~g})
$$

A sample originally weighing 1.7839 g weighed 1.5623 g after heating. Calculate the weight percent of $\mathrm{Ba}, \mathrm{K}$, and Cl in the original sample.

26-D. A mixture containing only aluminum tetrafluoroborate, $\mathrm{Al}\left(\mathrm{BF}_{4}\right)_{3}$ ( FM 287.39 ), and magnesium nitrate, $\mathrm{Mg}\left(\mathrm{NO}_{3}\right)_{2}$ ( FM 148.31 ), weighed 0.2828 g . It was dissolved in $1 \mathrm{wt} \% \mathrm{HF}(a q)$ and treated with nitron solution to precipitate a mixture of nitron tetrafluoroborate and nitron nitrate weighing 1.322 g . Find the $\mathrm{wt} \% \mathrm{Mg}$ in the original solid mixture.

26-E. A $50.0-\mathrm{mL}$ sample of 0.0800 M KSCN is titrated with $0.0400 \mathrm{M} \mathrm{Cu}^{+}$. The solubility product of CuSCN is $4.8 \times 10^{-15}$. At each of the following volumes of titrant, calculate $\mathrm{pCu}^{+}$, and construct a graph of $\mathrm{pCu}^{+}$versus milliliters of $\mathrm{Cu}^{+}$added: $0.10,10.0$, $25.0,50.0,75.0,95.0,99.0,99.9,100.0,100.1,101.0,110.0 \mathrm{~mL}$.
26-F. Consider the titration of $50.00( \pm 0.05) \mathrm{mL}$ of a mixture of $\mathrm{I}^{-}$ and $\mathrm{SCN}^{-}$with $0.0683( \pm 0.0001) \mathrm{M} \mathrm{Ag}^{+}$. The first equivalence point is observed at $12.6( \pm 0.4) \mathrm{mL}$, and the second occurs at 27.7 ( $\pm 0.3$ ) mL.
(a) Find the molarity and the uncertainty in molarity of thiocyanate in the original mixture.
(b) Suppose that the uncertainties are all the same, except that the uncertainty of the first equivalence point ( $12.6 \pm$ ? mL ) is variable. What is the maximum uncertainty (milliliters) of the first equivalence point if the uncertainty in $\mathrm{SCN}^{-}$molarity is to be $\leq 4.0 \%$ ?

## Problems

Gravimetric Analysis
26-1. (a) What is the difference between absorption and adsorption? (b) How is an inclusion different from an occlusion?

26-2. State four desirable properties of a gravimetric precipitate.
26-3. Why is high relative supersaturation undesirable in a gravimetric precipitation?
26-4. What measures can be taken to decrease the relative supersaturation during a precipitation?
26-5. Why are many ionic precipitates washed with electrolyte solution instead of pure water?
26-6. Why is it less desirable to wash AgCl precipitate with aqueous $\mathrm{NaNO}_{3}$ than with $\mathrm{HNO}_{3}$ solution?
26-7. Why would a reprecipitation be employed in a gravimetric analysis?

26-8. Explain what is done in thermogravimetric analysis.
26-9. Explain how the quartz crystal microbalance at the opening of Chapter 2 measures small masses.

26-10. A $50.00-\mathrm{mL}$ solution containing NaBr was treated with excess $\mathrm{AgNO}_{3}$ to precipitate 0.2146 g of AgBr (FM 187.772). What was the molarity of NaBr in the solution?
26-11. To find the $\mathrm{Ce}^{4+}$ content of a solid, 4.37 g were dissolved and treated with excess iodate to precipitate $\mathrm{Ce}\left(\mathrm{IO}_{3}\right)_{4}$. The precipitate was collected, washed well, dried, and ignited to produce 0.104 g of $\mathrm{CeO}_{2}$ (FM 172.114). What was the weight percent of Ce in the original solid?

26-12. Marie Curie dissolved 0.09192 g of $\mathrm{RaCl}_{2}$ and treated it with excess $\mathrm{AgNO}_{3}$ to precipitate 0.08890 g of AgCl . In her time (1900), the atomic mass of Ag was known to be 107.8 and that of Cl
was 35.4. From these values, find the atomic mass of Ra that Marie Curie would have calculated.

26-13. A $0.05002-\mathrm{g}$ sample of impure piperazine contained $71.29 \mathrm{wt} \%$ piperazine (FM 86.136). How many grams of product (FM 206.240) will be formed when this sample is analyzed by Reaction 26-6?

26-14. A $1.000-\mathrm{g}$ sample of unknown gave 2.500 g of bis(dimethylglyoximate)nickel(II) (FM 288.91) when analyzed by Reaction 26-7. Find the weight percent of Ni in the unknown.

26-15. Name the product obtained in Figure 26-4 when calcium salicylate monohydrate is heated to $550^{\circ} \mathrm{C}$ and to $1000^{\circ} \mathrm{C}$. Using the formula masses of these products, calculate what mass is expected to remain when 0.6356 g of calcium salicylate monohydrate is heated to $550^{\circ} \mathrm{C}$ and to $1000^{\circ} \mathrm{C}$.
26-16. A method to measure soluble organic carbon in seawater includes oxidation of the organic materials to $\mathrm{CO}_{2}$ with $\mathrm{K}_{2} \mathrm{~S}_{2} \mathrm{O}_{8}$, followed by gravimetric determination of the $\mathrm{CO}_{2}$ trapped by a column of NaOH coated asbestos. A water sample weighing 6.234 g produced 2.378 mg of $\mathrm{CO}_{2}$ (FM 44.010). Calculate the ppm carbon in the seawater.

26-17. How many milliliters of $2.15 \%$ alcoholic dimethylglyoxime should be used to provide a $50.0 \%$ excess for Reaction 26-7 with 0.9984 g of steel containing $2.07 \mathrm{wt} \% \mathrm{Ni}$ ? Assume that the density of the dimethylglyoxime solution is $0.790 \mathrm{~g} / \mathrm{mL}$.

26-18. Twenty dietary iron tablets with a total mass of 22.131 g were ground and mixed thoroughly. Then 2.998 g of the powder were dissolved in $\mathrm{HNO}_{3}$ and heated to convert all iron into $\mathrm{Fe}^{3+}$. Addition of $\mathrm{NH}_{3}$ precipitated $\mathrm{Fe}_{2} \mathrm{O}_{3} \cdot x \mathrm{H}_{2} \mathrm{O}$, which was ignited to give 0.264 g of $\mathrm{Fe}_{2} \mathrm{O}_{3}$ (FM 159.69). What is the average mass of $\mathrm{FeSO}_{4} \cdot 7 \mathrm{H}_{2} \mathrm{O}$ (FM 278.01) in each tablet?

26-19. Finely ground mineral ( 0.6324 g ) was dissolved in 25 mL of boiling 4 M HCl and diluted with $175 \mathrm{~mL} \mathrm{H}_{2} \mathrm{O}$ containing two drops of methyl red indicator. The solution was heated to $100^{\circ} \mathrm{C}$, and 50 mL of warm solution containing $2.0 \mathrm{~g}\left(\mathrm{NH}_{4}\right)_{2} \mathrm{C}_{2} \mathrm{O}_{4}$ were slowly added to precipitate $\mathrm{CaC}_{2} \mathrm{O}_{4}$. Then $6 \mathrm{M} \mathrm{NH}_{3}$ was added until the indicator changed from red to yellow, showing that the liquid was neutral or slightly basic. After slow cooling for 1 h , the liquid was decanted and the solid transferred to a filter crucible and washed with cold $0.1 \mathrm{wt} \%$ $\left(\mathrm{NH}_{4}\right)_{2} \mathrm{C}_{2} \mathrm{O}_{4}$ solution five times until no $\mathrm{Cl}^{-}$was detected in the filtrate upon addition of $\mathrm{AgNO}_{3}$ solution. The crucible was dried at $105^{\circ} \mathrm{C}$ for 1 h and then at $500^{\circ} \pm 25^{\circ} \mathrm{C}$ in a furnace for 2 h .

The mass of the empty crucible was 18.2311 g , and the mass of the crucible with $\mathrm{CaCO}_{3}(s)$ was 18.5467 g .
(a) Find the $\mathrm{wt} \% \mathrm{Ca}$ in the mineral.
(b) Why is the unknown solution heated to boiling and the precipitant solution, $\left(\mathrm{NH}_{4}\right)_{2} \mathrm{C}_{2} \mathrm{O}_{4}$, also heated before slowly mixing the two?
(c) What is the purpose of washing the precipitate with $0.1 \mathrm{wt} \%$ $\left(\mathrm{NH}_{4}\right)_{2} \mathrm{C}_{2} \mathrm{O}_{4}$ ?
(d) What is the purpose of testing the filtrate with $\mathrm{AgNO}_{3}$ solution?

26-20. Man in the vat problem. ${ }^{11}$ Long ago, a workman at a dye factory fell into a vat containing hot, concentrated sulfuric and nitric acids. He dissolved completely! Because nobody witnessed the accident, it was necessary to prove that he fell in so that the man's wife could collect his insurance money. The man weighed 70 kg , and a human body contains $\sim 6.3$ parts per thousand ( $\mathrm{mg} / \mathrm{g}$ ) phosphorus.

The acid in the vat was analyzed for phosphorus to see whether it contained a dissolved human.
(a) The vat contained $8.00 \times 10^{3} \mathrm{~L}$ of liquid, and a $100.0-\mathrm{mL}$ sample was analyzed. If the man did fall into the vat, what is the expected quantity of phosphorus in 100.0 mL ?
(b) The $100.0-\mathrm{mL}$ sample was treated with a molybdate reagent that precipitated ammonium phosphomolybdate, $\left(\mathrm{NH}_{4}\right)_{3}\left[\mathrm{P}_{( }\left(\mathrm{Mo}_{12} \mathrm{O}_{40}\right)\right]$. $12 \mathrm{H}_{2} \mathrm{O}$. This substance was dried at $110^{\circ} \mathrm{C}$ to remove waters of hydration and heated to $400^{\circ} \mathrm{C}$ until it reached the constant composition $\mathrm{P}_{2} \mathrm{O}_{5} \cdot 24 \mathrm{MoO}_{3}$, which weighed 0.3718 g . When a fresh mixture of the same acids (not from the vat) was treated in the same manner, 0.0331 g of $\mathrm{P}_{2} \mathrm{O}_{5} \cdot 24 \mathrm{MoO}_{3}$ (FM 3596.46 ) was produced. This blank determination gives the amount of phosphorus in the starting reagents. The $\mathrm{P}_{2} \mathrm{O}_{5} \cdot 24 \mathrm{MoO}_{3}$ that could have come from the dissolved man is therefore $0.3718-0.0331=0.3387 \mathrm{~g}$. How much phosphorus was present in the $100.0-\mathrm{mL}$ sample? Is this quantity consistent with a dissolved man?
26-21. A $1.475-\mathrm{g}$ sample containing $\mathrm{NH}_{4} \mathrm{Cl}$ (FM 53.492), $\mathrm{K}_{2} \mathrm{CO}_{3}$ (FM 138.21), and inert ingredients was dissolved to give 0.100 L of solution. A $25.0-\mathrm{mL}$ aliquot was acidified and treated with excess sodium tetraphenylborate, $\mathrm{Na}^{+} \mathrm{B}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{4}^{-}$, to precipitate $\mathrm{K}^{+}$and $\mathrm{NH}_{4}^{+}$ions completely:

$$
\begin{gathered}
\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{4} \mathrm{~B}^{-}+\mathrm{K}^{+} \rightarrow \underset{\mathrm{FM} 358.33}{\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{4} \mathrm{BK}(s)} \\
\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{4} \mathrm{~B}^{-}+\mathrm{NH}_{4}^{+} \rightarrow \underset{\mathrm{FM} 337.27}{\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{4} \mathrm{BNH}_{4}(s)}
\end{gathered}
$$

The resulting precipitate amounted to 0.617 g . A fresh $50.0-\mathrm{mL}$ aliquot of the original solution was made alkaline and heated to drive off all the $\mathrm{NH}_{3}$ :

$$
\mathrm{NH}_{4}^{+}+\mathrm{OH}^{-} \rightarrow \mathrm{NH}_{3}(g)+\mathrm{H}_{2} \mathrm{O}
$$

It was then acidified and treated with sodium tetraphenylborate to give 0.554 g of precipitate. Find the weight percent of $\mathrm{NH}_{4} \mathrm{Cl}$ and $\mathrm{K}_{2} \mathrm{CO}_{3}$ in the original solid.
26-22. A mixture containing only $\mathrm{Al}_{2} \mathrm{O}_{3}$ (FM 101.96) and $\mathrm{Fe}_{2} \mathrm{O}_{3}$ (FM 159.69) weighs 2.019 g . When heated under a stream of $\mathrm{H}_{2}$, $\mathrm{Al}_{2} \mathrm{O}_{3}$ is unchanged, but $\mathrm{Fe}_{2} \mathrm{O}_{3}$ is converted into metallic Fe plus $\mathrm{H}_{2} \mathrm{O}(\mathrm{g})$. If the residue weighs 1.774 g , what is the weight percent of $\mathrm{Fe}_{2} \mathrm{O}_{3}$ in the original mixture?
26-23. A solid mixture weighing 0.5485 g contained only ferrous ammonium sulfate hexahydrate and ferrous chloride hexahydrate. The sample was dissolved in $1 \mathrm{M} \mathrm{H}_{2} \mathrm{SO}_{4}$, oxidized to $\mathrm{Fe}^{3+}$ with $\mathrm{H}_{2} \mathrm{O}_{2}$, and precipitated with cupferron. The ferric cupferron complex was ignited to produce 0.1678 g of ferric oxide, $\mathrm{Fe}_{2} \mathrm{O}_{3}$ ( FM 159.69). Calculate the weight percent of Cl in the original sample.

26-24. Propagation of error. A mixture containing only silver nitrate and mercurous nitrate was dissolved in water and treated with
excess sodium cobalticyanide, $\mathrm{Na}_{3}\left[\mathrm{Co}(\mathrm{CN})_{6}\right]$ to precipitate both cobalticyanide salts:

| $\mathrm{AgNO}_{3}$ | FM 169.873 |
| :--- | :--- |
| $\mathrm{Ag}_{3}\left[\mathrm{Co}(\mathrm{CN})_{6}\right]$ | FM 538.643 |
| $\mathrm{Hg}_{2}\left(\mathrm{NO}_{3}\right)_{2}$ | FM 525.19 |
| $\left(\mathrm{Hg}_{2}\right)_{3}\left[\mathrm{Co}(\mathrm{CN})_{6}\right]_{2}$ | FM 1633.62 |

(a) The unknown weighed 0.4321 g and the product weighed 0.4515 g . Find wt $\% \mathrm{AgNO}_{3}$ in the unknown. Caution: Keep all the digits in your calculator or else serious rounding errors may occur. Do not round off until the end.
(b) Even a skilled analyst is not likely to have less than a $0.3 \%$ error in isolating the precipitate. Suppose that there is negligible error in all quantities, except the mass of product, which has an uncertainty of $0.30 \%$. Calculate the relative uncertainty in the mass of $\mathrm{AgNO}_{3}$ in the unknown.
26-25. The thermogravimetric trace below shows mass loss by $\mathrm{Y}_{2}(\mathrm{OH})_{5} \mathrm{Cl} \cdot x \mathrm{H}_{2} \mathrm{O}$ upon heating. In the first step, waters of hydration are lost to give $\sim 8.1 \%$ mass loss. After a second decomposition step, $19.2 \%$ of the original mass is lost. Finally, the composition stabilizes at $\mathrm{Y}_{2} \mathrm{O}_{3}$ above $800^{\circ} \mathrm{C}$.
(a) Find $x$ in the formula $\mathrm{Y}_{2}(\mathrm{OH})_{5} \mathrm{Cl} \cdot x \mathrm{H}_{2} \mathrm{O}$. Because the $8.1 \%$ mass loss is not accurately defined in the experiment, use the $31.8 \%$ total mass loss for your calculation.
(b) Suggest a formula for the material remaining at the $19.2 \%$ plateau. Be sure that the charges of all ions in your formula sum to 0 . The cation is $\mathrm{Y}^{3+}$.

Thermogravimetric analysis of $\mathrm{Y}_{2}(\mathrm{OH})_{5} \mathrm{Cl} \cdot x \mathrm{H}_{2} \mathrm{O}$. [From T. Hours, P. Bergez, J. Charpin, A. Larbot, C. Guizard, and L. Cot, "Preparation and Characterization of Yttrium Oxide by a Sol-Gel Process," Ceramic Bull. 1992, 71, 200.]
26-26. Thermogravimetric analysis and propagation of error. ${ }^{12}$ Crystals of deuterated potassium dihydrogen phosphate, $\mathrm{K}\left(\mathrm{D}_{x} \mathrm{H}_{1-x}\right)_{2} \mathrm{PO}_{4}$, are used in optics as a light valve, as a light deflector, and for frequency doubling of lasers. The optical properties are sensitive to the fraction of deuterium in the material. A publication states that deuterium content can be determined by measuring the mass lost by dehydration of the crystal after slow heating to $450^{\circ} \mathrm{C}$ in a Pt crucible under $\mathrm{N}_{2}$.

(a) Let $\alpha$ be the mass of product divided by the mass of reactant:

$$
\alpha=\frac{\text { mass of } \mathrm{KPO}_{3}}{\text { mass of } \mathrm{K}\left(\mathrm{D}_{x} \mathrm{H}_{1-x}\right)_{2} \mathrm{PO}_{4}}
$$

Show that the coefficient $x$ in $\mathrm{K}\left(\mathrm{D}_{x} \mathrm{H}_{1-x}\right)_{2} \mathrm{PO}_{4}$ is related to $\alpha$ by the equation

$$
x=\frac{58.6670}{\alpha}-67.6183
$$

What would be the value of $\alpha$ if starting material were $100 \%$ deuterated?
(b) One crystal measured in triplicate gave an average value of $\alpha=0.8567_{7}$. Find $x$ for this crystal.
(c) From Equation C. 1 in Appendix C, show that the uncertainty in $x\left(e_{x}\right)$ is related to the uncertainty in $\alpha\left(e_{\alpha}\right)$ by the equation

$$
e_{x}=\frac{58.6670 e_{\alpha}}{\alpha^{2}}
$$

(d) The uncertainty in deuterium:hydrogen stoichiometry is $e_{x}$. The authors estimate that their uncertainty in $\alpha$ is $e_{\alpha}=0.0001$. From $e_{\alpha}$, compute $e_{x}$. Write the stoichiometry in the form $x \pm e_{x}$. If $e_{\alpha}$ were 0.001 (which is perfectly reasonable), what would $e_{x}$ be?

26-27. When the high-temperature superconductor yttrium barium copper oxide (see Chapter 15 opening and Box 15-3) is heated under flowing $\mathrm{H}_{2}$, the solid remaining at $1000^{\circ} \mathrm{C}$ is a mixture of $\mathrm{Y}_{2} \mathrm{O}_{3}, \mathrm{BaO}$, and Cu . The starting material has the formula $\mathrm{YBa}_{2} \mathrm{Cu}_{3} \mathrm{O}_{7-x}$, in which the oxygen stoichiometry varies between 7 and $6.5(x=0$ to 0.5$)$.

(a) Thermogravimetric analysis. When 34.397 mg of $\mathrm{YBa}_{2} \mathrm{Cu}_{3} \mathrm{O}_{7-x}$ were subjected to this analysis, 31.661 mg of solid remained after heating to $1000^{\circ} \mathrm{C}$. Find the value of $x$ in $\mathrm{YBa}_{2} \mathrm{Cu}_{3} \mathrm{O}_{7-x}$.
(b) Propagation of error. Suppose that the uncertainty in each mass in part (a) is $\pm 0.002 \mathrm{mg}$. Find the uncertainty in the value of $x$.
26-28. A reprecipitation was employed to remove occluded $\mathrm{NO}_{3}^{-}$ from $\mathrm{BaSO}_{4}$ prior to isotopic analysis of oxygen for geologic studies. ${ }^{13}$ Approximately 30 mg of $\mathrm{BaSO}_{4}$ crystals were mixed with 15 mL of 0.05 M DTPA (Figure 11-4) in 1 M NaOH . After dissolving the solid at $70^{\circ} \mathrm{C}$, it was reprecipitated by adding 10 M HCl dropwise to obtain $\mathrm{pH} 3-4$ and allowing the mixture to stand for 1 h . The mixture was centrifuged, the mother liquor was removed, and the solid was resuspended in deionized water. Centrifugation and washing were repeated a second time to reduce the molar ratio $\left[\mathrm{NO}_{3}^{-}\right] /\left[\mathrm{SO}_{4}^{2-}\right]$ from 0.28 in the original precipitate to 0.001 in the purified material. What will be the predominant species of sulfate and DTPA at pH 14 and at pH 3 ? Explain why $\mathrm{BaSO}_{4}$ dissolves in DTPA in 1 M NaOH and then reprecipitates when the pH is lowered to 3-4.

## Combustion Analysis

26-29. What is the difference between combustion and pyrolysis?
26-30. What is the purpose of the $\mathrm{WO}_{3}$ and Cu in Figure 26-6?
26-31. Why is tin used to encapsulate a sample for combustion analysis?

26-32. Why is sample dropped into the preheated furnace before the oxygen concentration reaches its peak in Figure 26-7?

26-33. Write a balanced equation for the combustion of benzoic acid, $\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{CO}_{2} \mathrm{H}$, to give $\mathrm{CO}_{2}$ and $\mathrm{H}_{2} \mathrm{O}$. How many milligrams of $\mathrm{CO}_{2}$ and of $\mathrm{H}_{2} \mathrm{O}$ will be produced by the combustion of 4.635 mg of benzoic acid?
26-34. Write a balanced equation for the combustion of $\mathrm{C}_{8} \mathrm{H}_{7} \mathrm{NO}_{2} \mathrm{SBrCl}$ in a C,H,N,S elemental analyzer.
26-35. Combustion analysis of a compound known to contain just $\mathrm{C}, \mathrm{H}, \mathrm{N}$, and O demonstrated that it is $46.21 \mathrm{wt} \% \mathrm{C}, 9.02 \mathrm{wt} \% \mathrm{H}$, $13.74 \mathrm{wt} \% \mathrm{~N}$, and, by difference, $100-46.21-9.02-13.74=$ $31.03 \% \mathrm{O}$. This means that 100 g of unknown would contain 46.21 g of $\mathrm{C}, 9.02 \mathrm{~g}$ of H , and so on. Find the atomic ratio $\mathrm{C}: \mathrm{H}: \mathrm{N}: \mathrm{O}$ and express it as the lowest reasonable integer ratio.
26-36. A mixture weighing 7.290 mg contained only cyclohexane, $\mathrm{C}_{6} \mathrm{H}_{12}$ (FM 84.159), and oxirane, $\mathrm{C}_{2} \mathrm{H}_{4} \mathrm{O}$ (FM 44.053). When the mixture was analyzed by combustion analysis, 21.999 mg of $\mathrm{CO}_{2}$ (FM 44.010) were produced. Find the weight percent of oxirane in the mixture.

26-37. Combustion analysis of an organic compound gave the composition $71.17 \pm 0.41 \mathrm{wt} \% \mathrm{C}, 6.76 \pm 0.12 \mathrm{wt} \% \mathrm{H}$, and $10.34 \pm 0.08 \mathrm{wt} \% \mathrm{~N}$. Find the coefficients $h$ and $n$ and their uncertainties $x$ and $y$ in the formula $\mathrm{C}_{8} \mathrm{H}_{h \pm}{ }_{x} \mathrm{~N}_{n \pm y}$.
26-38. One way to determine sulfur is by combustion analysis. This procedure produces a mixture of $\mathrm{SO}_{2}$ and $\mathrm{SO}_{3}$ that can be passed through $\mathrm{H}_{2} \mathrm{O}_{2}$ to convert both into $\mathrm{H}_{2} \mathrm{SO}_{4}$, which is titrated with standard base. When 6.123 mg of a substance were burned, the $\mathrm{H}_{2} \mathrm{SO}_{4}$ required 3.01 mL of 0.01576 M NaOH for titration. Find the weight percent of sulfur in the sample.
26-39. Statistics of coprecipitation. ${ }^{14}$ In Experiment 1, 200.0 mL of solution containing 10.0 mg of $\mathrm{SO}_{4}^{2-}$ (from $\mathrm{Na}_{2} \mathrm{SO}_{4}$ ) were treated with excess $\mathrm{BaCl}_{2}$ solution to precipitate $\mathrm{BaSO}_{4}$ containing some coprecipitated $\mathrm{Cl}^{-}$. To find out how much coprecipitated $\mathrm{Cl}^{-}$was present, the precipitate was dissolved in 35 mL of $98 \mathrm{wt} \% \mathrm{H}_{2} \mathrm{SO}_{4}$ and boiled to liberate HCl , which was removed by bubbling $\mathrm{N}_{2}$ gas through the $\mathrm{H}_{2} \mathrm{SO}_{4}$. The $\mathrm{HCl} / \mathrm{N}_{2}$ stream was passed into a reagent solution that reacted with $\mathrm{Cl}^{-}$to give a color that was measured. Ten replicate trials gave values of $7.8,9.8,7.8,7.8,7.8,7.8,13.7,12.7$, 13.7, and $12.7 \mu \mathrm{~mol} \mathrm{Cl}{ }^{-}$. Experiment 2 was identical to the first one, except that the $200.0-\mathrm{mL}$ solution also contained $6.0 \mathrm{~g} \mathrm{of} \mathrm{Cl}{ }^{-}$ (from NaCl ). Ten replicate trials gave $7.8,10.8,8.8,7.8,6.9,8.8$, $15.7,12.7,13.7$, and $14.7 \mu \mathrm{~mol} \mathrm{Cl}^{-}$.
(a) Find the mean, standard deviation, and $95 \%$ confidence interval for $\mathrm{Cl}^{-}$in each experiment.
(b) Is there a significant difference between the two experiments? What does your answer mean?
(c) If there were no coprecipitate, what mass of $\mathrm{BaSO}_{4}$ ( FM 233.39 ) would be expected?
(d) If the coprecipitate is $\mathrm{BaCl}_{2}$ (FM 208.23), what is the average mass of precipitate $\left(\mathrm{BaSO}_{4}+\mathrm{BaCl}_{2}\right)$ in Experiment 1? By what percentage is the mass greater than the mass in part (c)?

## Shape of a Precipitation Curve

26-40. Describe the chemistry that occurs in each of the following regions in curve (a) in Figure 26-10: (i) before the first equivalence point; (ii) at the first equivalence point; (iii) between the first and second equivalence points; (iv) at the second equivalence point; and
(v) past the second equivalence point. For each region except (ii), write the equation that you would use to calculate $\left[\mathrm{Ag}^{+}\right]$.

26-41. Consider the titration of 25.00 mL of 0.08230 M KI with $0.05110 \mathrm{M} \mathrm{AgNO}_{3}$. Calculate $\mathrm{pAg}^{+}$at the following volumes of added $\mathrm{AgNO}_{3}$ : (a) 39.00 mL ; (b) $V_{\mathrm{e} \text {; }}$ (c) 44.30 mL .

26-42. The text claims that $\mathrm{I}^{-}$precipitation is not complete before $\mathrm{Cl}^{-}$begins to precipitate in Figure 26-10. Calculate $\left[\mathrm{Ag}^{+}\right]$at the equivalence point in the titration of $\mathrm{I}^{-}$alone. Show that this concentration of $\mathrm{Ag}^{+}$will precipitate $\mathrm{Cl}^{-}$.

26-43. A $25.00-\mathrm{mL}$ solution containing $0.03110 \mathrm{M} \mathrm{Na}_{2} \mathrm{C}_{2} \mathrm{O}_{4}$ was titrated with $0.02570 \mathrm{M} \mathrm{Ca}\left(\mathrm{NO}_{3}\right)_{2}$ to precipitate calcium oxalate: $\mathrm{Ca}^{2+}+\mathrm{C}_{2} \mathrm{O}_{4}^{2-} \rightarrow \mathrm{CaC}_{2} \mathrm{O}_{4}(s)$. Find $\mathrm{pCa}^{2+}$ at the following volumes of $\mathrm{Ca}\left(\mathrm{NO}_{3}\right)_{2}$ : (a) 10.00 ; (b) $V_{\mathrm{e}}$; (c) 35.00 mL .
26-44. In precipitation titrations of halides by $\mathrm{Ag}^{+}$, the ion pair $\operatorname{AgX}(a q)(\mathrm{X}=\mathrm{Cl}, \mathrm{Br}, \mathrm{I})$ is in equilibrium with the precipitate. Use Appendix J to find the concentrations of $\mathrm{AgCl}(a q), \mathrm{AgBr}(a q)$, and $\mathrm{AgI}(a q)$ during the precipitations.

## Titration of a Mixture

26-45. A $0.2386-\mathrm{g}$ sample contained only NaCl and KBr . It was dissolved in water and required 48.40 mL of $0.04837 \mathrm{M} \mathrm{AgNO}_{3}$ for complete titration of both halides [giving $\mathrm{AgCl}(s)$ and $\operatorname{AgBr}(s)$ ]. Calculate the weight percent of Br in the solid sample.

26-46. A procedure ${ }^{15}$ for determining halogens in organic compounds uses an argentometric titration. To 50 mL of anhydrous ether is added a carefully weighed sample ( $10-100 \mathrm{mg}$ ) of unknown, plus 2 mL of sodium dispersion and 1 mL of methanol. (Sodium dispersion is finely divided solid sodium suspended in oil. With methanol, it makes sodium methoxide, $\mathrm{CH}_{3} \mathrm{O}^{-} \mathrm{Na}^{+}$, which attacks the organic compound, liberating halides.) Excess sodium is destroyed by slow addition of 2-propanol, after which 100 mL of water are added. (Sodium should not be treated directly with water because the $\mathrm{H}_{2}$ produced can explode in the presence of $\mathrm{O}_{2}: 2 \mathrm{Na}+2 \mathrm{H}_{2} \mathrm{O} \rightarrow 2 \mathrm{NaOH}+\mathrm{H}_{2}$.) This procedure gives a twophase mixture, with an ether layer floating on top of the aqueous layer that contains halide salts. The aqueous layer is adjusted to pH 4 and titrated with $\mathrm{Ag}^{+}$, using the electrodes in Figure 26-11. How much $0.02570 \mathrm{M} \mathrm{AgNO}_{3}$ solution will be required to reach each equivalence point when 82.67 mg of 1-bromo-4-chlorobutane $\left(\mathrm{BrCH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{Cl}\right.$; FM 171.46) are analyzed?

## Using Spreadsheets

26-47. Derive an expression analogous to Equation 26-18 for the titration of $\mathrm{M}^{+}$(concentration $=C_{\mathrm{M}}^{0}$, volume $=V_{\mathrm{M}}^{0}$ ) with $\mathrm{X}^{-}$ (titrant concentration $=C_{\mathrm{X}}^{0}$ ). Your equation allows you to compute the volume of titrant $\left(V_{\mathrm{X}}\right)$ as a function of $\left[\mathrm{X}^{-}\right]$.
26-48. Use Equation 26-18 to reproduce the curves in Figure 26-9. Plot your results on a single graph.

26-49. Consider precipitation of $\mathrm{X}^{x-}$ with $\mathrm{M}^{m+}$ :

$$
x \mathrm{M}^{m+}+m \mathrm{X}^{x-} \rightleftharpoons \mathrm{M}_{x} \mathrm{X}_{m}(s) \quad K_{\mathrm{sp}}=\left[\mathrm{M}^{m+}\right]^{x}\left[\mathrm{X}^{x-}\right]^{m}
$$

Write mass balance equations for M and X and derive the equation

$$
V_{\mathrm{M}}=V_{\mathrm{X}}^{0}\left(\frac{x C_{\mathrm{X}}^{0}+m\left[\mathrm{M}^{m+}\right]-x\left[\mathrm{X}^{x-}\right]}{m C_{\mathrm{M}}^{0}-m\left[\mathrm{M}^{m+}\right]+x\left[\mathrm{X}^{x-}\right]}\right)
$$

where $\left[\mathrm{X}^{x-}\right]=\left(K_{\mathrm{sp}} /\left[\mathrm{M}^{m+}\right]^{x}\right)^{1 / m}$.
 titration curve for 10.0 mL of $0.100 \mathrm{M} \mathrm{CrO}_{4}^{2-}$ titrated with 0.100 M $\mathrm{Ag}^{+}$to produce $\mathrm{Ag}_{2} \mathrm{CrO}_{4}(s)$.

## End-Point Detection

26-51. Why does the surface charge of a precipitate change sign at the equivalence point?
26-52. Examine the procedure in Table 26-5 for the Fajans titration of $\mathrm{Zn}^{2+}$. Do you expect the charge on the precipitate to be positive or negative after the equivalence point?

26-53. Describe how to analyze a solution of NaI by using the Volhard titration.

26-54. A $30.00-\mathrm{mL}$ solution of $\mathrm{I}^{-}$was treated with 50.00 mL of $0.3650 \mathrm{M} \mathrm{AgNO}_{3} . \operatorname{AgI}(s)$ was filtered off, and the filtrate (plus $\mathrm{Fe}^{3+}$ ) was titrated with 0.2870 M KSCN . When 37.60 mL had been added, the solution turned red. How many milligrams of $\mathrm{I}^{-}$were in the original solution?

Map of Italy, showing where the
Po River was sampled. [From
E. Zuccato, C. Chiabrando, S. Castiglioni,
D. Calamari, R. Bagnati, S. Schiarea, and
R. Fanelli, "Cocaine in Surface Waters:

A New Evidence-Based Tool to Monitor
Community Drug Use," Environ. Health
2005, 4, 14, available at
www.ehjournal.net/content/4/1/14]

How honest do you expect people to be when questioned about illegal drug use? In Italy in 2001, $1.1 \%$ of people aged 15 to 34 years old acknowledged using cocaine "at least once in the preceding month." Researchers studying the occurrence of therapeutic drugs in sewage realized that they had a tool to measure illegal drug use.

After ingestion, cocaine is largely converted to benzoylecgonine before being excreted in urine. Scientists collected representative composite samples of water from the Po River and samples of wastewater entering treatment plants serving four Italian cities. They preconcentrated minute quantities of benzoylecgonine from large volumes of water by solidphase extraction, described on pages 713-714. Extracted chemicals were washed from the solid phase by a small quantity of solvent, separated by liquid chromatography, and measured by mass spectrometry. Cocaine use was estimated from the concentration of benzoylecgonine, the volume of water flowing in the river, and the fact that 5.4 million people live upstream of the collection site.

Benzoylecgonine in the Po River corresponded to $27 \pm 5100-\mathrm{mg}$ doses of cocaine per 1000 people per day by the 15 - to 34 -year-old population. Similar results were observed in water from four treatment plants. Cocaine use is much higher than people admit in a survey.

Heterogeneous: different composition from place to place in a material
Homogeneous: same composition everywhere

Achemical analysis is meaningless unless you begin with a meaningful sample. To measure cholesterol in a dinosaur skeleton or herbicide in a truckload of oranges, you must have a strategy for selecting a representative sample from a heterogeneous material. Figure 27-1 shows that the concentration of nitrate in sediment beneath a lake drops by two orders of magnitude in the first 3 mm below the surface. If you want to measure nitrate in sediment, it makes an enormous difference whether you select a core sample that is 1 m deep or skim the top 2 mm of sediment for analysis. Sampling is the process of collecting a representative sample for analysis. ${ }^{1}$ Real samples generally require some degree of sample preparation to remove substances that interfere in the analysis of the desired analyte and, perhaps, to convert analyte into a form suitable for analysis. ${ }^{2}$

FIGURE 27-2 Sampling is the process of selecting a representative bulk sample from the lot. Sample preparation is the process that converts a bulk sample into a homogeneous laboratory sample. Sample preparation also refers to steps that eliminate interfering species or that concentrate the analyte.

TABLE 27-1 Manganese concentration of serum stored in washed and unwashed polyethylene containers

| Container $^{\boldsymbol{a}}$ | $\mathrm{Mn}(\mathrm{ng} / \mathrm{mL})$ |
| :--- | :--- |
| Unwashed | 0.85 |
| Unwashed | 0.55 |
| Unwashed | 0.20 |
| Unwashed | 0.67 |
| Average | $0.57 \pm 0.27$ |
|  |  |
| Washed | 0.096 |
| Washed | 0.018 |
| Washed | 0.12 |
| Washed | 0.10 |
| Average | $0.084 \pm 0.045$ |

a. Washed containers were rinsed with water distilled twice from fused-silica vessels, which introduce less contamination into water than does glass. source: J. Versieck, Trends Anal. Chem. 1983, 2, 110.

FIGURE 27-1 Depth profile of nitrate in sediment from freshwater Lake Søbygård in Denmark. A similar profile was observed in saltwater sediment. Measurements were made with a biosensor containing live bacteria that convert $\mathrm{NO}_{3}^{-}$into $\mathrm{N}_{2} \mathrm{O}$, which was measured amperometrically by reduction at a silver cathode. [From L. H. Larsen, T. Kjær, and N. P. Revsbech, "A Microscale $\mathrm{NO}_{3}^{-}$Biosensor for Environmental Applications," Anal. Chem. 1997, 69, 3527.]

The terminology of sampling and sample preparation is shown in Figure 27-2. A lot is the total material (dinosaur skeleton or truckload of oranges) from which samples are taken. A bulk sample (also called a gross sample) is taken from the lot for analysis or archiving (storing for future reference). The bulk sample must be representative of the lot, and the choice of bulk sample is critical to producing a valid analysis. Box $0-1$ gave a strategy for sampling heterogeneous material.

From the representative bulk sample, a smaller, homogeneous laboratory sample is formed that must have the same composition as the bulk sample. For example, we might obtain a laboratory sample by grinding the entire solid bulk sample to fine powder, mixing thoroughly, and keeping one bottle of powder for testing. Small portions (called aliquots) of the laboratory sample are used for individual analyses. Sample preparation is the series of steps that convert a representative bulk sample into a form suitable for analysis.

Besides choosing a sample judiciously, we must be careful about storing the sample. The composition may change with time after collection because of chemical changes, reaction with air, or interaction of the sample with its container. Glass is a notorious ion exchanger that alters the concentrations of trace ions in solution. Therefore, plastic (especially Teflon) collection bottles are frequently employed. Even these materials can absorb trace levels of analytes. For example, a $0.2-\mu \mathrm{M} \mathrm{HgCl}_{2}$ solution lost $40-95 \%$ of its concentration in 4 h in polyethylene bottles. A $2-\mu \mathrm{M} \mathrm{Ag}^{+}$solution in a Teflon bottle lost $2 \%$ of its concentration in a day and $28 \%$ in a month. ${ }^{3}$

Plastic containers must be washed before use. Table 27-1 shows that manganese in blood serum samples increased by a factor of seven when stored in unwashed polyethylene containers prior to analysis. In the most demanding trace analysis of lead at $1 \mathrm{pg} / \mathrm{g}$ in polar ice cores, polyethylene containers contributed a measurable flux of 1 fg of lead per $\mathrm{cm}^{2}$ per day even after they had been soaked in acid for seven months. ${ }^{4}$ Steel needles are an avoidable source of metal contamination in biochemical analysis.

A study of mercury in Lake Michigan found levels near $1.6 \mathrm{pM}\left(1.6 \times 10^{-12} \mathrm{M}\right)$, which is two orders of magnitude below concentrations observed in earlier studies. ${ }^{5}$ Previous investigators apparently unknowingly contaminated their samples. A study of handling techniques for the analysis of lead in rivers investigated variations in sample collection, sample containers, protection during transportation, filtration, preservatives, and preconcentration procedures. ${ }^{6}$ Each step that deviated from best practice doubled the apparent concentration of lead in stream water. Clean rooms with filtered air supplies are essential in trace analysis. Even with the best precautions, the precision of trace analysis becomes poorer as the concentration of analyte decreases (Box 5-2).
"Unless the complete history of any sample is known with certainty, the analyst is well advised not to spend his [or her] time in analyzing it." ${ }^{7}$ Your laboratory notebook should describe how a sample was collected and stored and exactly how it was handled, as well as stating how it was analyzed.

## 27-1 Statistics of Sampling ${ }^{8}$

For random errors, the overall variance, $s_{\mathrm{o}}^{2}$, is the sum of the variance of the analytical procedure, $s_{\mathrm{a}}^{2}$, and the variance of the sampling operation, $s_{\mathrm{s}}^{2}$ :

## Additivity of variance:

$$
\begin{equation*}
s_{\mathrm{o}}^{2}=s_{\mathrm{a}}^{2}+s_{\mathrm{s}}^{2} \tag{27-1}
\end{equation*}
$$

If either $s_{\mathrm{a}}$ or $s_{\mathrm{s}}$ is sufficiently smaller than the other, there is little point in trying to reduce the smaller one. For example, if $s_{\mathrm{s}}$ is $10 \%$ and $s_{\mathrm{a}}$ is $5 \%$, the overall standard deviation is $11 \%$ $\left(\sqrt{0.10^{2}+0.05^{2}}=0.11\right)$. A more expensive and time-consuming analytical procedure that reduces $s_{\mathrm{a}}$ to $1 \%$ only improves $s_{\mathrm{o}}$ from 11 to $10 \%\left(\sqrt{0.10^{2}+0.01^{2}}=0.10\right)$.

## Origin of Sampling Variance

To understand the nature of the uncertainty in selecting a sample for analysis, consider a random mixture of two kinds of solid particles. The theory of probability allows us to state the likelihood that a randomly drawn sample has the same composition as the bulk sample. It might surprise you to learn how large a sample is required for accurate sampling. ${ }^{9}$

Suppose that the mixture contains $n_{\mathrm{A}}$ particles of type A and $n_{\mathrm{B}}$ particles of type B. The probabilities of drawing A or B from the mixture are

$$
\begin{gather*}
p=\text { probability of drawing } \mathrm{A}=\frac{n_{\mathrm{A}}}{n_{\mathrm{A}}+n_{\mathrm{B}}}  \tag{27-2}\\
q=\text { probability of drawing } \mathrm{B}=\frac{n_{\mathrm{B}}}{n_{\mathrm{A}}+n_{\mathrm{B}}}=1-p \tag{27-3}
\end{gather*}
$$

If $n$ particles are drawn at random, the expected number of particles of type A are $n p$ and the standard deviation of many drawings is known from the binomial distribution to be

## Standard deviation

in sampling operation:

$$
\begin{equation*}
\mathrm{s}_{n}=\sqrt{n p q} \tag{27-4}
\end{equation*}
$$

## EXAMPLE Statistics of Drawing Particles

A mixture contains $1 \% \mathrm{KCl}$ particles and $99 \% \mathrm{KNO}_{3}$ particles. If $10^{4}$ particles are taken, what is the expected number of KCl particles, and what will be the standard deviation if the experiment is repeated many times?

## Solution The expected number is

Expected number of KCl particles $=n p=\left(10^{4}\right)(0.01)=100$ particles
and the standard deviation will be

$$
\text { Standard deviation }=\sqrt{n p q}=\sqrt{\left(10^{4}\right)(0.01)(0.99)}=9.9
$$

The standard deviation $\sqrt{n p q}$ applies to both kinds of particles. The standard deviation is $9.9 \%$ of the expected number of KCl particles, but only $0.1 \%$ of the expected number of $\mathrm{KNO}_{3}$ particles ( $n q=9900$ ). To measure nitrate, this sample is probably sufficient. For chloride, $9.9 \%$ uncertainty may not be acceptable.

Test Yourself It $10^{5}$ particles are taken, what is the relative standard deviation of each measurement? (Answer: $3 \%$ for KCl and $0.03 \%$ for $\mathrm{KNO}_{3}$ )

How much sample corresponds to $10^{4}$ particles? Suppose that the particles are 1 -mmdiameter spheres. The volume of a 1 -mm-diameter sphere is $\frac{4}{3} \pi(0.5 \mathrm{~mm})^{3}=0.524 \mu \mathrm{~L}$. The density of KCl is $1.984 \mathrm{~g} / \mathrm{mL}$ and that of $\mathrm{KNO}_{3}$ is $2.109 \mathrm{~g} / \mathrm{mL}$, so the average density of the mixture is $(0.01)(1.984)+(0.99)(2.109)=2.108 \mathrm{~g} / \mathrm{mL}$. The mass of mixture containing $10^{4}$ particles is $\left(10^{4}\right)\left(0.524 \times 10^{-3} \mathrm{~mL}\right)(2.108 \mathrm{~g} / \mathrm{mL})=11.0 \mathrm{~g}$. If you take $11.0-\mathrm{g}$ test portions from a larger laboratory sample, the expected sampling standard deviation for chloride is $9.9 \%$. The sampling standard deviation for nitrate will be only $0.1 \%$.

How can you prepare a mixture of 1-mm-diameter particles? You might make such a mixture by grinding larger particles and passing them through a 16 mesh sieve, whose screen openings are squares with sides of length 1.18 mm (Table 27-2). Particles that pass through the screen are then passed through a 20 mesh sieve, whose openings are 0.85 mm , and material that does not pass is
variance $=(\text { standard deviation })^{2}$
$\underset{\text { variance }}{\text { total }}=\underset{\text { variance }}{\text { analytical }}+\begin{gathered}\text { sampling } \\ \text { variance }\end{gathered}$

Wow! I'm surprised that an $11.0-\mathrm{g}$ sample has such a large standard deviation.

TABLE 27-2 Standard test sieves

NOTE: Uncertainty is $\pm 1$ standard deviation.
Source: J. G. Dunn, D. N. Phillips, and W. van Bronswijk. "An Exercise to Illustrate the Importance of Sample Preparation in Analytical Chemistry," J. Chem. Ed. 1997, 74, 1188.

There is no advantage to reducing the analytical uncertainty if the sampling uncertainty is high, and vice versa.

TABLE 27-3 Nickel content of crushed ore

| Particle <br> mesh size | Ni content <br> (wt\%) |
| :--- | :--- |
| $<230$ | $13.52 \pm 0.69$ |
| $120 / 230$ | $13.20 \pm 0.74$ |
| $25 / 120$ | $13.22 \pm 0.49$ |
| $10 / 25$ | $10.54 \pm 0.84$ |
| $>10$ | $9.08 \pm 0.69$ |

| 40 | 0.425 | 400 | 0.038 |

EXAMPLE: Particles designated 50/100 mesh pass through a 50 mesh sieve but are retained by a 100 mesh sieve. Their size is in the range $0.150-0.300 \mathrm{~mm}$.
retained for your sample. This procedure gives particles whose diameters are in the range $0.85-1.18 \mathrm{~mm}$. We refer to the size range as $16 / 20$ mesh.

Suppose that much finer particles of $80 / 120$ mesh size (average diameter $=152 \mu \mathrm{~m}$, average volume $=1.84 \mathrm{~nL}$ ) were used instead. Now the mass containing $10^{4}$ particles is reduced from 11.0 to 0.0388 g . We could analyze a larger sample to reduce the sampling uncertainty for chloride.

## EXAMPLE Reducing Sample Uncertainty with a Larger Test Portion

How many grams of $80 / 120$ mesh sample are required to reduce the chloride sampling uncertainty to $1 \%$ ?

Solution We are looking for a standard deviation of $1 \%$ of the number of KCl particles ( $=1 \%$ of $n p$ ):

$$
\sigma_{n}=\sqrt{n p q}=(0.01) n p
$$

Using $p=0.01$ and $q=0.99$, we find $n=9.9 \times 10^{5}$ particles. With a particle volume of 1.84 nL and an average density of $2.108 \mathrm{~g} / \mathrm{mL}$, the mass required for $1 \%$ chloride sampling uncertainty is

$$
\text { Mass }=\left(9.9 \times 10^{5} \text { particles }\right)\left(1.84 \times 10^{-6} \frac{\mathrm{~mL}}{\text { particle }}\right)\left(2.108 \frac{\mathrm{~g}}{\mathrm{~mL}}\right)=3.84 \mathrm{~g}
$$

Even with an average particle diameter of $152 \mu \mathrm{~m}$, we must analyze 3.84 g to reduce the sampling uncertainty to $1 \%$. There is no point using an expensive analytical method with a precision of $0.1 \%$, because the overall uncertainty will still be $1 \%$ from sampling.

Test Yourself What mass of 170/200 mesh particles reduces the KCl sampling uncertainty to $1 \%$ ? (Answer: particle diameter $=0.082_{5} \mathrm{~mm}, 9.9 \times 10^{5}$ particles, 0.61 g$)$

Sampling uncertainty arises from the random nature of drawing particles from a mixture. If the mixture is a liquid and the particles are molecules, there are about $10^{22}$ particles $/ \mathrm{mL}$. It will not require much volume of homogeneous liquid solution to reduce the sampling error to will not require much volume of homogeneous liquid solution to reduce the sampling error to
a negligible value. Solids, however, must be ground to very fine dimensions, and large quantities must be used to ensure a small sampling variance. Grinding invariably contaminates the sample with material from the grinding apparatus.

Table 27-3 illustrates another problem with heterogeneous materials. Nickel ore was
crushed into small particles that were sieved and analyzed. Parts of the ore that are deficient in nickel are relatively resistant to fracture, so the larger particles do not have the same chemical nickel are relatively resistant to fracture, so the larger particles do not have the same chemical
composition as the smaller particles. It is necessary to grind the entire ore to a fine powder to have any hope of obtaining a representative sample.

## Choosing a Sample Size

A well-mixed powder containing KCl and $\mathrm{KNO}_{3}$ is an example of a heterogeneous material in which the variation from place to place is random. How much of a random mixture should be analyzed to reduce the sampling variance for one analysis to a desired level?

To answer this question, consider Figure 27-3, which shows results for sampling the radioisotope ${ }^{24} \mathrm{Na}$ in human liver. The tissue was "homogenized" in a blender but was not truly homogeneous because it was a suspension of small particles in water. The average number of radioactive counts per second per gram of sample was about 237. When the mass of sample for each analysis was about 0.09 g , the standard deviation (shown by the error bar at the left in the diagram) was $\pm 31$ counts per second per gram of homogenate, which is $\pm 13.1 \%$ of the mean value (237). When the sample size was increased to about 1.3 g , the standard deviation decreased to $\pm 13$ counts $/ \mathrm{s} / \mathrm{g}$, or $\pm 5.5 \%$ of the mean. For a sample size near 5.8 g , the standard deviation was reduced to $\pm 5.7$ counts $/ \mathrm{s} / \mathrm{g}$, or $\pm 2.4 \%$ of the mean.

Equation 27-4 told us that, when $n$ particles are drawn from a mixture of two kinds of particles (such as liver tissue particles and droplets of water), the sampling standard deviation will be $\sigma_{n}=\sqrt{n p q}$, where $p$ and $q$ are the fraction of each kind of particle present. The relative standard deviation is $\sigma_{n} / n=\sqrt{n p q} / n=\sqrt{p q / n}$. The relative variance is

$$
\begin{equation*}
\text { Relative variance } \equiv R^{2}=\left(\frac{\sigma_{n}}{n}\right)^{2}=\frac{p q}{n} \quad \Rightarrow n R^{2}=p q \tag{27-5}
\end{equation*}
$$

Noting that the mass of sample drawn, $m$, is proportional to the number of particles drawn, we can rewrite Equation 27-5 in the form

Sampling constant:

$$
\begin{equation*}
m R^{2}=K_{\mathrm{s}} \tag{27-6}
\end{equation*}
$$

in which $R$ is the relative standard deviation (expressed as a percentage) due to sampling and $K_{\mathrm{s}}$ is called the sampling constant. $K_{\mathrm{s}}$ is the mass of sample producing a relative sampling standard deviation of $1 \%$.

Let's see if Equation 27-6 describes Figure 27-3. Table 27-4 shows that $m R^{2}$ is approximately constant for large samples, but agreement is poor for the smallest sample. Attributing the poor agreement at low mass to random sampling variation, we assign $K_{\mathrm{s}} \approx 36 \mathrm{~g}$ in Equation 27-6. This is the average from the 1.3- and $5.8-\mathrm{g}$ samples in Table 27-4.

## EXAMPLE Mass of Sample Required to Produce a Given Sampling Variance

What mass in Figure 27-3 will give a sampling standard deviation of $\pm 7 \%$ ?
Solution With the sampling constant $K_{\mathrm{s}} \approx 36 \mathrm{~g}$, the answer is

$$
m=\frac{K_{\mathrm{s}}}{R^{2}}=\frac{36 \mathrm{~g}}{7^{2}}=0.73 \mathrm{~g}
$$

A 0.7 -g sample should give $\sim 7 \%$ sampling standard deviation. This is strictly a sampling standard deviation. The net variance will be the sum of variances from sampling and from analysis (Equation 27-1).

Test Yourself By what factor must the mass increase to reduce the sampling standard deviation by a factor of 2 ? (Answer: mass must be $4 \times$ greater)

FIGURE 27-3 Sampling diagram of experimental results for ${ }^{24} \mathrm{Na}$ in liver homogenate. Dots are experimental points, and error bars extend $\pm 1$ standard deviation about the mean. Abscissa is logarithmic. [From B. Kratochvil and J. K. Taylor, "Sampling for Chemical Analysis," Anal. Chem. 1981, 53, 925A; National Bureau of Standards Internal Report 80-2164, 1980, p. 66.]

TABLE 27-4 Calculation of sampling constant for Figure 27-3

| Sample <br> mass, $m$ <br> $(\mathrm{~g})$ | Relative <br> standard <br> deviation $(\%)$ | $m R^{2}$ <br> $(\mathrm{~g})$ |
| :--- | :--- | :--- |
| 0.09 | 13.1 | 15.4 |
| 1.3 | 5.5 | 39.3 |
| 5.8 | 2.4 | 33.4 |

FIGURE 27-4 Data for Mn in powdered algae show that the sampling constant, $K_{\text {s, }}$ in Equation 27-6 is approximately proportional to sample mass, $m$, over six orders of magnitude of mass. [From M. Rossbach and E. Zeiller, "Assessment of Element-Specific Homogeneity in Reference Materials Using Microanalytical Techniques," Anal. Bioanal. Chem. 2003, 377, 334.]

The sampling contribution to the overall uncertainty can be reduced by analyzing more samples.

Figure 27-4 shows an example in which Equation 27-6 is approximately valid over six orders of magnitude of sample mass.

## Choosing the Number of Replicate Analyses

We just saw that a single $0.7-\mathrm{g}$ sample is expected to give a sampling standard deviation of $\pm 7 \%$. How many $0.7-\mathrm{g}$ samples must be analyzed to give $95 \%$ confidence that the mean is known to within $\pm 4 \%$ ? The meaning of $95 \%$ confidence is that there is only a $5 \%$ chance that the true mean lies more than $\pm 4 \%$ away from the measured mean. The question we just asked refers only to sampling uncertainty and assumes that analytical uncertainty is negligible.

Rearranging Student's $t$ equation 4-6 allows us to answer the question:
Required number of replicate analyses:

$$
\begin{equation*}
\underbrace{\mu-\bar{x}}_{e}=\frac{t s_{\mathrm{s}}}{\sqrt{n}} \Rightarrow n=\frac{t^{2} s_{\mathrm{s}}^{2}}{e^{2}} \tag{27-7}
\end{equation*}
$$

in which $\mu$ is the true population mean, $\bar{x}$ is the measured mean, $n$ is the number of samples needed, $s_{\mathrm{s}}^{2}$ is the sampling variance, and $e$ is the sought-for uncertainty. Both $s_{\mathrm{s}}$ and $e$ must be expressed as absolute uncertainties or both must be expressed as relative uncertainties. Student's $t$ is taken from Table 4-2 for $95 \%$ confidence at $n-1$ degrees of freedom. Because $n$ is not yet known, the value of $t$ for $n=\infty$ can be used to estimate $n$. After a value of $n$ is calculated, repeat the process a few times until $n$ becomes constant.

## EXAMPLE Sampling a Random Bulk Material

How many $0.7-\mathrm{g}$ samples must be analyzed to give $95 \%$ confidence that the mean is known to within $\pm 4 \%$ ?

Solution A $0.7-\mathrm{g}$ sample gives $s_{\mathrm{s}}=7 \%$, and we are seeking $e=4 \%$. We will express both uncertainties in relative form. Taking $t=1.960$ (from Table 4-2 for $95 \%$ confidence and $\infty$ degrees of freedom) as a starting value, we find

$$
n \approx \frac{(1.960)^{2}(0.07)^{2}}{(0.04)^{2}}=11.8 \approx 12
$$

For $n=12$, there are 11 degrees of freedom, so a second trial value of Student's $t$ (interpolated from Table 4-2) is 2.209. A second cycle of calculation gives

$$
n \approx \frac{(2.209)^{2}(0.07)^{2}}{(0.04)^{2}}=14.9 \approx 15
$$

For $n=15$, there are 14 degrees of freedom and $t=2.150$, which gives

$$
n \approx \frac{(2.150)^{2}(0.07)^{2}}{(0.04)^{2}}=14.2 \approx 14
$$

For $n=14$, there are 13 degrees of freedom and $t=2.170$, which gives

$$
n \approx \frac{(2.170)^{2}(0.07)^{2}}{(0.04)^{2}}=14.4 \approx 14
$$

The calculations reach a constant value near $n \approx 14$, so we need 14 samples of $0.7-\mathrm{g}$ size to determine the mean value to within $4 \%$ with $95 \%$ confidence.

Test Yourself How many $2.8-\mathrm{g}$ samples must be analyzed to give $95 \%$ confidence that the mean is known to within $\pm 4 \%$ ? (Answer: 6)

For the preceding calculations, we needed prior knowledge of the standard deviation. A preliminary study of the sample must be made before the remainder of the analysis can be planned. If there are many similar samples to be analyzed, a thorough analysis of one sample might allow you to plan less thorough-but adequate-analyses of the remainder.

## 27-2 Dissolving Samples for Analysis ${ }^{10}$

Once a bulk sample is selected, a laboratory sample must be prepared for analysis (Figure 27-2). A coarse solid sample should be ground and mixed so that the lab sample has the same composition as the bulk. Solids are typically dried at $110^{\circ} \mathrm{C}$ at atmospheric pressure to remove adsorbed water prior to analysis. Temperature-sensitive samples may simply be stored in an environment that brings them to a constant, reproducible moisture level.

The laboratory sample is usually dissolved for analysis. It is important to dissolve the entire sample, or else we cannot be sure that all of the analyte dissolved. If the sample does not dissolve under mild conditions, acid digestion or fusion may be used. Organic material may be destroyed by combustion (also called dry ashing) or wet ashing (oxidation with liquid reagents) to place inorganic elements in suitable form for analysis.

## Grinding

Solids can be ground in a mortar and pestle like those shown in Figure 27-5. The steel mor$\operatorname{tar}$ (also called a percussion mortar or "diamond" mortar) is a hardened steel tool into which the sleeve and pestle fit snugly. Ores and minerals can be crushed by striking the pestle lightly with a hammer. The agate mortar (or similar ones made of porcelain, mullite, or alumina) is designed for grinding small particles into a fine powder. Less expensive mortars tend to be more porous and more easily scratched, which leads to contamination of the sample with mortar material or portions of previously ground samples. A ceramic mortar can be cleaned by wiping with a wet tissue and washing with distilled water. Difficult residues can be removed by grinding with 4 M HCl in the mortar or by grinding an abrasive cleaner (such as Ajax), followed by washing with HCl and water. A boron carbide mortar and pestle is five times harder than agate and less likely to contaminate the sample.

FIGURE 27-5 Steel, agate, and boron carbide mortars and pestles. The mortar is the bowl and the pestle is the grinding tool. The boron carbide mortar is a hemispheric shell enclosed in a plastic or aluminum body. The pestle has a boron carbide button at the tip of a plastic handle. [Courtesy Thomas Scientific, Swedesboro, NJ; and Spex Industries, Edison, NJ.]

A ball mill is a grinding device in which steel or ceramic balls are rotated inside a drum to crush the sample to a fine powder. A Wig-L-Bug ${ }^{\circledR}$ pulverizes a sample by shaking it in a vial with a ball that moves back and forth. For soft materials, plastic vials and balls are appropriate. For harder materials, steel, agate, and tungsten carbide are used. A Shatterbox laboratory mill spins a puck and ring inside a grinding container at 825 revolutions per minute to pulverize up to 100 g of material (Figure 27-6). Tungsten carbide and zirconia containers are used for very hard samples.

HF causes excruciating burns. Exposure of just $2 \%$ of your body to concentrated ( $48 \mathrm{wt} \%$ ) HF can kill you. Flood the affected area with water for 5 min and then coat the skin with 2.5\% calcium gluconate gel kept in the lab for this purpose, and seek medical help. If the gel is not available, use whatever calcium salt is handy. HF damage can continue to develop days after exposure.

FIGURE 27-6 Shatterbox laboratory mill spins a puck and ring inside a container at high speed to grind up to 100 mL of sample to a fine powder. [Courtesy Spex Industries, Edison, NJ.]

## Dissolving Inorganic Materials with Acids

Table 27-5 lists acids commonly used for dissolving inorganic materials. The nonoxidizing acids $\mathrm{HCl}, \mathrm{HBr}, \mathrm{HF}, \mathrm{H}_{3} \mathrm{PO}_{4}$, dilute $\mathrm{H}_{2} \mathrm{SO}_{4}$, and dilute $\mathrm{HClO}_{4}$ dissolve metals by the redox reaction

$$
\begin{equation*}
\mathrm{M}+n \mathrm{H}^{+} \rightarrow \mathrm{M}^{n+}+\frac{n}{2} \mathrm{H}_{2} \tag{27-8}
\end{equation*}
$$

Metals with negative reduction potentials should dissolve, although some, such as Al , form a protective oxide coat that inhibits dissolution. Volatile species formed by protonation of anions such as carbonate $\left(\mathrm{CO}_{3}^{2-} \rightarrow \mathrm{H}_{2} \mathrm{CO}_{3} \rightarrow \mathrm{CO}_{2}\right)$, sulfide $\left(\mathrm{S}^{2-} \rightarrow \mathrm{H}_{2} \mathrm{~S}\right)$, phosphide $\left(\mathrm{P}^{3-} \rightarrow \mathrm{PH}_{3}\right)$, fluoride $\left(\mathrm{F}^{-} \rightarrow \mathrm{HF}\right)$, and borate $\left(\mathrm{BO}_{3}^{3-} \rightarrow \mathrm{H}_{3} \mathrm{BO}_{3}\right)$ will be lost from hot acids in open vessels. Volatile metal halides such as $\mathrm{SnCl}_{4}$ and $\mathrm{HgCl}_{2}$ and some molecular oxides such as $\mathrm{OsO}_{4}$ and $\mathrm{RuO}_{4}$ also can be lost. Hot hydrofluoric acid is especially useful for dissolving silicates. Glass or platinum vessels can be used for $\mathrm{HCl}, \mathrm{HBr}, \mathrm{H}_{2} \mathrm{SO}_{4}, \mathrm{H}_{3} \mathrm{PO}_{4}$, and

TABLE 27-5 Acids for sample dissolution

| Acid | Typical composition (wt\% and density) | Notes |
| :---: | :---: | :---: |
| HCl | $\begin{aligned} & 37 \% \\ & 1.19 \mathrm{~g} / \mathrm{mL} \end{aligned}$ | Nonoxidizing acid useful for many metals, oxides, sulfides, carbonates, and phosphates. Constant boiling composition at $109^{\circ} \mathrm{C}$ is $20 \% \mathrm{HCl}$. $\mathrm{As}, \mathrm{Sb}, \mathrm{Ge}$, and Pb form volatile chlorides that may be lost from an open vessel. |
| HBr | 48-65\% | Similar to HCl in solvent properties. Constant boiling composition at $124^{\circ} \mathrm{C}$ is $48 \% \mathrm{HBr}$. |
| $\mathrm{H}_{2} \mathrm{SO}_{4}$ | $\begin{aligned} & 95-98 \% \\ & 1.84 \mathrm{~g} / \mathrm{mL} \end{aligned}$ | Good solvent at its boiling point of $338^{\circ} \mathrm{C}$. Attacks metals. Dehydrates and oxidizes organic compounds. |
| $\mathrm{H}_{3} \mathrm{PO}_{4}$ | $\begin{aligned} & 85 \% \\ & 1.70 \mathrm{~g} / \mathrm{mL} \end{aligned}$ | Hot acid dissolves refractory oxides insoluble in other acids. Becomes anhydrous above $150^{\circ} \mathrm{C}$. Dehydrates to pyrophosphoric acid $\left(\mathrm{H}_{2} \mathrm{PO}_{3}-\mathrm{O}-\mathrm{PO}_{3} \mathrm{H}_{2}\right)$ above $200^{\circ} \mathrm{C}$ and dehydrates further to metaphosphoric acid $\left(\left[\mathrm{HPO}_{3}\right]_{n}\right)$ above $300^{\circ} \mathrm{C}$. |
| HF | $\begin{aligned} & 50 \% \\ & 1.16 \mathrm{~g} / \mathrm{mL} \end{aligned}$ | Used primarily to dissolve silicates, making volatile $\mathrm{SiF}_{4}$. This product and excess HF are removed by adding $\mathrm{H}_{2} \mathrm{SO}_{4}$ or $\mathrm{HClO}_{4}$ and heating. Constant boiling composition at $112^{\circ} \mathrm{C}$ is $38 \% \mathrm{HF}$. Used in Teflon, silver, or platinum containers. Extremely harmful upon contact or inhalation. Fluorides of As, $\mathrm{B}, \mathrm{Ge}, \mathrm{Se}, \mathrm{Ta}, \mathrm{Nb}, \mathrm{Ti}$, and Te are volatile. $\mathrm{LaF}_{3}, \mathrm{CaF}_{2}$, and $\mathrm{YF}_{3}$ precipitate. $\mathrm{F}^{-}$is removed by adding $\mathrm{H}_{3} \mathrm{BO}_{3}$ and taking to dryness with $\mathrm{H}_{2} \mathrm{SO}_{4}$ present. |
| $\mathrm{HClO}_{4}$ | $\begin{aligned} & 60-72 \% \\ & 1.54-1.67 \mathrm{~g} / \mathrm{mL} \end{aligned}$ | Cold and dilute acid are not oxidizing, but hot, concentrated acid is an extremely powerful, explosive oxidant, especially useful for organic matter that has already been partially oxidized by hot $\mathrm{HNO}_{3}$. Constant boiling composition at $203^{\circ} \mathrm{C}$ is $72 \%$. Before using $\mathbf{H C l O}_{4}$, evaporate the sample to near dryness several times with hot $\mathrm{HNO}_{3}$ to destroy as much organic material as possible. |

$\mathrm{HClO}_{4}$. HF should be used in Teflon, polyethylene, silver, or platinum vessels. The highest quality acids must be used to minimize contamination by the concentrated reagent.

Substances that do not dissolve in nonoxidizing acids may dissolve in the oxidizing acids $\mathrm{HNO}_{3}$, hot, concentrated $\mathrm{H}_{2} \mathrm{SO}_{4}$, or hot, concentrated $\mathrm{HClO}_{4}$. Nitric acid attacks most metals, but not Au and Pt , which dissolve in the $3: 1(\mathrm{vol} / \mathrm{vol})$ mixture of $\mathrm{HCl}: \mathrm{HNO}_{3}$ called aqua regia. Strong oxidants such as $\mathrm{Cl}_{2}$ or $\mathrm{HClO}_{4}$ in HCl dissolve difficult materials such as Ir at elevated temperature. A mixture of $\mathrm{HNO}_{3}$ and HF attacks the refractory carbides, nitrides, and borides of $\mathrm{Ti}, \mathrm{Zr}, \mathrm{Ta}$, and W . A powerful oxidizing solution known as "piranha solution" is a mixture of concentrated ( $30 \mathrm{wt} \%$ ) $\mathrm{H}_{2} \mathrm{O}_{2}$ plus concentrated ( $98 \mathrm{wt} \%$ ) $\mathrm{H}_{2} \mathrm{SO}_{4}$ variously described as $1: 1$ or $3: 7$ ( $\mathrm{vol} / \mathrm{vol}$ ) mixtures. Hot, concentrated $\mathrm{HClO}_{4}$ (described later for organic substances) is a DANGEROUS, powerful oxidant whose oxidizing power is increased by adding concentrated $\mathrm{H}_{2} \mathrm{SO}_{4}$ and catalysts such as $\mathrm{V}_{2} \mathrm{O}_{5}$ or $\mathrm{CrO}_{3}$.

Digestion is conveniently carried out in a Teflon-lined bomb (a sealed vessel) heated in a microwave oven. ${ }^{11}$ The vessel in Figure 27-7 has a volume of 23 mL and digests up to 1 g of inorganic material in up to 15 mL of concentrated acid or digests 0.1 g of organic material, which releases a great deal of $\mathrm{CO}_{2}(\mathrm{~g})$. Microwave energy heats the contents to $200^{\circ} \mathrm{C}$ in a minute. To prevent explosions, the lid releases gas from the vessel if the internal pressure exceeds 8 MPa ( 80 bar ). The bomb cannot be made of metal, which absorbs microwaves. The bomb is cooled prior to opening to prevent loss of volatile products.

An example of a complex sample that can be digested by microwave heating is mixed electronic waste. ${ }^{12}$ Components such as circuit boards are cut into small pieces and mixed thoroughly. Then 0.1 g is digested with $6 \mathrm{~mL} 70 \mathrm{wt} \% \mathrm{HNO}_{3} / 2 \mathrm{~mL} 30 \mathrm{wt} \% \mathrm{H}_{2} \mathrm{O}_{2} / 1 \mathrm{~mL}$ $49 \mathrm{wt} \% \mathrm{HF}$. Raw plastics can be digested with $9 \mathrm{~mL} 70 \mathrm{wt} \% \mathrm{HNO}_{3}$. Power was ramped from 0 to 600 W over 5 min , held for 15 min , ramped to 1400 W over 5 min , and held for 20 min .

## Dissolving Inorganic Materials by Fusion

Substances that will not dissolve in acid can usually be dissolved by a hot, molten inorganic flux (Table 27-6). Finely powdered unknown is mixed with 2 to 20 times its mass of solid flux, and fusion (melting) is carried out in a platinum-gold alloy crucible at $300^{\circ}$ to $1200^{\circ} \mathrm{C}$ in a furnace or over a burner. Apparatus in Figure 27-8 fuses three samples at once over propane burners while rotating the crucibles to homogenize the melt. Then the molten flux is poured into beakers containing $10 \mathrm{wt} \%$ aqueous $\mathrm{HNO}_{3}$ to dissolve the product.

Most fusions use lithium tetraborate $\left(\mathrm{Li}_{2} \mathrm{~B}_{4} \mathrm{O}_{7}\right.$, m.p. $\left.930^{\circ} \mathrm{C}\right)$, lithium metaborate $\left(\mathrm{LiBO}_{2}\right.$, m.p. $845^{\circ} \mathrm{C}$ ), or a mixture of the two. A nonwetting agent such as KI can be added to prevent the flux from sticking to the crucible. For example, 0.2 g of cement might be fused with 2 g of $\mathrm{Li}_{2} \mathrm{~B}_{4} \mathrm{O}_{7}$ and 30 mg of KI .

A disadvantage of a flux is that impurities are introduced by the large mass of solid reagent. If part of the unknown can be dissolved with acid prior to fusion, it should be dissolved. Then the insoluble component is dissolved with less flux and the two portions are combined for analysis.

Basic fluxes in Table 27-6 $\left(\mathrm{LiBO}_{2}, \mathrm{Na}_{2} \mathrm{CO}_{3}, \mathrm{NaOH}, \mathrm{KOH}\right.$, and $\left.\mathrm{Na}_{2} \mathrm{O}_{2}\right)$ are best used to dissolve acidic oxides of Si and P . Acidic fluxes $\left(\mathrm{Li}_{2} \mathrm{~B}_{4} \mathrm{O}_{7}, \mathrm{Na}_{2} \mathrm{~B}_{4} \mathrm{O}_{7}, \mathrm{~K}_{2} \mathrm{~S}_{2} \mathrm{O}_{7}\right.$, and $\left.\mathrm{B}_{2} \mathrm{O}_{3}\right)$ are most suitable for basic oxides (including cements and ores) of the alkali metals, alkaline earths, lanthanides, and Al. $\mathrm{KHF}_{2}$ is useful for lanthanide oxides. Sulfides and some oxides,

FIGURE 27-7 Microwave digestion bomb lined with Teflon. The outer container retains strength to $150^{\circ} \mathrm{C}$ but rarely reaches $50^{\circ} \mathrm{C}$. [Courtesy Parr Instrument Co., Moline, IL.]

FIGURE 27-8 Automated apparatus that fuses three samples at once over propane burners. The Pt/Au crucibles rotate while they are inclined. [Courtesy Claisse, Quebec.]

Fusion is a last resort because the flux can introduce impurities.

TABLE 27-6 Fluxes for sample dissolution

| Flux | Crucible | Uses |
| :---: | :---: | :---: |
| $\mathrm{Na}_{2} \mathrm{CO}_{3}$ | Pt | For dissolving silicates (clays, rocks, minerals, glasses), refractory oxides, insoluble phosphates, and sulfates. |
| $\mathrm{Li}_{2} \mathrm{~B}_{4} \mathrm{O}_{7}$ or $\mathrm{LiBO}_{2}$ or $\mathrm{Na}_{2} \mathrm{~B}_{4} \mathrm{O}_{7}$ | Pt, graphite Au-Pt alloy, $\mathrm{Au}-\mathrm{Rh}-\mathrm{Pt}$ alloy | Individual or mixed borates are used to dissolve aluminosilicates, carbonates, and samples with high concentrations of basic oxides. $\mathrm{B}_{4} \mathrm{O}_{7}^{2-}$ is called tetraborate and $\mathrm{BO}_{2}^{-}$ is metaborate. |
| NaOH or KOH | $\mathrm{Au}, \mathrm{Ag}$ | Dissolves silicates and SiC. Frothing occurs when $\mathrm{H}_{2} \mathrm{O}$ is eliminated from flux, so it is best to prefuse flux and then add sample. Analytical capabilities are limited by impurities in NaOH and KOH . |
| $\mathrm{Na}_{2} \mathrm{O}_{2}$ | Zr , Ni | Strong base and powerful oxidant good for silicates not dissolved by $\mathrm{Na}_{2} \mathrm{CO}_{3}$. Useful for iron and chromium alloys. Because it slowly attacks crucibles, a good procedure is to coat the inside of a Ni crucible with molten $\mathrm{Na}_{2} \mathrm{CO}_{3}$, cool, and add $\mathrm{Na}_{2} \mathrm{O}_{2}$. The peroxide melts at lower temperature than the carbonate, which shields the crucible from the melt. |
| $\mathrm{K}_{2} \mathrm{~S}_{2} \mathrm{O}_{7}$ | Porcelain, $\mathrm{SiO}_{2}, \mathrm{Au}, \mathrm{Pt}$ | Potassium pyrosulfate $\left(\mathrm{K}_{2} \mathrm{~S}_{2} \mathrm{O}_{7}\right)$ is prepared by heating $\mathrm{KHSO}_{4}$ until all water is lost and foaming ceases. Alternatively, potassium persulfate $\left(\mathrm{K}_{2} \mathrm{~S}_{2} \mathrm{O}_{8}\right)$ decomposes to $\mathrm{K}_{2} \mathrm{~S}_{2} \mathrm{O}_{7}$ upon heating. Good for refractory oxides, not silicates. |
| $\mathrm{B}_{2} \mathrm{O}_{3}$ | Pt | Useful for oxides and silicates. Principal advantage is that flux can be completely removed as volatile methyl borate $\left(\left[\mathrm{CH}_{3} \mathrm{O}\right]_{3} \mathrm{~B}\right)$ by several treatments with HCl in methanol. |
| $\begin{aligned} & \mathrm{Li}_{2} \mathrm{~B}_{4} \mathrm{O}_{7}+ \\ & \mathrm{Li}_{2} \mathrm{SO}_{4} \\ & (2: 1 \mathrm{wt} / \mathrm{wt}) \end{aligned}$ | Pt | Example of a powerful mixture for dissolving refractory silicates and oxides in $10-20 \mathrm{~min}$ at $1000^{\circ} \mathrm{C}$. One gram of flux dissolves 0.1 g of sample. The solidified melt dissolves readily in 20 mL of hot 1.2 M HCl . |

some iron and platinum alloys, and some silicates require an oxidizing flux for dissolution. For this purpose, pure $\mathrm{Na}_{2} \mathrm{O}_{2}$ may be suitable or oxidants such as $\mathrm{KNO}_{3}, \mathrm{KClO}_{3}$, or $\mathrm{Na}_{2} \mathrm{O}_{2}$ can be added to $\mathrm{Na}_{2} \mathrm{CO}_{3}$. Boric oxide can be converted into $\mathrm{B}\left(\mathrm{OCH}_{3}\right)_{3}$ after fusion and completely evaporated. Solidified flux is treated with 100 mL of $\mathrm{CH}_{3} \mathrm{OH}$ saturated with HCl gas and heated gently. The procedure is repeated several times to remove all of the boron.

Platinum crucibles are expensive and should be heated in air, not a reducing atmosphere. Hot Pt should only be handled with Pt-tipped tongs. You can put Pt foil on the tip of ordinary tongs to handle Pt crucibles. The hot crucible should only be placed on a clean, inert surface, or in a Pt/Ir triangle. Carbon from smoky flames can embrittle Pt. Other elements including $\mathrm{Sb}, \mathrm{As}, \mathrm{Pb}, \mathrm{P}, \mathrm{Se}, \mathrm{Te}$, and Zn also embrittle Pt. Molten $\mathrm{Ag}, \mathrm{Au}$, and most base metals dissolve Pt. Oxides of Fe and Pb harm Pt above $1000^{\circ} \mathrm{C}$, as will silicates under reducing conditions.

## Decomposition of Organic Substances

Digestion of organic material is classified as either dry ashing, when the procedure does not include liquid, or wet ashing, when liquid is used. Occasionally, fusion with $\mathrm{Na}_{2} \mathrm{O}_{2}$ (called

Parr oxidation) or alkali metals may be carried out in a sealed bomb. Section 26-4 discussed combustion analysis, in which $\mathrm{C}, \mathrm{H}, \mathrm{N}, \mathrm{S}$, and halogens are measured.

One form of dry ashing is microwave-induced combustion, an example of which is the analysis of halogens in coal. ${ }^{13}$ Pellets of coal weighing 50 to 500 mg were wrapped in lowash filter paper and placed on a quartz holder in a quartz vessel containing 6 mL of 50 mM $\left(\mathrm{NH}_{4}\right)_{2} \mathrm{CO}_{3}$ solution at the bottom. After wetting the filter paper with 50 mL of $6 \mathrm{M} \mathrm{NH}_{4} \mathrm{NO}_{3}$ (an oxidizer), the vessel was capped and pressurized with 20 bar of $\mathrm{O}_{2}$. Application of 1400 W of microwave power initiated combustion in which the coal reached a temperature of $1400^{\circ} \mathrm{C}$. Halides released by combustion dissolved in the $\left(\mathrm{NH}_{4}\right)_{2} \mathrm{CO}_{3}$ solution and were measured by ion chromatography.

Convenient wet ashing procedures include microwave digestion with acid in a Teflon bomb (Figure 27-7). For example, 0.25 g of animal tissue can be digested for metal analysis by placing the sample in a $60-\mathrm{mL}$ Teflon vessel containing 1.5 mL of high-purity $70 \% \mathrm{HNO}_{3}$ plus 1.5 mL of high-purity $96 \% \mathrm{H}_{2} \mathrm{SO}_{4}$ and heating it in a $700-\mathrm{W}$ kitchen microwave oven for $1 \mathrm{~min} .{ }^{14}$ Teflon bombs fitted with temperature and pressure sensors allow safe, programmable control of digestion conditions. An important wet-ashing process is Kjeldahl digestion with $\mathrm{H}_{2} \mathrm{SO}_{4}$ for nitrogen analysis (Section 10-8).

In the Carius method, digestion is performed with fuming $\mathrm{HNO}_{3}$ (which contains excess dissolved $\mathrm{NO}_{2}$ ) in a sealed, heavy-walled glass tube at $200^{\circ}-300^{\circ} \mathrm{C}$. For safety, the glass Carius tube should be contained in a steel vessel pressurized to approximately the same pressure expected inside the glass tube. ${ }^{15}$ For trace analysis, sample should be placed inside a fused silica tube inside the glass tube. Silica provides as little as $1-10 \%$ as much extractable metal as glass. ${ }^{16}$

Figure 27-9 shows microwave wet-ashing apparatus. Sulfuric acid or a mixture of $\mathrm{H}_{2} \mathrm{SO}_{4}$ and $\mathrm{HNO}_{3}(\sim 15 \mathrm{~mL}$ of acid per gram of unknown) are added to an organic substance in a glass digestion tube fitted with the reflux cap. In the first step, sample is carbonized for 10 to 20 min at gentle reflux until all particles have dissolved and the solution has a uniform black appearance. Power is turned off and the sample is allowed to cool for $1-2 \mathrm{~min}$. Next, oxidation is carried out by adding $\mathrm{H}_{2} \mathrm{O}_{2}$ or $\mathrm{HNO}_{3}$ through the reflux cap until the color disappears or the solution is just barely tinted. If the solution is not homogeneous, the power is turned up and the sample is heated to bring all solids into solution. Repeated cycles of oxidation and dissolution may be required. Once conditions for a particular type of material are worked out, the procedure is automated, with power levels and reagent delivery (by the peristaltic pump) programmed into the controller.

FIGURE 27-10 High-pressure autoclave allows digestion up to $270^{\circ} \mathrm{C}$ without $\mathrm{H}_{2} \mathrm{SO}_{4}$ in open vessels inside autoclave. [Adapted from B. Maichin, M. Zischka, and G. Knapp, "Pressurized Wet Digestion in Open Vessels," Anal. Bioanal. Chem. 2003, 376, 715.]

FIGURE 27-11 Reflux cap for wet ashing in an Erlenmeyer flask. The hole allows vapor to escape. The curved spout touches the inside of the flask. [From D. D. Siemer and H. G. Brinkley, "Erlenmeyer Flask-Reflux Cap for Acid Sample Decomposition," Anal. Chem. 1981, 53, 750.]
$\mathrm{HClO}_{4}$ with organic material is an extreme explosion hazard. Always oxidize first with $\mathrm{HNO}_{3}$. Always use a blast shield for $\mathrm{HClO}_{4}$.

Fenton's reagent generates $\mathrm{OH} \cdot$ radical and, possibly, $\mathrm{Fe}^{\text {II }} \mathrm{OOH}$ as the active species. ${ }^{18}$

Section 23-4 described solid-phase microextraction, purge and trap, and thermal desorption-sample preparation methods that are especially useful for gas chromatography.

The high-pressure asher in Figure 27-10 uses a resistive heating element inside a sealed chamber for digestion at temperatures up to $270^{\circ} \mathrm{C}$ under a pressure up to 140 bar. High pressure allows acids to be heated to high temperature without boiling. At high temperature, $\mathrm{HNO}_{3}$ oxidizes organic matter without assistance from $\mathrm{H}_{2} \mathrm{SO}_{4}$, which is not as pure as $\mathrm{HNO}_{3}$ and is therefore less suitable for trace analysis. Silica or fluoropolymer vessels inside the sealed chamber are loosely sealed by Teflon caps that permit evolved gases to escape. The bottom of the vessel is filled with $5 \mathrm{vol} \% \mathrm{H}_{2} \mathrm{O}_{2}$ in $\mathrm{H}_{2} \mathrm{O}$. Hydrogen peroxide reduces nitrogen oxides generated by digestion of organic matter. As an example, a $1-\mathrm{g}$ sample of animal tissue could be digested in a $50-\mathrm{mL}$ fused-silica vessel containing 5 mL of high-purity $70 \mathrm{vol} \%$ $\mathrm{HNO}_{3}$ plus 0.2 mL of high-purity $37 \mathrm{vol} \% \mathrm{HCl}$. Metallic elements in the digestion solution could be measured at part per billion to part per million levels by inductively coupled plasma-atomic emission.

Wet ashing with refluxing $\mathrm{HNO}_{3}-\mathrm{HClO}_{4}$ (Figure 27-11) is a widely applicable, but hazardous, procedure. ${ }^{17}$ Perchloric acid has caused numerous explosions. Use a good blast shield in a metal-lined fume hood designed for $\mathrm{HClO}_{4}$. First, heat the sample slowly to boiling with $\mathrm{HNO}_{3}$ but without $\mathrm{HClO}_{4}$. Boil to near dryness to destroy easily oxidized material that might explode in the presence of $\mathrm{HClO}_{4}$. Add fresh $\mathrm{HNO}_{3}$ and repeat the evaporation several times. After the sample cools to room temperature, add $\mathrm{HClO}_{4}$ and heat again. If possible, $\mathrm{HNO}_{3}$ should be present during the $\mathrm{HClO}_{4}$ treatment. A large excess of $\mathrm{HNO}_{3}$ should be present when oxidizing organic materials.

Bottles of $\mathrm{HClO}_{4}$ should not be stored on wooden shelves, because acid spilled on wood can form explosive cellulose perchlorate esters. Perchloric acid also should not be stored near organic reagents or reducing agents. A reviewer of this book once wrote, "I have seen someone substitute perchloric acid for sulfuric acid in a Jones reductor experiment with spectacular results-no explosion but the tube melted!"

The combination of $\mathrm{Fe}^{2+}$ and $\mathrm{H}_{2} \mathrm{O}_{2}$, called Fenton's reagent, oxidizes organic material in dilute aqueous solutions. ${ }^{19}$ For example, organic components of urine could be destroyed in 30 min at $50^{\circ} \mathrm{C}$ to release traces of mercury for analysis. ${ }^{20}$ To do so, a $50-\mathrm{mL}$ sample was adjusted to $\mathrm{pH} 3-4$ with $0.5 \mathrm{M} \mathrm{H}_{2} \mathrm{SO}_{4}$. Then $50 \mu \mathrm{~L}$ of saturated aqueous ferrous ammonium sulfate, $\mathrm{Fe}\left(\mathrm{NH}_{4}\right)_{2}\left(\mathrm{SO}_{4}\right)_{2}$, were added, followed by $100 \mu \mathrm{~L}$ of $30 \% \mathrm{H}_{2} \mathrm{O}_{2}$.

## 27-3 Sample Preparation Techniques

Sample preparation is the series of steps required to transform a sample so that it is suitable for analysis. Sample preparation may include dissolving the sample, extracting analyte from a complex matrix, concentrating a dilute analyte to a level that can be measured, chemically converting analyte into a detectable form, and removing or masking interfering species.

## Liquid Extraction Techniques

In extraction, analyte is dissolved in a solvent that does not necessarily dissolve the entire sample and does not decompose the analyte. In a typical microwave-assisted extraction of pesticides from soil, a mixture of soil plus acetone and hexane is placed in a Teflon-lined

bomb (Figures 27-7 and 27-12) and heated by microwaves to $150^{\circ} \mathrm{C}$. This temperature is $50^{\circ}$ to $100^{\circ}$ higher than the boiling points of solvents at atmospheric pressure. Pesticides dissolve, but the soil remains behind. The liquid is then analyzed by chromatography.

Acetone absorbs microwaves, so it can be heated in a microwave oven. Hexane does not absorb microwaves. To perform an extraction with pure hexane, the liquid is placed in a fluoropolymer insert inside the Teflon vessel in Figure 27-7. ${ }^{21}$ The walls of the insert contain carbon black, which absorbs microwaves and heats the solvent.

Supercritical fluid extraction uses a supercritical fluid (Box 24-3) as the extraction solvent. ${ }^{23} \mathrm{CO}_{2}$ is the most common supercritical fluid because it is inexpensive and it eliminates the need for costly disposal of waste organic solvents. Addition of a second solvent such as methanol increases the solubility of polar analytes. Nonpolar substances, such as petroleum hydrocarbons, can be extracted with supercritical argon. ${ }^{24}$ The extraction process can be monitored by infrared spectroscopy because Ar has no infrared absorption.

Figure 27-13a shows how a supercritical fluid extraction can be carried out. Pressurized fluid is pumped through a heated extraction vessel. Fluid can be left in contact with the sample

FIGURE 27-12 Extraction vessels in a microwave oven that processes up to 12 samples in under 30 min . Each $100-\mathrm{mL}$ vessel has a vent tube that releases vapor if the pressure exceeds 14 bar. Vapors from the chamber are ultimately vented to a fume hood. The temperature inside each vessel can be monitored and used to control the microwave power. [Courtesy CEM Corp., Matthews, NC.]

Some chelators can extract metal ions into supercritical $\mathrm{CO}_{2}$ (containing small quantities of methanol or water). The ligand below dissolves lanthanides and actinides: ${ }^{22}$

FIGURE 27-13 (a) Apparatus for supercritical fluid extraction. (b) Vessel for extracting house dust at $50^{\circ} \mathrm{C}$ with $20 \mathrm{~mol} \%$ methanol $/ 80 \mathrm{~mol} \% \mathrm{CO}_{2}$ at 24.0 MPa ( 240 bar ). (c) Gas chromatogram of $\mathrm{CH}_{2} \mathrm{Cl}_{2}$ solution of extract using a $30-\mathrm{m} \times 0.25-\mathrm{mm}$ diphenyl $\mathrm{l}_{0.05}$ dimethyl $\mathrm{l}_{0.95}$ siloxane column ( $1-\mu \mathrm{m}$ film thickness) with a temperature ranging from $40^{\circ}$ to $280^{\circ} \mathrm{C}$ and flame ionization detection. [From T. S. Reighard and S. V. Olesik, "Comparison of Supercritical Fluids and Enhanced-Fluidity Liquids for the Extraction of Phenolic Pollutants from House Dust," Anal. Chem. 1996, 68, 3612.]

FIGURE 27-14 Continuous liquid-liquid extraction apparatus used when extraction solvent is (a) denser than the liquid being extracted or (b) lighter than the liquid being extracted.

for some time or it can be pumped through continuously. At the outlet of the extraction vessel, the fluid flows through a capillary tube to release pressure. Exiting $\mathrm{CO}_{2}$ evaporates, leaving extracted analyte in the collection vessel. Alternatively, the $\mathrm{CO}_{2}$ can be bubbled through a solvent in the collection vessel to leave a solution of analyte.

Figure $27-13 \mathrm{~b}$ shows the extraction of organic compounds from dust collected with a vacuum cleaner from doormats at the chemistry building of Ohio State University. The chromatogram of the extract in Figure 27-13c exhibits myriad organic compounds that you and I inhale in every breath. In another study, polybrominated diphenyl ether flame retardants were found in house dust. ${ }^{25}$ Levels in the U.S. were an order of magnitude higher than levels in Europe. Ingested dust was estimated to provide $0.1-6 \mu \mathrm{~g}$ of flame retardants per day to toddlers aged 1-4.

Figure 27-14 shows glassware for continuous liquid-liquid extraction of a nonvolatile analyte. In Figure 27-14a, the extracting solvent is denser than the liquid being extracted. Solvent boils from the flask and condenses into the extraction vessel. Dense droplets of solvent falling through the liquid column extract the analyte. When the liquid level is high enough, extraction solvent is pushed through the return tube to the solvent reservoir. By this means, analyte is slowly transferred from the light liquid at the left into the dense liquid in the reservoir. Figure 27-14b shows the procedure when the extraction solvent is less dense than the liquid being extracted.

One way to reduce solvent use in liquid-liquid extraction is solid-supported liquid-liquid extraction (Figure 27-15). ${ }^{26}$ Solid-supported liquid-liquid extraction is conveniently carried out with a 96 -well plate described in the next section. In a representative procedure for the extraction of prescription drugs, human plasma was diluted with an equal volume of 0.5 M $\mathrm{NH}_{3}$. Then $200 \mu \mathrm{~L}$ of diluted plasma were applied to a small column of microporous diatomaceous earth with suction for 10 s . After allowing 5 min for the aqueous phase to disperse through the solid phase, the column was washed with 1 mL of immiscible organic solvent (hexane:2-methyl-1-butanol, $98: 2 \mathrm{vol} / \mathrm{vol}$ ), which flowed for 5 min by gravity. Suction was applied for 2 min to complete the elution. After evaporating the solvent to dryness, the residue was dissolved in mobile phase for liquid chromatography. In addition to using small volumes of liquid, solid-supported liquid-liquid extraction does not create emulsions, which plague ordinary liquid-liquid extraction.

## Solid-Phase Extraction ${ }^{27}$

Solid-phase extraction uses a small volume of a chromatographic stationary phase or molecular imprinted polymer ${ }^{28}$ (Box 25-2) to isolate analytes from a sample. The extraction removes much of the sample matrix to simplify the analysis.

Figure 27-16 shows typical steps in the solid-phase extraction of $10 \mathrm{ng} / \mathrm{mL}$ of steroids from urine. First, a syringe containing 1 mL of $\mathrm{C}_{18}$-silica is conditioned with 2 mL of methanol to remove adsorbed organic material. Then the column is washed with 2 mL of water. When the $10-\mathrm{mL}$ urine sample is applied, nonpolar components adhere to the $\mathrm{C}_{18}$-silica, and polar components pass through. The column is then rinsed with 4 mL of 25 mM borate buffer at pH 8 to remove polar substances (Figure 27-16c). Then rinses with 4 mL of $40 \mathrm{vol} \%$ methanol/60\% water and 4 mL of $20 \%$ acetone $/ 80 \%$ water remove less polar substances. Finally, elution with two $0.5-\mathrm{mL}$ aliquots of $73 \%$ methanol $/ 27 \%$ water washes the steroids from the column.

Figure 27-17 compares chromatograms of the drug Naproxen in blood serum with or without sample cleanup by solid-phase extraction. Without cleanup, serum proteins overlap and obscure the signal from Naproxen. Solid-phase extraction removes most of the protein.

Solid-phase extraction was used to preconcentrate and partially purify traces of cocaine and benzoylecgonine at the opening of this chapter. A $500-\mathrm{mL}$ volume of river water was filtered, spiked with 10 ng of internal standard, and acidified to pH 2.0 with HCl . A solid-phase cation-exchange extraction cartridge containing 60 mg of resin was conditioned before use by washing with 6 mL of $\mathrm{CH}_{3} \mathrm{OH}, 3 \mathrm{~mL}$ of deionized $\mathrm{H}_{2} \mathrm{O}$, and 3 mL of $\mathrm{H}_{2} \mathrm{O}$ acidified to pH 2.0 with HCl . River water was sucked through the cartridge at $20 \mathrm{~mL} / \mathrm{min}$. Liquid was removed from the cartridge by suction for 5 min . Analytes were then eluted from the cartridge with 2 mL of $\mathrm{CH}_{3} \mathrm{OH}$ followed by 2 mL of $2 \%$ ammonia solution in $\mathrm{CH}_{3} \mathrm{OH}$. This process preconcentrates the sample by a factor of $500 \mathrm{~mL} / 4 \mathrm{~mL}=125$.

FIGURE 27-16 Steps in solid-phase extraction.

FIGURE 27-15 Solid-supported liquid-liquid extraction.

FIGURE 27-17 HPLC of Naproxen in blood serum with no cleanup (upper trace) or with prior sample cleanup (lower trace) by solidphase extraction on $\mathrm{C}_{8}$-silica. [From R. E. Majors and A. D. Broske, "New Directions in Solid-Phase Extraction Particle Design," Am Lab., February 2002, p. 22.]

In Figure 27-18, the notation $1 \mathrm{meq} / \mathrm{g}$ means 1 milliequivalent of ion-exchange sites per gram of resin. A milliequivalent is one millimole of charged sites.

Mixed-mode Cation eXchange (MCX) reversed-phase sorbent $\mathrm{p} K_{\mathrm{a}}<1 ; 1 \mathrm{meq} / \mathrm{g}$

Mixed-mode Weak Cation
eXchange (WCX) reversed-phase sorbent $\mathrm{p} K_{\mathrm{a}} \sim 5 ; 0.75 \mathrm{meq} / \mathrm{g}$

Mixed-mode Anion eXchange (MAX) reversed-phase sorbent $0.25 \mathrm{meq} / \mathrm{g}$

Mixed-mode Weak Anion eXchange (WAX) reversedphase sorbent $\mathrm{p} K_{\mathrm{a}} \sim 6 ; 0.6 \mathrm{meq} / \mathrm{g}$

FIGURE 27-18 Water-wettable, hydrophobic ion-exchange Oasis ${ }^{\circledR}$ polymer sorbents for solid-phase extraction. [From Waters Corporation, Milford, MA.]

The solid-phase extraction cartridge used to preconcentrate cocaine from river water is the mixed-mode cation-exchange reversed-phase sorbent at the upper left in Figure 27-18. This is one of a family of resins whose backbone contains lipophilic benzene rings and hydrophilic pyrrolidone rings. The resins are wettable by water and have affinity for both polar and nonpolar substances. The four ion-exchange derivatives are useful for retaining and then releasing different types of analytes when conditions such as pH , solvent, and ionic strength are changed.

Preconcentration of cocaine from 500 mL of river water was done with just 60 mg of resin in a single syringe. For multiple samples or exploratory research, a 96 -well plate such as those shown in Figure 27-19 can be used. The conventional plate at the upper right has eight rows of 12 syringe-like wells, each of which can contain 5 to 60 mg of resin. The $\mu$ Elution ${ }^{\circledR}$ plate at the upper left has 96 Pasteur-pipet-like wells with a small volume, which can be eluted by $25-50 \mu \mathrm{~L}$ of solvent.

Solid-phase extractions reduce solvent consumption in analytical chemistry. One standard procedure for the analysis of pesticides in wastewater requires 200 mL of dichloromethane for the liquid-liquid extraction of 1 L of water. The same analytes can be isolated by solidphase extraction on $\mathrm{C}_{18}$-silica disks. The pesticides are recovered from the disks by supercritical fluid extraction with $\mathrm{CO}_{2}$ that is finally vented into a small volume of hexane. This one kind of analysis can save $10^{5} \mathrm{~kg}$ of $\mathrm{CH}_{2} \mathrm{Cl}_{2}$ per year. ${ }^{29}$

Ion-exchange resins can capture basic or acidic gases. Carbonate liberated as $\mathrm{CO}_{2}$ from $(\mathrm{ZrO})_{2} \mathrm{CO}_{3}(\mathrm{OH})_{2} \cdot x \mathrm{H}_{2} \mathrm{O}$ used in nuclear fuel reprocessing can be measured by placing a known amount of powdered solid in the test tube in Figure 27-20 and adding $3 \mathrm{M} \mathrm{HNO}_{3}$. When the solution is purged with $\mathrm{N}_{2}, \mathrm{CO}_{2}$ is captured quantitatively by moist anion-exchange resin in the sidearm:

$$
\begin{gathered}
\mathrm{CO}_{2}+\mathrm{H}_{2} \mathrm{O} \rightarrow \mathrm{H}_{2} \mathrm{CO}_{3} \\
2 \mathrm{resin}^{+} \mathrm{OH}^{-}+\mathrm{H}_{2} \mathrm{CO}_{3} \rightarrow\left(\mathrm{resin}^{+}\right)_{2} \mathrm{CO}_{3}^{2-}+2 \mathrm{H}_{2} \mathrm{O}
\end{gathered}
$$

FIGURE 27-19 96-Well Plate and 96-well $\mu$ Elution Plate ${ }^{\circledR}$ for solid-phase extraction. [Courtesy Waters Corporation, Milford, MA.]

Carbonate is eluted from the resin with $1 \mathrm{M} \mathrm{NaNO}_{3}$ and measured by titration with acid. Table 27-7 gives other applications of this technique.

## Derivatization

Derivatization is a procedure in which analyte is chemically modified to make it easier to detect or separate. For example, formaldehyde and other aldehydes and ketones in air, breath, or cigarette smoke ${ }^{30}$ can be trapped and derivatized by passing air through a tiny cartridge containing 0.35 g of silica coated with $0.3 \mathrm{wt} \%$ 2,4-dinitrophenylhydrazine. Carbonyls are converted into the 2,4-dinitrophenylhydrazone derivative, which is eluted with 5 mL of acetonitrile and analyzed by HPLC. The products are readily detected by their strong ultraviolet absorbance near 360 nm .

FIGURE 27-20 Apparatus for trapping basic or acidic gases by ion exchange. [From D. D. Siemer, "Ion Exchange Resins for Trapping Gases: Carbonate Determination," Anal. Chem. 1987, 59, 2439.]

solid-phase extraction supercritical fluid extraction wet ashing

## Summary

The variance of an analysis is the sum of the sampling variance and the analytical variance. Sampling variance can be understood in terms of the statistics of selecting particles from a heterogeneous mixture. If the probabilities of selecting two kinds of particles from a two-particle mixture are $p$ and $q$, the standard deviation in selecting $n$ particles is $\sqrt{n p q}$. You should be able to use this relation to estimate how large a sample is required to reduce the sampling variance to a desired level. Student's $t$ can be used to estimate how many repetitions of the analysis are required to reach a level of confidence in the final result.

Many inorganic materials can be dissolved in strong acids with heating. Glass vessels are often useful, but Teflon, platinum, or silver
are required for HF , which dissolves silicates. If a nonoxidizing acid is insufficient, aqua regia or other oxidizing acids may do the job. A Teflon-lined bomb heated in a microwave oven is a convenient means of dissolving difficult samples. If acid digestion fails, fusion in a molten salt will usually work, but the large quantity of flux adds trace impurities. Organic materials are decomposed by wet ashing with hot concentrated acids or by dry ashing with heat.

Analytes can be separated from complex matrices by sample preparation techniques that include liquid extraction, supercritical fluid extraction, and solid-phase extraction. Derivatization transforms the analyte into a more easily detected or separated form.

## Exercises

27-A. A box contains 120000 red marbles and 880000 yellow marbles.
(a) If you draw a random sample of 1000 marbles from the box, what are the expected numbers of red and yellow marbles?
(b) Now put those marbles back in the box and repeat the experiment. What will be the absolute and relative standard deviations for the numbers in part (a) after many drawings of 1000 marbles?
(c) What will be the absolute and relative standard deviations after many drawings of 4000 marbles?
(d) If you quadruple the size of the sample, you decrease the sampling standard deviation by a factor of $\qquad$ . If you increase the sample size by a factor of $n$, you decrease the sampling standard deviation by a factor of $\qquad$ —.
(e) What sample size is required to reduce the sampling standard deviation of red marbles to $\pm 2 \%$ ?

27-B. (a) What mass of sample in Figure 27-3 is expected to give a sampling standard deviation of $\pm 10 \%$ ?
(b) With the mass from part (a), how many samples should be taken to assure $95 \%$ confidence that the mean is known to within $\pm 20$ counts per second per gram?
27-C. A soil sample contains some acid-soluble inorganic matter, some organic material, and some minerals that do not dissolve in any combination of hot acids that you try. Suggest a procedure for dissolving the entire sample.

## Problems

## Statistics of Sampling

27-1. Explain what is meant by the statement, "Unless the complete history of any sample is known with certainty, the analyst is well advised not to spend his or her time in analyzing it."
27-2. Explain what is meant by "analytical quality" and "data quality" in the following quotation: "We need to update the environmental data quality model to explicitly distinguish analytical quality from data quality. We need to begin spending as much effort ensuring sample and subsample representativeness for heterogeneous matrices as we spend overseeing the analysis of an extract. We need to stop acting like data variability stemming from laboratory analysis is all-important while variability stemming from the sampling process can be ignored . . ., ${ }^{, 31}$

27-3. (a) In the analysis of a barrel of powder, the standard deviation of the sampling operation is $\pm 4 \%$ and the standard deviation of the analytical procedure is $\pm 3 \%$. What is the overall standard deviation?
(b) To what value must the sampling standard deviation be reduced so that the overall standard deviation is $\pm 4 \%$ ?

27-4. What mass of sample in Figure 27-3 is expected to give a sampling standard deviation of $\pm 6 \%$ ?
27-5. Explain how to prepare a powder with an average particle diameter near $100 \mu \mathrm{~m}$ by using sieves from Table 27-2. How would such a particle mesh size be designated?

27-6. An example of a mixture of 1-mm-diameter particles of KCl and $\mathrm{KNO}_{3}$ in a number ratio 1:99 follows Equation 27-4. A sample containing $10^{4}$ particles weighs 11.0 g . What is the expected number and relative standard deviation of KCl particles in a sample weighing $11.0 \times 10^{2} \mathrm{~g}$ ?
27-7. When you flip a coin, the probability of its landing on each side is $p=q=\frac{1}{2}$ in Equations 27-2 and 27-3. If you flip it $n$ times, the expected number of heads equals the expected number of tails $=n p=n q=\frac{1}{2} n$. The expected standard deviation for $n$ flips is $\sigma_{n}=\sqrt{n p q}$. From Table 4-1, we expect that $68.3 \%$ of the results will lie within $\pm 1 \sigma_{n}$ and $95.5 \%$ of the results will lie within $\pm 2 \sigma_{n}$.
(a) Find the expected standard deviation for the number of heads in 1000 coin flips.
(b) By interpolation in Table 4-1, find the value of $z$ that includes $90 \%$ of the area of the Gaussian curve. We expect that $90 \%$ of the results will lie within this number of standard deviations from the mean.
(c) If you repeat the 1000 coin flips many times, what is the expected range for the number of heads that includes $90 \%$ of the results? (For example, your answer might be, "The range 490 to 510 will be observed $90 \%$ of the time.")

27-8. In analyzing a lot with random sample variation, you find a sampling standard deviation of $\pm 5 \%$. Assuming negligible error in the analytical procedure, how many samples must be analyzed to
give $95 \%$ confidence that the error in the mean is within $\pm 4 \%$ of the true value? Answer the same question for a confidence level of $90 \%$.

27-9. In an experiment analogous to that in Figure 27-3, the sampling constant is found to be $K_{\mathrm{s}}=20 \mathrm{~g}$.
(a) What mass of sample is required for a $\pm 2 \%$ sampling standard deviation?
(b) How many samples of the size in part (a) are required to produce $90 \%$ confidence that the mean is known to within $1.5 \%$ ?
$27-10 .{ }^{87} \mathrm{Sr} /{ }^{86} \mathrm{Sr}$ isotope ratios were measured in polar ice cores of varying sample size. The $95 \%$ confidence interval, expressed as a percentage of the mean ${ }^{87} \mathrm{Sr} /{ }^{86} \mathrm{Sr}$ isotope ratio decreased with increasing quantity of Sr measured:

|  | Confidence <br> interval | pg Sr | Confidence <br> interval |
| :--- | :--- | :--- | :--- |
| 57 | $\pm 0.057 \%$ | 506 | $\pm 0.035 \%$ |
| 68 | $\pm 0.069 \%$ | 515 | $\pm 0.027 \%$ |
| 110 | $\pm 0.049 \%$ | 916 | $\pm 0.018 \%$ |
| 110 | $\pm 0.045 \%$ | 955 | $\pm 0.022 \%$ |

Source: G. R. Burton, V. I. Morgan, C. F. Boutron, and K. J. R. Rosman, "High-Sensitivity Measurements of Strontium Isotopes in Polar Ice," Anal. Chim. Acta 2002, 469, 225.

We postulate that the confidence interval is related to the mass of sample by the relation $m R^{2}=K_{\mathrm{s}}$, where $m$ is the mass of Sr in picograms, $R$ is the confidence interval expressed as a percentage of the isotope ratio ( $R=0.022$ for the $955-\mathrm{pg}$ sample), and $K_{\mathrm{s}}$ is a constant with units of picograms. Find the average value of $K_{\mathrm{s}}$ and its standard deviation. Justify why we expect $m R^{2}=K_{\mathrm{s}}$ to hold if all measurements are made with the same number of replications.

27-11. Consider a random mixture containing 4.00 g of $\mathrm{Na}_{2} \mathrm{CO}_{3}$ (density $2.532 \mathrm{~g} / \mathrm{mL}$ ) and 96.00 g of $\mathrm{K}_{2} \mathrm{CO}_{3}$ (density $2.428 \mathrm{~g} / \mathrm{mL}$ ) with a uniform spherical particle radius of 0.075 mm .
(a) Calculate the mass of a single particle of $\mathrm{Na}_{2} \mathrm{CO}_{3}$ and the number of particles of $\mathrm{Na}_{2} \mathrm{CO}_{3}$ in the mixture. Do the same for $\mathrm{K}_{2} \mathrm{CO}_{3}$.
(b) What is the expected number of particles in 0.100 g of the mixture?
(c) Calculate the relative sampling standard deviation in the number of particles of each type in a $0.100-\mathrm{g}$ sample of the mixture.

## Sample Preparation

27-12. From their standard reduction potentials, which of the following metals would you expect to dissolve in HCl by the reaction $\mathrm{M}+n \mathrm{H}^{+} \rightarrow \mathrm{M}^{n+} \rightarrow \frac{n}{2} \mathrm{H}_{2}: \mathrm{Zn}, \mathrm{Fe}, \mathrm{Co}, \mathrm{Al}, \mathrm{Hg}, \mathrm{Cu}, \mathrm{Pt}, \mathrm{Au}$ ? (When the potential predicts that the element will not dissolve, it probably will not. If it is expected to dissolve, it may dissolve if some other process does not interfere. Predictions based on standard reduction potentials at $25^{\circ} \mathrm{C}$ are only tentative, because the potentials and activities in hot, concentrated solutions vary widely from those in the table of standard potentials.)

27-13. The following wet-ashing procedure was used to measure arsenic in organic soil samples by atomic absorption spectroscopy: A $0.1-$ to $0.5-\mathrm{g}$ sample was heated in a $150-\mathrm{mL}$ Teflon bomb in a microwave oven for 2.5 min with 3.5 mL of $70 \% \mathrm{HNO}_{3}$. After the sample cooled, a mixture containing 3.5 mL of $70 \% \mathrm{HNO}_{3}, 1.5 \mathrm{~mL}$ of $70 \% \mathrm{HClO}_{4}$, and 1.0 mL of $\mathrm{H}_{2} \mathrm{SO}_{4}$ was added and the sample was reheated for three $2.5-\mathrm{min}$ intervals with $2-\mathrm{min}$ unheated periods in between. The final solution was diluted with 0.2 M HCl for analysis. Explain why $\mathrm{HClO}_{4}$ was not introduced until the second heating.

27-14. Barbital can be isolated from urine by solid-phase extraction with $\mathrm{C}_{18}$-silica. The barbital is then eluted with $1: 1 \mathrm{vol} / \mathrm{vol}$ acetone:chloroform. Explain how this procedure works.

27-15. To preconcentrate cocaine and benzoylecgonine from river water at the opening of this chapter, solid-phase extraction was carried out at pH 2 using the mixed-mode cation-exchange resin in Figure 27-18. After passing 500 mL of river water through 60 mg of resin, the retained analytes were eluted first with 2 mL of $\mathrm{CH}_{3} \mathrm{OH}$ and then with 2 mL of $2 \%$ ammonia solution in $\mathrm{CH}_{3} \mathrm{OH}$. Explain the purpose of using pH 2 for retention and dilute ammonia for elution.

27-16. Referring to Table 27-7, explain how an anion-exchange resin can be used for absorption and analysis of $\mathrm{SO}_{2}$ released by combustion.

27-17. Why is it advantageous to use large particles ( $50 \mu \mathrm{~m}$ ) for solidphase extraction, but small particles ( $5 \mu \mathrm{~m}$ ) for chromatography?

27-18. In 2002, workers at the Swedish National Food Administration discovered that heated, carbohydrate-rich foods, such as french fries, potato chips, and bread, contain alarming levels ( 0.1 to $4 \mu \mathrm{~g} / \mathrm{g}$ ) of acrylamide, a known carcinogen. ${ }^{32}$

After the discovery, simplified methods were developed to measure ppm levels of acrylamide in food. In one procedure, 10 g of pulverized, frozen french fries were mixed for 20 min with 50 mL of $\mathrm{H}_{2} \mathrm{O}$ to extract acrylamide, which is very soluble in water $(216 \mathrm{~g} / 100 \mathrm{~mL})$. The liquid was decanted and centrifuged to remove suspended

Chromatograms of acrylamide extract after passage through solid-phase extraction column. Left: Phenomenex Synergi Polar-RP $4-\mu \mathrm{m}$ column eluted with 96:4 (vol/vol) $\mathrm{H}_{2} \mathrm{O}: \mathrm{CH}_{3} \mathrm{CN}$. Right: Phenomenex Synergi Hydro-RP 4- $\mu \mathrm{m}$ column eluted with 96:4:0.1 (vol/vol/vol) $\mathrm{H}_{2} \mathrm{O}: \mathrm{CH}_{3} \mathrm{OH}: \mathrm{HCO}_{2} \mathrm{H}$.
[From L. Peng, T. Farkas, L. Loo, J. Teuscher, and K. Kallury, "Rapid and Reproducible Extraction of Acrylamide in French Fries Using a Single Solid-Phase Sorbent," Am. Lab. News Ed., October 2003, p. 10.]
matter. The internal standard ${ }^{2} \mathrm{H}_{3}$-acrylamide was added to 1 mL of extract. A solid-phase extraction column containing 100 mg of cation-exchange polymer with protonated sulfonic acid groups $\left(-\mathrm{SO}_{3} \mathrm{H}\right)$ was washed twice with $1-\mathrm{mL}$ portions of methanol and twice with 1-mL portions of water. The aqueous food extract ( 1 mL ) was then passed through the column to bind protonated acrylamide $\left(-\mathrm{NH}_{3}^{+}\right)$to sulfonate $\left(-\mathrm{SO}_{3}^{-}\right)$on the column. The column was dried for 30 s at 0.3 bar and then acrylamide was eluted with 1 mL of $\mathrm{H}_{2} \mathrm{O}$. Eluate was analyzed by liquid chromatography with a polar bonded phase. The chromatograms show the results monitored by ultraviolet absorbance or by mass spectrometry. The retention time of acrylamide is different on the two columns because they have different dimensions and different flow rates.
(a) What is the purpose of solid-phase extraction prior to chromatography? How does the ion-exchange sorbent retain acrylamide? (b) Why are there many peaks when chromatography is monitored by ultraviolet absorbance?
(c) Mass spectral detection used selected reaction monitoring (Figure 21-26) with the $m / z 72 \rightarrow 55$ transition for acrylamide and $75 \rightarrow 58$ for ${ }^{2} \mathrm{H}_{3}$-acrylamide. Explain how this detection method works and suggest structures for the ions with $\mathrm{m} / \mathrm{z} 72$ and 55 from acrylamide.
(d) Why does mass spectral detection give just one major peak?
(e) How is the internal standard used for quantitation with mass spectral detection?
(f) Where does ${ }^{2} \mathrm{H}_{3}$-acrylamide appear with ultraviolet absorbance? With mass spectral selected reaction monitoring?
(g) Why does the mass spectral method give quantitative results even though retention of acrylamide by the ion-exchange sorbent is not quantitative and elution of acrylamide from the sorbent by 1 mL of water might not be quantitative?

27-19. Many metals in seawater can be preconcentrated for analysis by coprecipitation with $\mathrm{Ga}(\mathrm{OH})_{3}$. A $200-\mu \mathrm{L} \mathrm{HCl}$

Depth profile of elements in seawater near hydrothermal vents. [From T. Akagi and H. Haraguchi, "Simultaneous Multielement Determination of Trace Metals Using 10 mL of Seawater by Inductively Coupled Plasma Atomic Emission Spectrometry with Gallium Coprecipitation and Microsampling Technique," Anal. Chem. 1990, 62, 81.]
solution containing $50 \mu \mathrm{~g}$ of $\mathrm{Ga}^{3+}$ is added to 10.00 mL of the seawater. When the pH is brought to 9.1 with NaOH , a jellylike precipitate forms. After centrifugation to pack the precipitate, the water is removed and the gel is washed with water. Then the gel is dissolved in $50 \mu \mathrm{~L}$ of $1 \mathrm{M} \mathrm{HNO}_{3}$ and aspirated into an inductively coupled plasma for atomic emission analysis. The preconcentration factor is $10 \mathrm{~mL} / 50 \mu \mathrm{~L}=200$. The figure shows elemental concentrations in seawater as a function of depth near hydrothermal vents.
(a) What is the atomic ratio ( Ga added):( Ni in seawater) for the sample with the highest concentration of Ni ?
(b) The results given by gray lines were obtained with seawater samples that were not filtered prior to coprecipitation. The colored lines refer to filtered samples. The results for Ni do not vary between the two procedures, but the results for Fe do vary. Explain what this means.

27-20. Barium titanate, a ceramic used in electronics, was analyzed by the following procedure: Into a Pt crucible was placed 1.2 g of $\mathrm{Na}_{2} \mathrm{CO}_{3}$ and 0.8 g of $\mathrm{Na}_{2} \mathrm{~B}_{4} \mathrm{O}_{7}$ plus 0.314 g of unknown. After fusion at $1000^{\circ} \mathrm{C}$ in a furnace for 30 min , the cooled solid was extracted with 50 mL of 6 M HCl , transferred to a $100-\mathrm{mL}$ volumetric flask, and diluted to the mark. A $25.00-\mathrm{mL}$ aliquot was treated with 5 mL of $15 \%$ tartaric acid (which complexes $\mathrm{Ti}^{4+}$ and keeps it in aqueous solution) and 25 mL of ammonia buffer, pH 9.5 . The solution was treated with organic reagents that complex $\mathrm{Ba}^{2+}$, and the Ba complex was extracted into $\mathrm{CCl}_{4}$. After acidification (to release the $\mathrm{Ba}^{2+}$ from its organic complex), the $\mathrm{Ba}^{2+}$ was backextracted into 0.1 M HCl . The final aqueous sample was treated with ammonia buffer and methylthymol blue (a metal ion indicator) and titrated with 32.49 mL of 0.01144 M EDTA. Find the weight percent of Ba in the ceramic.

27-21. Acid-base equilibria of $\mathrm{Cr}(\mathrm{III})$ were summarized in Problem 9-37. $\mathrm{Cr}(\mathrm{VI})$ in aqueous solution above pH 6 exists as the yellow tetrahedral chromate ion, $\mathrm{CrO}_{4}^{2-}$. Between pH 2 and $6, \mathrm{Cr}(\mathrm{VI})$ exists as an equilibrium mixture of $\mathrm{HCrO}_{4}^{-}$and orange-red dichromate, $\mathrm{Cr}_{2} \mathrm{O}_{7}^{2-} . \mathrm{Cr}(\mathrm{VI})$ is a carcinogen, but $\mathrm{Cr}(\mathrm{III})$ is not considered to be as harmful. The following procedure was used to measure $\mathrm{Cr}(\mathrm{VI})$ in airborne particulate matter in workplaces.

1. Particles were collected by drawing a known volume of air through a polyvinyl chloride filter with $5-\mu \mathrm{M}$ pore size.
2. The filter was placed in a centrifuge tube and 10 mL of 0.05 M $\left(\mathrm{NH}_{4}\right)_{2} \mathrm{SO}_{4} / 0.05 \mathrm{M} \mathrm{NH}_{3}$ buffer, pH 8 , were added. The immersed filter was agitated by ultrasonic vibration for 30 min at $35^{\circ} \mathrm{C}$ to extract all $\mathrm{Cr}(\mathrm{III})$ and $\mathrm{Cr}(\mathrm{VI})$ into solution.
3. A measured volume of extract was passed through a "strongly basic" anion exchanger (Table 25-1) in the $\mathrm{Cl}^{-}$form. Then the resin was washed with distilled water. Liquid containing $\mathrm{Cr}(\mathrm{III})$ from the extract, and the wash was discarded.
4. $\mathrm{Cr}(\mathrm{VI})$ was then eluted from the column with 0.5 M $\left(\mathrm{NH}_{4}\right)_{2} \mathrm{SO}_{4} / 0.05 \mathrm{M} \mathrm{NH}_{3}$ buffer, pH 8 , and collected in a vial.
5. The eluted $\mathrm{Cr}(\mathrm{VI})$ solution was acidified with HCl and treated with a solution of 1,5-diphenylcarbazide, a reagent that forms a colored complex with $\mathrm{Cr}(\mathrm{VI})$. The concentration of the complex was measured by its visible absorbance.
(a) What are the dominant species of $\mathrm{Cr}(\mathrm{VI})$ and $\mathrm{Cr}(\mathrm{III})$ at pH 8 ?
(b) What is the purpose of the anion exchanger in step 3?
(c) Why is a "strongly basic" anion exchanger used instead of a "weakly basic" exchanger?
(d) Why is $\mathrm{Cr}(\mathrm{VI})$ eluted in step 4 but not step 3 ?

27-22. The county landfill in the diagram was monitored to verify that toxic compounds were not leaching into the local water supply. Wells drilled at 21 locations were monitored over a year and pollutants were observed only at sites $8,11,12$, and 13. Monitoring all 21 sites each month is very expensive. Suggest a strategy to use composite samples (Box 0-1) made from more than one well at a time to reduce the cost of routine monitoring. How will your scheme affect the minimum detectable level for pollutants at a particular site?

Diagram of county landfill, showing the location of wells used to monitor groundwater. [Adapted from P.-C. Li and R. Rajagopal, Am. Environ. Lab., October 1994, p. 37.]

## Chapter 2

1. V. Tsionsky, "The Quartz-Crystal Microbalance in an Undergraduate Laboratory Experiment," J. Chem. Ed. 2007, 84, 1334, 1337, 1340.
2. $\mathrm{A} \mathrm{GaPO}_{4}$ crystal microbalance has better properties than quartz for variableand high-temperature measurements. (J. W. Elam and M. J. Pellin, "GaPO ${ }_{4}$ Sensors for Gravimetric Monitoring during Atomic Layer Deposition at High Temperature," Anal. Chem. 2005, 77, 3531.)
3. A vibrating cantilever is $10^{7}$ times more sensitive than a quartz crystal microbalance and can measure 1 fg ( $\mathrm{fg}=$ femtogram $=10^{-15} \mathrm{~g}$ ). (D. Maraldo, K. Rijal, G. Campbell, and R. Mutharasan, "Method for Label-Free Detection of Femtogram Quantities of Biologics in Flowing Liquid Samples," Anal. Chem. 2007, 79, 2762.)
4. The change in frequency for a given mass loading goes as the square of the vibrational frequency. Careful design and micromachining can produce a $62-\mathrm{MHz}$ quartz oscillator. Commercial quartz microbalances oscillate at $5-10 \mathrm{MHz}$. The mass sensitivity of the custom oscillator is a factor of at least $(62 / 10)^{2}=38$ greater. (P. Kao, A. Patwardham, D. Allara, and S. Tadigadapa, "Human Serum Albumin Adsorption Study on 62-MHz Miniaturized Quartz Gravimetric Sensors," Anal. Chem. 2008, 80, 5930.)

Woolf, "Air Buoyancy Corrections for Single-Pan Balances," J. Chem. Ed. 1971, 48, 639; F. F. Cantwell, B. Kratochvil, and W. E. Harris, "Air Buoyancy Errors and the Optical Scale of a Constant-Load Balance," Anal. Chem. 1978, 50, 1010; G. D. Chapman, "Weighing with Electronic Balances," National Research Council of Canada, Report NRCC 38659 (1996).
13. Air density $(\mathrm{g} / \mathrm{L})=(0.003485 B-0.001318 \mathrm{v}) / T$, where $B$ is barometric pressure $(\mathrm{Pa}), v$ is the vapor pressure of water in the air $(\mathrm{Pa})$, and $T$ is air temperature ( K ).
14. U. Henriksson and J. C. Eriksson, "Thermodynamics of Capillary Rise: Why Is the Meniscus Curved?" J. Chem. Ed. 2004, 81, 150.
15. Cleaning solution is prepared by dissolving 36 g of ammonium peroxydisulfate, $\left(\mathrm{NH}_{4}\right)_{2} \mathrm{~S}_{2} \mathrm{O}_{8}$, in a loosely stoppered 2.2-L ("one gallon") bottle of $98 \mathrm{wt} \%$ sulfuric acid (H. M. Stahr, W. Hyde, and L. Sigler, "Oxidizing Acid Baths—without Chromate Hazards," Anal. Chem. 1982, 54, 1456A). Add $\left(\mathrm{NH}_{4}\right)_{2} \mathrm{~S}_{2} \mathrm{O}_{8}$ every few weeks to maintain oxidizing power. Keep it loosely stoppered to prevent gas buildup (P. S. Surdhar, "Laboratory Hazard," Anal. Chem. 1992, 64, 310A). The commercial cleaning solution EOSULF (containing the metal binder, EDTA, and a sulfonate detergent) is an alternative for removing baked-on lipid or protein from glassware. (P. L. Manske, T. M. Stimpfel, and E. L. Gershey, "A Less Hazardous Chromic Acid Substitute for Cleaning Glassware," J. Chem. Ed. 1990, 67, A280.) Another powerful, oxidizing cleaning solution, called "piranha solution," is a $1: 1$ ( $\mathrm{vol} / \mathrm{vol}$ ) mixture of $30 \mathrm{wt} \% \mathrm{H}_{2} \mathrm{O}_{2}$ plus $98 \mathrm{wt} \% \mathrm{H}_{2} \mathrm{SO}_{4}$.

Norton, "Applying a Simple Linear Least-Squares Algorithm to Data with Uncertainties in Both Variables," J. Chem. Ed. 1992, 69, A130.
7. In this book, we plot analytical response on the $y$-axis versus concentration on the $x$-axis. The inverse calibration ( $y=$ concentration, $x=$ response) provides a more precise estimate of concentration from a measured response. The advantage of the inverse calibration increases as the noise in the response increases. There are cases, such as some spectrophotometric measurements, in which uncertainty in response (absorbance) is smaller than uncertainty in concentration. In such case, you should plot response on the $x$-axis and concentration on the $y$-axis. See J. Tellinghuisen, "Inverse vs Classical Calibration for Small Data Sets," Fresenius J. Anal. Chem. 2000, 368, 585; V. Centner, D. L. Massart, and S. de Jong, "Inverse Calibration Predicts Better Than Classical Calibration," Fresenius J. Anal. Chem. 1998, 361, 2; D. Winefordner, "Limit of Detection," Anal. Chem. 1983, 55, 713A; W. R. Porter, "Proper Statistical Evaluation of Calibration Data," Anal. Chem. 1983, 55, 1290A; S. Geiß and J. W. Einmax, "Comparison of Detection Limits in Environmental Analysis," Fresenius J. Anal. Chem. 2001, 370, 673; M. E. Zorn, R. D. Gibbons, and W. C. Sonzogni, "Evaluation of Approximate Methods for Calculating the Limit of Detection and Limit of Quantitation," Environ. Sci. Technol. 1999, 33, 2291; J. D. Burdge, D. L. MacTaggart, and S. O. Farwell, "Realistic Detection Limits from Confidence Bands," J. Chem. Ed. 1999, 76, 434.
8. The procedure in the text leading to Equation 5-5 is the one most recommended for determining the detection limit. If you do not have replicate determinations of the blank and a low-concentration sample, but you do have a linear calibration curve such as the one in Figure 4-13, you can use the leastsquares parameters to estimate a limit of detection for analyte at a desired confidence level. The formula below comes from ISO 11843-2:2000 (International Organization for Standardization, Geneva, www.iso.org). Suppose you measure $I$ calibration standards (including the blank), with $J$ replicates at each concentration. Then you make $K$ replicate measurements of unknown. The detection limit is

$$
\begin{equation*}
\text { Detection limit }=\frac{2 t s_{y}}{m} \sqrt{\frac{1}{K}+\frac{1}{I \times J}+\frac{\bar{x}^{2}}{J \sum\left(x_{i}-\bar{x}\right)^{2}}} \tag{A}
\end{equation*}
$$

where $s_{y}$ is the standard deviation of $y$ (Equation 4-20), $m$ is the slope (Equation 4-16), and $\bar{x}$ is the mean value of $x$ for the standards (including the blank). Student's $t$ is selected from Table 4-2 for $(I \times J)-2$ degrees of freedom. Column headings in Table 4-2 are for a two-tailed distribution. The required value of $t$ in Equation A is for a one-tailed distribution. The equation gives the concentration of analyte that will lead with a probability $(1-\beta)$ to the conclusion that the concentration of analyte in the unknown is larger than that of a blank. For $95 \%$ confidence, $\beta=0.05$. In this case select $t$ from the column labeled $90 \%$ confidence. For $99 \%$ confidence, $\beta=0.01$, and you select $t$ from the column labeled $98 \%$ confidence.
Example: Consider the calibration data in Problem 4-33, for which $m=869.1$ $\mathrm{mV} / \mathrm{vol} \%, s_{y}=18.05 \mathrm{mV}, \bar{x}=0.544 \mathrm{vol} \%$, and $\sum\left(x_{i}-\bar{x}\right)^{2}=2.878 \mathrm{vol} \%^{2}$. There are seven calibration points, including the blank, so $I=7$ and degrees of freedom $=7-2=5$. There is one measurement at each calibration concentration, so $J=1$. There are four replicate measurements of unknown, so $K=4$. Suppose we want a $99 \%$ confidence level detection limit. Therefore, select $t=3.365$ from Table 4-2 for $98 \%$ confidence and 5 degrees of freedom.

$$
\begin{aligned}
\text { Detection limit } & =\frac{2(3.365)(18.05 \mathrm{mV})}{(869.1 \mathrm{mV} / \mathrm{vol} \%)} \sqrt{\frac{1}{4}+\frac{1}{7 \times 1}+\frac{(0.544 \mathrm{vol} \%)^{2}}{(1)(2.878 \mathrm{vol} \%)^{2}}} \\
& =(0.140) \sqrt{0.250+0.143+0.0357}=0.092 \mathrm{vol} \%
\end{aligned}
$$

If more replicate measurements of unknown are made, the first term in the square root becomes smaller and the detection limit would decrease.

Barrett, "The Formaldehyde Clock Reaction," J. Chem. Ed. 1955, 32, 78. See also J. J. Fortman and J. A. Schreier, "Some Modified Two-Color Formaldehyde Clock Salutes for Schools with Colors of Gold and Green or Gold and Red," J. Chem. Ed. 1991, 68, 324; M. G. Burnett, "The Mechanism of the Formaldehyde Clock Reaction," J. Chem. Ed. 1982, 59, 160; and P. Warneck, "The Formaldehyde-Sulfite Clock Reaction Revisited," J. Chem. Ed. 1989, 66, 334.
11. Many other clock reactions are described in the literature. For a summary, see A. P. Oliveira and R. B. Faria, "The Chlorate-Iodine Clock Reaction," J. Am. Chem. Soc. 2005, 127, 18022.
12. The chemical we call sodium bisulfite $\left(\mathrm{NaHSO}_{3}\right)$ is apparently not the solid in the reagent bottle, which is reported to be sodium metabisulfite $\left(\mathrm{Na}_{2} \mathrm{~S}_{2} \mathrm{O}_{5}\right)$ (D. Tudela, "Solid $\mathrm{NaHSO}_{3}$ Does Not Exist," J. Chem. Ed. 2000, 77, 830; see also H. D. B. Jenkins and D. Tudela, "New Methods to Estimate Lattice Energies: Application to Bisulfite and Metabisulfite," J. Chem. Ed. 2003, 80, 1482). $\mathrm{NaHSO}_{3}$ is produced when $\mathrm{Na}_{2} \mathrm{~S}_{2} \mathrm{O}_{5}$ reacts with $\mathrm{H}_{2} \mathrm{O}$. A reagent bottle I use for the formaldehyde clock reaction is labeled "sodium bisulfite," but no formula is given. The label gives the reagent assay "as $\mathrm{SO}_{2}$ : minimum $58.5 \%$." Pure $\mathrm{NaHSO}_{3}$ is equivalent to $61.56 \mathrm{wt} \% \mathrm{SO}_{2}$ and pure $\mathrm{Na}_{2} \mathrm{~S}_{2} \mathrm{O}_{5}$ is equivalent to $67.40 \mathrm{wt} \% \mathrm{SO}_{2}$.

## Chapter 12

1. J. Gorman in Science News, 9 September 2000, p. 165.
2. R. F. Wright et al., "Recovery of Acidified European Surface Waters,"

Environ. Sci. Technol. 2005, 39, 64A.
3. Books about equilibrium calculations: W. B. Guenther, Unified Equilibrium Calculations (New York: Wiley, 1991); J. N. Butler, Ionic Equilibrium: Solubility and pH Calculations (New York: Wiley, 1998); and M. Meloun, Computation of Solution Equilibria (New York: Wiley, 1988). Software for equilibrium calculations: http://www.micromath.com/ and http://www.acadsoft.co.uk/
4. R. G. Bates, Determination of pH, 2nd ed. (New York: Wiley, 1973), p. 86, is the authoritative reference on pH . The pH uncertainty of primary standards could be greater than $\pm 0.006$ at temperatures other than $25^{\circ} \mathrm{C}$.
5. Excel might be used to solve for two unknown concentrations simultaneously: R. de Levie, "How to Compute Labile Metal-Ligand Equilibria," J. Chem. Ed. 2007, 84, 136.
6. R. B. Martin, "Aluminum: A Neurotoxic Product of Acid Rain," Acc. Chem. Res. 1994, 27, 204.
7. R. Jugdaohsingh, M. M. Campbell, R. P. H. Thompson, C. R. McCrohan, K. N. White, and J. J. Powell, "Mucus Secretion by the Freshwater Snail Lymnaea stagnalis Limits Aluminum Concentrations of the Aqueous Environment," Environ. Sci. Technol. 1998, 32, 2591; M. Ravichandran, G. R. Aiken, M. M. Reddy, and J. N. Ryan, "Enhanced Dissolution of Cinnabar (Mercuric Sulfide) by Dissolved Organic Matter Isolated from the Florida Everglades," Environ. Sci. Technol. 1998, 32, 3305; S. Sauvé, M. McBride, and W. Hendershot, "Lead Phosphate Solubility in Water and Soil Suspensions," Environ. Sci. Technol. 1998, 32, 388.
8. Our approach is similar to one by J. L. Guiñón, J. Garcia-Antón, and V. Pérez-Herranz, "Spreadsheet Techniques for Evaluating the Solubility of Sparingly Soluble Salts of Weak Acids," J. Chem. Ed. 1999, 76, 1157.
9. A. Kraft, "Determination of the $\mathrm{p} K_{\mathrm{a}}$ of Multiprotic, Weak Acids by Analyzing Potentiometric Acid-Base Titration Data with Difference Plots," J. Chem. Ed. 2003, 80, 554.
10. G. B. Kauffman, "Niels Bjerrum: A Centennial Evaluation," J. Chem. Ed. 1980, 57, 779, 863.
11. Table 6-1 gives $\mathrm{p} K_{\mathrm{w}}=13.995$ at $\mu=0$ at $25^{\circ} \mathrm{C}$. The expression of $K_{\mathrm{w}}$ to which this value applies is given in terms of molalities, $m$ :

$$
K_{\mathrm{w}}=\frac{m_{\mathrm{H}^{+}} \gamma_{\mathrm{H}^{+}} m_{\mathrm{OH}^{-}} \gamma_{\mathrm{OH}^{-}}}{\mathcal{A}_{\mathrm{H}_{2} \mathrm{O}}}=10^{-13.995}
$$

We want to evaluate $K_{w}^{\prime}$ for 0.1 M KCl . The factor for converting molality into molarity in 0.1 M K is 0.994 in Table 12-1-1A of H. S. Harned and B. B. Owen, Physical Chemistry of Electrolyte Solutions, 3rd ed. (New York: Reinhold, 1958), p. 725. The factor $\gamma_{\mathrm{H}^{+}} \gamma_{\mathrm{OH}^{-}} / \mathcal{A}_{\mathrm{H}_{2} \mathrm{O}}$ is 0.626 in 0.10 M KCl , interpolated from Table 15-2-1A of Harned and Owen, p. 752. $K_{w}^{\prime}$ is the product of concentrations $\left[\mathrm{H}^{+}\right]\left[\mathrm{OH}^{-}\right]$:

$$
\begin{aligned}
{\left[\mathrm{H}^{+}\right]\left[\mathrm{OH}^{-}\right] } & =\frac{m_{\mathrm{H}^{+}}(0.994) \gamma_{\mathrm{H}^{+}} m_{\mathrm{OH}^{-}}(0.994) \gamma_{\mathrm{OH}^{-}}}{\mathcal{A}_{\mathrm{H}_{2} \mathrm{O}}} \frac{\mathcal{A}_{\mathrm{H}_{2} \mathrm{O}}}{\gamma_{\mathrm{H}^{+}} \gamma_{\mathrm{OH}^{-}}} \\
& =10^{-13.995}\left(0.994^{2}\right)\left(\frac{1}{0.626}\right)=10^{-13.797}
\end{aligned}
$$

## Chapter 13

16. W. F. Koch, G. Marinenko, and R. C. Paule, "An Interlaboratory Test of pH Measurements in Rainwater," J. Res. Natl. Bur. Stand. 1986, 91, 23.
17. Free diffusion junction electrodes are designed to minimize junction potentials. The junction is a Teflon capillary tube containing electrolyte that is periodically renewed by syringe.
18. Spectrophotometry with acid-base indictors is another means for measuring the pH of low ionic strength natural waters. (C. R. French, J. J. Carr, E. M. Dougherty, L. A. K. Eidson, J. C. Reynolds, and M. D. DeGrandpre, "Spectrophotometric pH Measurements of Freshwater," Anal. Chim. Acta 2002, 453, 13.)
19. The reference electrode in the Ross combination electrode is $\mathrm{Pt} \mid \mathrm{I}_{2}, \mathrm{I}^{-}$. This electrode is claimed to give improved precision and accuracy over conventional pH electrodes (R. C. Metcalf, Analyst 1987, 112, 1573).
20. A. N. Bezbaruah and T. C. Zhang, "Fabrication of Anodically Electrodeposited Iridium Oxide Film pH Microelectrodes for Microenvironmental Studies," Anal. Chem. 2002, 74, 5726. Iridium oxide electrodes are commercially available or can be prepared by methods such as those described by J.-P. NdoboEpoy, E. Lesniewska, and J.-P. Guicquero, "Nano-pH Sensor for the Study of Reactive Materials," Anal. Chem. 2007, 79, 7560 or R.-G. Du, R.-G. Hu, R.-S. Huang, and C.-J. Lin, "In Situ Measurement of $\mathrm{Cl}^{-}$Concentrations and pH at the Reinforcing Steel/Concrete Interface by Combination Sensors," Anal. Chem. 2006, 78, 3179.
21. L. W. Niedrach, "Electrodes for Potential Measurements in Aqueous Systems at High Temperatures and Pressures," Angew. Chem. 1987, 26, 161.
22. History of ion-selective electrodes: M. S. Frant, "Where Did Ion Selective Electrodes Come From?" J. Chem. Ed. 1997, 74, 159; J. Ruzicka, "The Seventies: Golden Age for Ion Selective Electrodes," J. Chem. Ed. 1997, 74, 167; T. S. Light, "Industrial Use and Applications of Ion Selective Electrodes," J. Chem. Ed. 1997, 74, 171; and C. C. Young, "Evolution of Blood Chemistry Analyzers Based on Ion Selective Electrodes," J. Chem. Ed. 1997, 74, 177; R. P. Buck and E. Lindner, "Tracing the History of Selective Ion Sensors," Anal. Chem. 2001, 73, 88A.
23. E. Bakker and E. Pretsch, "Modern Potentiometry", Angew. Chem. Int. Ed. 2007, 46, 5660.
24. E. Bakker and E. Pretsch, "The New Wave of Ion-Selective Electrodes," Anal. Chem. 2002, 74, 420A.
25. For interfering ions $X$ with charge different from the primary ion $A$, you will find the incorrect, empirical Nicolsky-Eisenman equation in the literature:

$$
E=\text { constant } \pm \frac{0.05916}{z_{\mathrm{A}}} \log \left[\mathcal{A}_{\mathrm{A}}+\sum_{\mathrm{X}} K_{\mathrm{A}, \mathrm{X}}^{\mathrm{Pot}} \mathcal{A}_{\mathrm{X}}^{\left(z_{\mathrm{A}} / z_{\mathrm{x}}\right)}\right]
$$

where $z_{\mathrm{A}}$ is the charge of primary ion A and $z_{\mathrm{X}}$ is the charge of interfering ion X. This equation should not be used. (Y. Umezawa, K. Umezawa, and H. Sato, "Selectivity Coefficients for Ion-Selective Electrodes: Recommended Methods for Reporting $K_{\mathrm{A}, \mathrm{X}}^{\text {Pot }}$ Values," Pure Appl. Chem. 1995, 67, 507.) Correct equations for interfering ions with charges different from that of the primary ion are complicated. You can find them in E. Bakker, R. Meruva, E. Pretsch, and M. Meyerhoff, "Selectivity of Polymer Membrane-Based Ion-Selective Electrodes: Self-Consistent Model Describing the Potentiometric Response in Mixed Ion Solutions of Different Charge," Anal. Chem. 1994, 66, 3021, and N. Nägele, E. Bakker, and E. Pretsch, "General Description of the Simultaneous Response of Potentiometric Ionophore-Based Sensors to Ions of Different Charge," Anal. Chem. 1999, 71, 1041.
26. E. Bakker, E. Pretsch, and P. Bühlmann, "Selectivity of Potentiometric Ion Sensors," Anal. Chem. 2000, 72, 1127; E. Bakker, "Determination of Unbiased Selectivity Coefficients of Neutral Carrier-Based Cation-Selective Electrodes," Anal. Chem. 1997, 69, 1061.
27. Y. Umezawa, K. Umezawa, and H. Sato, "Selectivity Coefficients for IonSelective Electrodes: Recommended Methods for Reporting $K_{\mathrm{A}, \mathrm{X}}^{\text {Pot }}$ Values," Pure Appl. Chem. 1995, 67, 507.

36. P. Gründler, Chemical Sensors: An Introduction for Scientists and Engineers (New York: Springer, 2007).
37. Resistivity, $\rho$, measures how well a substance retards the flow of electric current when an electric field is applied: $J=E / \rho$, where $J$ is current density (current flowing through a unit cross section of the material, $\mathrm{A} / \mathrm{m}^{2}$ ) and $E$ is electric field $(\mathrm{V} / \mathrm{m})$. Units of resistivity are $\mathrm{V} \cdot \mathrm{m} / \mathrm{A}$ or $\Omega \cdot \mathrm{m}$, because $\Omega=\mathrm{V} / \mathrm{A}$, where $\Omega=$ ohm. Conductors have resistivities near $10^{-8} \Omega \cdot \mathrm{~m}$, semiconductors have resistivities of $10^{-4}$ to $10^{7} \Omega \cdot \mathrm{~m}$, and insulators have resistivities of $10^{12}$ to $10^{20} \Omega \cdot \mathrm{~m}$. The reciprocal of resistivity is conductivity. Resistivity does not depend on the dimensions of the substance. Resistance, $R$, is related to resistivity by the equation $R=\rho l / A$, where $l$ is the length and $A$ is the crosssectional area of the conducting substance.

6. Equations 15-9 and 15-10 are analogous to the Henderson-Hasselbalch equation of acid-base buffers. Prior to the equivalence point, the redox titration is buffered to a potential near $E_{+}=$formal potential for $\mathrm{Fe}^{3+} \mid \mathrm{Fe}^{2+}$ by the presence of $\mathrm{Fe}^{3+}$ and $\mathrm{Fe}^{2+}$. After the equivalence point, the reaction is buffered to a potential near $E_{+}=$formal potential for $\mathrm{Ce}^{4+} \mid \mathrm{Ce}^{3+}$. (R. de Levie, "Redox Buffer Strength," J. Chem. Ed. 1999, 76, 574.)

Ed. 1987, 64, 847; D. C. Harris, "Oxidation State Chemical Analysis," in T. A. Vanderah, ed., Chemistry of Superconductor Materials (Park Ridge, NJ: Noyes, 1992); B. D. Fahlman, "Superconductor Synthesis: An Improvement," J. Chem. Ed. 2001, 78, 1182. Superconductor demonstration kits can be purchased from several vendors, including Sargent-Welch, 7400 N. Linder Ave., Skokie, IL 60077-1026.
27. Experiments with an ${ }^{18} \mathrm{O}$-enriched superconductor show that the $\mathrm{O}_{2}$ evolved in Reaction 1 is all derived from the solid, not from the solvent (M. W. Shafer, R. A. de Groot, M. M. Plechaty, G. J. Scilla, B. L. Olson, and E. I. Cooper, "Evolution and Chemical State of Oxygen Upon Acid Dissolution of $\mathrm{YBa}_{2} \mathrm{Cu}_{3} \mathrm{O}_{6.98}$," Mater. Res. Bull. 1989, 24, 687; P. Salvador, E. FernandezSanchez, J. A. Garcia Dominguez, J. Amdor, C. Cascales, and I. Rasines, "Spontaneous $\mathrm{O}_{2}$ Release from $\mathrm{SmBa}_{2} \mathrm{Cu}_{3} \mathrm{O}_{7-x}$ High $\mathrm{T}_{\mathrm{c}}$ Superconductor in Contact with Water," Solid State Commun. 1989, 70, 71).
28. A more sensitive and elegant iodometric procedure is described by E. H. Appelman, L. R. Morss, A. M. Kini, U. Geiser, A. Umezawa, G. W. Crabtree, and K. D. Carlson, "Oxygen Content of Superconducting Perovskites $\mathrm{La}_{2}{ }_{-x} \mathrm{Sr}_{x} \mathrm{CuO}_{y}$ and $\mathrm{YBa}_{2} \mathrm{Cu}_{3} \mathrm{O}_{y}$," Inorg. Chem. 1987, 26, 3237. This method can be modified by adding standard $\mathrm{Br}_{2}$ to analyze superconductors with oxygen in the range $6.0-6.5$, in which there is formally $\mathrm{Cu}^{+}$and $\mathrm{Cu}^{2+}$. The use of electrodes instead of starch to find the end point in iodometric titrations of superconductors is recommended (P. Phinyocheep and I. M. Tang,
"Determination of the Hole Concentration (Copper Valency) in the High $\mathrm{T}_{\mathrm{c}}$ Superconductors," J. Chem. Ed. 1994, 71, A115).

34. The oxygen liberated in Reaction 4 of this problem may be derived from the superconductor, not from solvent water. In any case, $\mathrm{BiO}_{3}^{-}$reacts with $\mathrm{Fe}^{2+}$, and $\mathrm{Cu}^{3+}$ does not, when the sample is dissolved in acid.

Chem. 2000, 72, 346A; A. M. Bond, Broadening Electrochemical Horizons (Oxford: Oxford University Press, 2002).
23. To clean a Hg spill, consolidate the droplets with a piece of cardboard. Use an evacuated filter flask to suck up Hg with a Pasteur pipet attached to a hose. To remove residual Hg , sprinkle elemental zinc powder on the surface and dampen the powder with $5 \%$ aqueous $\mathrm{H}_{2} \mathrm{SO}_{4}$ to make a paste. Mercury dissolves in the zinc. After working the paste into contaminated areas with a sponge or brush, allow the paste to dry and sweep it up. Discard the powder as contaminated Hg waste. This procedure is better than sprinkling sulfur on the spill. Sulfur coats Hg but does not react with the bulk of the droplet [D. N. Easton, "Management and Control of Hg Exposure," Am. Lab., July 1988, p. 66].
24. Low background current in diamond is attributed to (i) the absence of redox-active surface groups and (ii) low capacitance due to the absence of ionizable surface groups and low internal charge carrier concentration. (A. E. Fischer, Y. Show, and G. M. Swain, "Electrochemical Performance of Diamond Thin-Film Electrodes from Different Commercial Sources," Anal. Chem. 2004, 76, 2553.)
25. To remove traces of $\mathrm{O}_{2}$ from $\mathrm{N}_{2}$, bubble the gas through two consecutive columns of liquid. The first column removes $\mathrm{O}_{2}$ by reaction with $\mathrm{V}^{2+}$, and the second saturates the gas stream with water at the same vapor pressure as that in the voltammetry cell. Fill the second column with the same supporting electrolyte solution used for voltammetry. Prepare the first column by boiling $2 \mathrm{~g} \mathrm{NH}_{4} \mathrm{VO}_{3}$ (ammonium metavanadate) with 25 mL 12 M HCl and reduce $\mathrm{VO}_{3}^{-}$to $\mathrm{V}^{2+}$ with zinc amalgam. (Amalgam is prepared by covering granulated Zn with $2 \mathrm{wt} \% \mathrm{HgCl}_{2}$ solution and stirring for 10 min to reduce $\mathrm{Hg}^{2+}$ to Hg , which coats the Zn . The liquid is decanted, and the amalgam is washed three times with water by decantation. Amalgamation increases the overpotential for $\mathrm{H}^{+}$ reduction at the Zn surface, so the Zn is not wasted by reaction with acid.) The
blue or green oxidized vanadium solution turns violet upon reduction. When the violet color is exhausted through use, it can be regenerated by adding more zinc amalgam or HCl or both. Two $\mathrm{V}^{2+}$ bubble tubes can be used in series (in addition to a third tube with supporting electrolyte). When $\mathrm{V}^{2+}$ in the first tube is expended, the second tube is still effective.

Sci. Tech. 2006, 40, 5036; T. R. Martz, J. J. Carr, C. R. French, and M. D. DeGrandpre, "A Submersible Autonomous Sensor for Spectrophotometric pH Measurements of Natural Waters," Anal. Chem. 2003, 75, 1844; W. Yao and R. H. Byrne, "Spectrophotometric Determination of Freshwater pH Using Bromocresol Purple and Phenol Red," Environ. Sci. Technol. 2001, 35, 1197; H. Yamazaki, R. P. Sperline, and H. Freiser, "Spectrophotometric Determination of pH and Its

Applications to Determination of Thermodynamic Equilibrium Constants," Anal. Chem. 1992, 64, 2720.
5. To multiply a matrix times a vector, multiply each row of the matrix times each element of the vector as follows:

$$
\left[\begin{array}{ll}
a_{1} & a_{2} \\
b_{1} & b_{2}
\end{array}\right]\left[\begin{array}{l}
\mathrm{X} \\
\mathrm{Y}
\end{array}\right]=\left[\begin{array}{l}
a_{1} \mathrm{X}+a_{2} \mathrm{Y} \\
b_{1} \mathrm{X}+b_{2} \mathrm{Y}
\end{array}\right]
$$

The product is a vector. The product of a matrix times a matrix is another matrix obtained by multiplying rows times columns:

$$
\begin{aligned}
{\left[\begin{array}{ll}
a_{1} & a_{2} \\
b_{1} & b_{2}
\end{array}\right]\left[\begin{array}{ll}
c_{1} & c_{2} \\
d_{1} & d_{2}
\end{array}\right] } & =\left[\begin{array}{ll}
\text { row } 1 \times \text { column } 1 & \text { row } 1 \times \text { column } 2 \\
\text { row } 2 \times \text { column } 1 & \text { row } 2 \times \text { column } 2
\end{array}\right] \\
& =\left[\begin{array}{ll}
a_{1} c_{1}+a_{2} d_{1} & a_{1} c_{2}+a_{2} d_{2} \\
b_{1} c_{1}+b_{2} d_{1} & b_{1} c_{2}+b_{2} d_{2}
\end{array}\right]
\end{aligned}
$$

The matrix $\mathbf{B}$ below is the inverse of $\mathbf{A}$ because their product is the unit matrix:

$$
\left[\begin{array}{ll}
1 & 2 \\
3 & 4
\end{array}\right]\left[\begin{array}{cc}
-2 & 1 \\
\frac{3}{2} & -\frac{1}{2}
\end{array}\right]=\left[\begin{array}{ll}
1 \cdot-2+2 \cdot \frac{3}{2} & 1 \cdot 1+2 \cdot-\frac{1}{2} \\
3 \cdot-2+4 \cdot \frac{3}{2} & 3 \cdot 1+4 \cdot-\frac{1}{2}
\end{array}\right]=\left[\begin{array}{ll}
1 & 0 \\
0 & 1
\end{array}\right]
$$

A B
Unit matrix

29. Let voltages $V_{\text {dif }}^{0}$ and $V_{\text {ref }}^{0}$ be recorded with pure solvent in both cells. Let voltages $V_{\text {dif }}$ and $V_{\text {ref }}$ be recorded with sample in one cell and solvent in the other cell. Absorbance is related to these voltages by $A=-\log \left[\left(1+V_{\text {dif }} / V_{\text {ref }}\right) /\right.$ $\left.\left(1+V_{\mathrm{dif}}^{0} / V_{\mathrm{ref}}^{0}\right)\right]$.

## Chapter 20

1. E. R. Denoyer, K. J. Fredeen, and J. W. Hager, "Laser Solid Sampling for Inductively Coupled Plasma Mass Spectrometry," Anal. Chem. 1991, 63, 445A; K. Niemax, "Laser Ablation-Reflections on a Very Complex Technique for Solid Sampling," Fresenius J. Anal. Chem. 2001, 370, 332. A major challenge for laser ablation-mass spectrometry is quantitative analysis. One scheme achieves semiquantitative analysis without standards by comparing the signal from each element with the total mass spectrometric signal: A. M. Leach and G. M. Hieftje, "Standardless Semiquantitative Analysis of Metals Using SingleShot Laser Ablation Inductively Coupled Plasma Time-of-Flight Mass Spectrometry," Anal. Chem. 2001, 73, 2959.

19. A better measure of noise is the root-mean-square noise (Equation 19-14), which is $\sim 5$ times less than the peak-to-peak noise. Therefore, 2 times the peak-to-peak noise level is $\sim 10$ times the root-mean-square noise. The detection limit that is 2 times the peak-to-peak noise level is close to the limit of quantitation in Equation 5-6. The lesson is that you should define how you express a detection limit when you report one.

22. A diagnostic for whether emission from an Ar plasma will be sensitive to matrix effects is the ratio of emission from $\mathrm{Mg}^{+}$and Mg atoms (at 280.270 and 285.213 nm , respectively). When the relative intensity is above 10 , the plasma is not sensitive to variations in the sample matrix. When the ratio is below 4, there is high sensitivity to matrix effects. See J.-M. Mermet, "Mg as a Test Element for ICP Atomic Emission Diagnostics," Anal. Chim. Acta 1991, 250, 85 and J.-M. Mermet and E. Poussel, "ICP Emission Spectrometers: Analytical Figures of Merit," Appl. Spectros. 1995, 49[10], 12A. Intensities of the two lines must be corrected for different grating diffraction efficiencies at the two wavelengths. (J. W. Olesik, J. A. Kinser, and B. 13. M. T. Bowser, G. M. Bebault, X. Peng, and D. D. Y. Chen, "Redefining the Separation Factor: Pathway to a Unified Separation Science," Electrophoresis 1997, 18, 2928. The conventional equation is resolution $=\frac{\sqrt{N}}{4}\left(\frac{\alpha-1}{\alpha}\right)\left(\frac{k_{2}^{\prime}}{1+k_{\mathrm{av}}^{\prime}}\right)$, where $\alpha$ is relative retention, $k_{2}^{\prime}$ is the retention factor for the more retained component, and $k_{\mathrm{av}}^{\prime}$ is the average retention factor for the two components. This expression is equivalent to $\frac{\sqrt{N}}{4}(\gamma-1)$ for closely spaced peaks for which $k_{\mathrm{A}}^{\prime} \approx k_{\mathrm{B}}^{\prime} \approx k_{\mathrm{av}}^{\prime}$.

12. In programmed temperature runs with a constant inlet pressure, the flow rate decreases during the run because the viscosity of the carrier gas increases as temperature increases. The effect can be significant (e.g., $30 \%$ decrease in linear velocity for a $200^{\circ}$ temperature increase), so it is a good idea to set the initial linear velocity above the optimum value so that it does not decrease too far below the optimum. Equations for calculating flow rates as a function of temperature and pressure are given by J. V. Hinshaw and L. S. Ettre, Introduction to Open Tubular Gas Chromatography (Cleveland, OH: Advanstar Communications, 1994) and L. S. Ettre and J. V. Hinshaw, Basic Relationships of Gas Chromatography (Cleveland, OH: Advanstar Communications, 1993).

19. J. W. Dolan, "Column Care," LCGC 2008, 26, 692.
20. Washing normal-phase column: Remove the guard column so that impurities from the guard column are not washed into the analytical column. Bare silica and diol-bonded phases can be washed (in order) with heptane, chloroform, ethyl acetate, acetone, ethanol, and water. Then the order is reversed, using dried solvents, to reactivate the column. Use 15 mobile phase volumes ( $15 V_{\mathrm{m}}$ ) of each solvent. Amino-bonded phases are washed in the same manner as silica, but 0.5 M ammonia is used after water. [F. Rabel and K. Palmer, Am. Lab., August 1992, p. 65.] Between uses, normal-phase columns can be stored in 2-propanol or hexane.

30. For a concise, readable, and expert guide to method development for reversed-phase separations, see J. W. Dolan, "The Perfect Method," LCGC, 2007, 25, 546, 632, 704, 944, 1014, 1094, 1178.
31. Acetonitrile can be hydrolyzed to sodium acetate and poured down the drain for disposal: $\mathrm{CH}_{3} \mathrm{CN}+\mathrm{NaOH}+\mathrm{H}_{2} \mathrm{O} \rightarrow \mathrm{CH}_{3} \mathrm{CO}_{2} \mathrm{Na}+\mathrm{NH}_{3}$. Dilute the chromatography eluate to $10 \mathrm{vol} \% \mathrm{CH}_{3} \mathrm{CN}$ with water. To 1.0 L of $10 \mathrm{vol} \%$ $\mathrm{CH}_{3} \mathrm{CN}$, add 475 mL of 10 M NaOH . The solution can be left at $20^{\circ} \mathrm{C}$ for 25 days in a hood or heated to $80^{\circ} \mathrm{C}$ for 70 min to reduce the $\mathrm{CH}_{3} \mathrm{CN}$ concentration to $0.025 \mathrm{vol} \%$. Mix the hydrolysate with waste acid so that it is approximately neutral before disposal. (K. Gilomen, H. P. Stauffer, and V. R. Meyer, LCGC 1996, 14, 56.)
32. Tetrahydrofuran can be stored for at least half a year without oxidation by adding $25 \mathrm{vol} \% \mathrm{H}_{2} \mathrm{O}$. (J. Zhao and P. W. Carr, "The Magic of Water in Tetrahydrofuran-Preventing Peroxide Formation," LCGC 1999, 17, 346.)

38. At a wavelength of 190 nm , phosphate at pH 7.2 has about three times the absorbance of borate at pH 9.2 . Glycine, citrate, HEPES, and TRIS buffers have significant absorption near 210 nm . Borate buffer should be prepared from sodium tetraborate (borax, $\mathrm{Na}_{2} \mathrm{~B}_{4} \mathrm{O}_{7} \cdot 10 \mathrm{H}_{2} \mathrm{O}$ ), not from boric acid $\left(\mathrm{B}(\mathrm{OH})_{3}\right)$, which has somewhat different acid-base chemistry. An ultraviolet-absorbing impurity in borate buffer can be removed by passage through a $\mathrm{C}_{18}$ solid-phase extraction column.

This page intentionally left blank
ablation Vaporization of a small volume of material by a laser pulse. abscissa Horizontal ( $x$ ) axis of a graph.
absolute uncertainty An expression of the margin of uncertainty associated with a measurement. Absolute error also could refer to the difference between a measured value and the "true" value.
absorbance, $A$ Defined as $A=\log \left(P_{0} / P\right)$, where $P_{0}$ is the radiant power of light (power per unit area) striking the sample on one side and $P$ is the radiant power emerging from the other side. Also called optical density. absorptance, $a$ Fraction of incident radiant power absorbed by a sample. absorption Occurs when a substance is taken up inside another. See also adsorption.
absorption coefficient Light absorbed by a sample is attenuated at the rate $P_{2} / P_{1}=\mathrm{e}^{-\alpha b}$, where $P_{1}$ is the initial radiant power, $P_{2}$ is the power after traversing a pathlength $b$, and $\alpha$ is called the absorption coefficient. absorption spectrum A graph of absorbance of light versus wavelength, frequency, or wavenumber.
accuracy A measure of how close a measured value is to the "true" value. acid A substance that increases the concentration of $\mathrm{H}^{+}$when added to water.
acid-base titration One in which the reaction between analyte and titrant is an acid-base reaction.
acid dissociation constant, $K_{\mathrm{a}}$ Equilibrium constant for the reaction of an acid, HA, with $\mathrm{H}_{2} \mathrm{O}$ :

$$
\mathrm{HA}+\mathrm{H}_{2} \mathrm{O} \stackrel{K_{\mathrm{a}}}{\rightleftharpoons} \mathrm{~A}^{-}+\mathrm{H}_{3} \mathrm{O}^{+} \quad K_{\mathrm{a}}=\frac{\mathcal{A}_{\mathrm{A}}-\mathcal{A}_{\mathrm{H}_{3} \mathrm{O}^{+}}}{\mathcal{A}_{\mathrm{HA}}}
$$

acid error Systematic error that occurs in strongly acidic solutions, where glass electrodes tend to indicate a value of pH that is too high. acidic solution One in which the activity of $\mathrm{H}^{+}$is greater than the activity of $\mathrm{OH}^{-}$.
acidity In natural waters, the quantity of carbonic acid and other dissolved acids that react with strong base when the pH of the sample is raised to 8.3. Expressed as $\mathrm{mmol} \mathrm{OH}^{-}$needed to raise the pH of 1 L to pH 8.3 .
acid wash Procedure in which glassware is soaked in $3-6 \mathrm{M} \mathrm{HCl}$ for $>1 \mathrm{~h}$ (followed by rinsing well with distilled water and soaking in distilled water) to remove traces of cations adsorbed on the surface of the glass and to replace them with $\mathrm{H}^{+}$.
activation energy, $E_{\text {a }}$ Energy needed for a process to overcome a barrier that otherwise prevents the process from occurring.
activity, $\mathcal{A}$ The value that replaces concentration in a thermodynamically correct equilibrium expression. The activity of X is given by $\mathcal{A}_{\mathrm{X}}=[\mathrm{X}] \gamma_{\mathrm{X}}$, where $\gamma_{\mathrm{X}}$ is the activity coefficient and $[\mathrm{X}]$ is the concentration. activity coefficient, $\gamma$ The number by which the concentration must be multiplied to give activity.
adduct Product formed when a Lewis base combines with a Lewis acid.
adjusted retention time, $t_{\mathrm{r}}^{\prime}$ In chromatography, this parameter is $t_{\mathrm{r}}^{\prime}=t_{\mathrm{r}}-t_{\mathrm{m}}$, where $t_{\mathrm{r}}$ is the retention time of a solute and $t_{\mathrm{m}}$ is the time needed for mobile phase to travel the length of the column.
adsorption Occurs when a substance becomes attached to the surface of another substance. See also absorption.
adsorption chromatography A technique in which solute equilibrates between the mobile phase and adsorption sites on the stationary phase. adsorption indicator Used for precipitation titrations, it becomes attached to a precipitate and changes color when the surface charge of the precipitate changes sign at the equivalence point.
aerosol A suspension of very small liquid or solid particles in air or gas. Examples include fog and smoke.
affinity chromatography A technique in which a particular solute is retained by a column by virtue of a specific interaction with a molecule covalently bound to the stationary phase.
aliquot Portion.
alkali flame detector Modified flame ionization detector that responds to N and P , which produce ions when they contact a $\mathrm{Rb}_{2} \mathrm{SO}_{4}$-containing glass bead in the flame. Also called nitrogen-phosphorus detector. alkalimetric titration With reference to EDTA, this technique involves titration of the protons liberated from EDTA upon binding to a metal. alkaline error See sodium error.
alkalinity In natural water, the quantity of base (mainly $\mathrm{HCO}_{3}^{-}, \mathrm{CO}_{3}^{2-}$, and $\mathrm{OH}^{-}$) that reacts with strong acid when the pH of the sample is lowered to 4.5. Expressed as $\mathrm{mmol} \mathrm{H}^{+}$needed to lower the pH of 1 L to pH 4.5 . amalgam A solution of anything in mercury.
amine A compound with the general formula $\mathrm{RNH}_{2}, \mathrm{R}_{2} \mathrm{NH}$, or $\mathrm{R}_{3} \mathrm{~N}$, where $R$ is any group of atoms.
amino acid One of 20 building blocks of proteins, having the general structure

$$
\begin{gathered}
\stackrel{\mathrm{R}}{+\mathrm{J}} \underset{\mathrm{H}_{3}}{\mathrm{NCCO}}{ }_{2}^{-}
\end{gathered}
$$

where R is a different substituent for each acid.
ammeter Device for measuring electric current.
ammonium ion The ammonium ion is $\mathrm{NH}_{4}^{+}$. An ammonium ion is any ion of the type $\mathrm{RNH}_{3}^{+}, \mathrm{R}_{2} \mathrm{NH}_{2}^{+}, \mathrm{R}_{3} \mathrm{NH}^{+}$, or $\mathrm{R}_{4} \mathrm{~N}^{+}$, where R is an organic substituent.
ampere, $\mathbf{A}$ One ampere is the current that will produce a force of exactly $2 \times 10^{-7} \mathrm{~N} / \mathrm{m}$ when that current flows through two "infinitely" long, parallel conductors of negligible cross section, with a spacing of 1 m , in a vacuum.
amperometric detector See electrochemical detector.
amperometric titration One in which the end point is determined by monitoring the current passing between two electrodes immersed in the sample solution and maintained at a constant potential difference.
amperometry Measurement of electric current for analytical purposes. amphiprotic molecule One that can act as both a proton donor and a proton acceptor. The intermediate species of polyprotic acids are amphiprotic. analysis of variance A statistical tool used to dissect the overall random error into contributions from several sources.
analyte Substance being measured or detected.
analytical chromatography Chromatography of small quantities of material conducted for the purpose of qualitative or quantitative analysis or both. analytical concentration See formal concentration.
anhydrous Adjective describing a substance from which all water has been removed.
anion A negatively charged ion.
anion exchanger An ion exchanger with positively charged groups covalently attached to the support. It can reversibly bind anions.
anode Electrode at which oxidation occurs. In electrophoresis, it is the positively charged electrode.
anodic depolarizer A molecule that is easily oxidized, thereby preventing the anode potential of an electrochemical cell from becoming too positive. anodic wave In voltammetry, a flow of current due to oxidation at the working electrode.
anolyte Solution present in the anode chamber of an electrochemical cell. antibody A protein manufactured by an organism to sequester foreign molecules and mark them for destruction.
antigen A molecule that is foreign to an organism and causes the organism to make antibodies.
antilogarithm The antilogarithm of $a$ is $b$ if $10^{a}=b$.
apparent mobility Constant of proportionality, $\mu_{\text {app }}$, between the net speed, $u_{\text {net }}$, of an ion in solution and the applied electric field, $E: u_{\text {net }}=\mu_{\text {app }} E$. Apparent mobility is the sum of the electrophoretic and electroosmotic mobilities: $\mu_{\mathrm{app}}=\mu_{\mathrm{ep}}+\mu_{\mathrm{eo}}$.
aprotic solvent One that cannot donate protons (hydrogen ions) in an acid-base reaction.
aptamer A short (15-40 bases) length of single- or double-stranded DNA (deoxyribonucleic acid) or RNA (ribonucleic acid) that strongly binds to a selected molecule.
aqua regia A 3:1 (vol/vol) mixture of concentrated ( $37 \mathrm{wt} \%$ ) HCl and concentrated ( $70 \mathrm{wt} \%$ ) $\mathrm{HNO}_{3}$.
aqueous In water (as an aqueous solution).
aquo ion The species $\mathrm{M}\left(\mathrm{H}_{2} \mathrm{O}\right)_{n}^{m+}$, containing just the cation M and its tightly bound water ligands.
argentometric titration One using $\mathrm{Ag}^{+}$ion.
ashless filter paper Specially treated paper that leaves a negligible residue after ignition. It is used for gravimetric analysis.
assessment In quality assurance, the process of (1) collecting data to show that analytical procedures are operating within specified limits and (2) verifying that final results meet use objectives.
asymmetry potential When the activity of analyte is the same on the inside and outside of an ion-selective electrode, there should be no voltage across the membrane. In fact, the two surfaces are never identical, and some voltage (called the asymmetry potential) is usually observed. atmosphere, atm One atm is defined as a pressure of 101325 Pa . It is equal to the pressure exerted by a column of Hg 760 mm in height at Earth's surface. atmospheric pressure chemical ionization A method to interface liquid chromatography to mass spectrometry. Liquid is nebulized into a fine aerosol by a coaxial gas flow and the application of heat. Electrons from a high-voltage corona discharge create cations and anions from analyte exiting the chromatography column. The most common species observed with this interface is $\mathrm{MH}^{+}$, the protonated analyte, with little fragmentation.
atomic absorption spectroscopy A technique in which the absorption of light by free gaseous atoms in a plasma, flame, or furnace is used to measure the concentration of atoms.
atomic emission spectroscopy A technique in which the emission of light by thermally excited atoms in a flame or furnace is used to measure the concentration of atoms.
atomic fluorescence spectroscopy A technique in which electronic transitions of atoms in a flame, furnace, or plasma are excited by light, and the fluorescence is observed at a right angle to the incident beam.
atomic mass Number of grams of an element containing Avogadro's number of atoms.
atomization Process in which a compound is decomposed into its atoms at high temperature.
attenuated total reflection An analytical technique based on passage of light through a waveguide or optical fiber by total internal reflection. The absorption of the cladding is sensitive to the presence of analyte. Some of the evanescent wave is absorbed in the cladding during each reflection in the presence of analyte. The more analyte, the more signal is lost.
autoprotolysis The reaction in which two molecules of the same species transfer a proton from one to the other; e.g., $\mathrm{CH}_{3} \mathrm{OH}+\mathrm{CH}_{3} \mathrm{OH} \rightleftharpoons$ $\mathrm{CH}_{3} \mathrm{OH}_{2}^{+}+\mathrm{CH}_{3} \mathrm{O}^{-}$.
autoprotolysis constant The equilibrium constant for an autoprotolysis reaction.
autotitrator A device that dispenses measured amounts of titrant into a solution and monitors a property such as pH or electrode potential after each addition. The instrument performs the titration automatically and can determine the end point automatically. Data can be transferred to a spreadsheet for further interpretation.
auxiliary complexing agent A species, such as ammonia, that is added to a solution to stabilize a metal ion and keep that metal in solution. It binds loosely enough to be displaced by a titrant.
auxiliary electrode Current-carrying partner of the working electrode in an electrolysis. Also called counter electrode.
average The sum of several values divided by the number of values. Also called mean.
Avogadro's number The number of atoms in exactly 0.012 kg of ${ }^{12} \mathrm{C}$, approximately $6.022 \times 10^{23}$.
azeotrope The constant-boiling distillate produced by two liquids. It is of constant composition, containing both substances.
background correction In atomic spectroscopy, a means of distinguishing signal due to analyte from signal due to absorption, emission, or scattering by the flame, furnace, plasma, or sample matrix.
background electrolyte In capillary electrophoresis, the buffer in which separation is carried out. Also called run buffer.
back titration One in which an excess of standard reagent is added to react with analyte. Then the excess reagent is titrated with a second reagent or with a standard solution of analyte.
ball mill A drum in which solid sample is ground to fine powder by tumbling with hard ceramic balls.
band gap Energy separating the valence band and conduction band in a semiconductor.
band-pass filter A filter that allows a band of wavelengths to pass through it while absorbing or reflecting other wavelengths.
bandwidth Usually, the range of wavelengths or frequencies of an absorption or emission band, typically measured at a height equal to half of the peak height. Also, the width of radiation emerging from the exit slit of a monochromator.
base A substance that decreases the concentration of $\mathrm{H}^{+}$when added to water.
base "dissociation" constant A misnomer for base hydrolysis constant, $K_{\mathrm{b}}$. base hydrolysis constant, $K_{\mathrm{b}}$ The equilibrium constant for the reaction of a base, B , with $\mathrm{H}_{2} \mathrm{O}$ :

$$
\mathrm{B}+\mathrm{H}_{2} \mathrm{O} \stackrel{K_{\mathrm{b}}}{\rightleftharpoons} \mathrm{BH}^{+}+\mathrm{OH}^{-} \quad K_{\mathrm{b}}=\frac{\mathcal{A}_{\mathrm{BH}^{+}} \mathcal{A}_{\mathrm{OH}^{-}}}{\mathcal{A}_{\mathrm{B}}}
$$

base peak Most intense peak in a mass spectrum.
basic solution One in which the activity of $\mathrm{OH}^{-}$is greater than the activity of $\mathrm{H}^{+}$.
beam chopper A rotating mirror that directs light alternately through the sample and reference cells of a double-beam spectrophotometer.
beam chopping A technique using a rotating beam chopper to modulate the signal in a spectrophotometer at a frequency at which noise is reduced. In atomic absorption, periodic blocking of the beam allows a distinction to be made between light from the source and light from the flame.
beamsplitter A partially reflective, partially transparent plate that reflects some light and transmits some light.
Beer's law Relates the absorbance, $A$, of a sample to its concentration, $c$, pathlength, $b$, and molar absorptivity, $\varepsilon: A=\varepsilon b c$. More correctly called Beer-Lambert-Bouguer law.
biamperometric titration An amperometric titration conducted with two polarizable electrodes held at a constant potential difference.
bilayer Formed by a surfactant, a two-dimensional membrane structure in which polar or ionic headgroups are pointing outward and nonpolar tails are pointing inward.
biological oxygen demand, BOD In a water sample, the quantity of dissolved oxygen consumed by microorganisms during a 5-day incubation in a sealed vessel at $20^{\circ} \mathrm{C}$. Oxygen consumption is limited by organic nutrients, so BOD is a measure of pollutant concentration.
biosensor Device that uses biological components such as enzymes, antibodies, or DNA, in combination with electric, optical, or other signals, to achieve a highly selective response to one analyte.
bipotentiometric titration A potentiometric titration in which a constant current is passed between two polarizable electrodes immersed in the sample solution. An abrupt change in potential characterizes the end point.
Bjerrum plot See difference plot.
blackbody An ideal surface that absorbs all photons striking it. If the blackbody is at constant temperature, it must emit as much radiant energy as it absorbs.
blackbody radiation Radiation emitted by a blackbody. The energy and spectral distribution of the emission depend only on the temperature of the blackbody.
blank solution A solution not intended to contain analyte. It could be made from all reagents-except unknown-that would be used in an analytical procedure. Analyte signal measured with a blank solution could be due to impurities in the reagents or, possibly, interference.
blank titration One in which a solution containing all reagents except analyte is titrated. The volume of titrant needed in the blank titration should be subtracted from the volume needed to titrate unknown.
blind sample See performance test sample.
blocking Occurs when a metal ion binds tightly to a metal ion indicator. A blocked indicator is unsuitable for a titration because no color change is observed at the end point.
Boltzmann distribution Relative population of two states at thermal equilibrium:

$$
\frac{N_{2}}{N_{1}}=\frac{g_{2}}{g_{1}} \mathrm{e}^{-\left(E_{2}-E_{1}\right) / k T}
$$

where $N_{i}$ is the population of the state, $g_{i}$ is the degeneracy of the state, $E_{i}$ is the energy of the state, $k$ is Boltzmann's constant, and $T$ is temperature in kelvins. Degeneracy refers to the number of states with the same energy. bomb Sealed vessel for conducting high-temperature, high-pressure reactions.
bonded stationary phase In high-performance liquid chromatography, a stationary liquid phase covalently attached to the solid support.
Brønsted-Lowry acid A proton (hydrogen ion) donor.
Brønsted-Lowry base A proton (hydrogen ion) acceptor.
Brownian motion Random motion of a small particle in a liquid caused by collisions with molecules moving with random speeds in random directions.
buffer A mixture of a weak acid and its conjugate base. A buffered solution is one that resists changes in pH when acids or bases are added.
buffer capacity, $\beta$ A measure of the ability of a buffer to resist changes in pH . The larger the buffer capacity, the greater the resistance to pH change. The definition of buffer capacity is $\beta=d C_{\mathrm{b}} / d \mathrm{pH}=-d C_{\mathrm{a}} / d \mathrm{pH}$, where $C_{\mathrm{a}}$ and $C_{\mathrm{b}}$ are the number of moles of strong acid or base per liter needed to produce a unit change in pH . Also called buffer intensity. buffer intensity See buffer capacity.
bulk sample Material taken from lot being analyzed-usually chosen to be representative of the entire lot. Also called gross sample.
bulk solution Chemists' jargon referring to the main body of a solution. In electrochemistry, we distinguish properties of the bulk solution from properties that may be different in the immediate vicinity of an electrode.
buoyancy Upward force exerted on an object in a liquid or gaseous fluid. An object weighed in air appears lighter than its actual mass by an amount equal to the mass of air that it displaces.
buret A calibrated glass tube with a stopcock at the bottom. Used to deliver known volumes of liquid.
calibration Process of relating the actual physical quantity (such as mass, volume, force, or electric current) to the quantity indicated on the scale of an instrument.
calibration check In a series of analytical measurements, a calibration check is an analysis of a solution formulated by the analyst to contain a known concentration of analyte. It is the analyst's own check that procedures and instruments are functioning correctly.
calibration curve A graph showing the value of some property versus concentration of analyte. When the corresponding property of an unknown is measured, its concentration can be determined from the graph.
calomel electrode A common reference electrode based on the halfreaction $\mathrm{Hg}_{2} \mathrm{Cl}_{2}(s)+2 \mathrm{e}^{-} \rightleftharpoons 2 \mathrm{Hg}(l)+2 \mathrm{Cl}^{-}$. See also S.C.E. candela, cd Luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540 THz and that has a radiant intensity of $1 / 683 \mathrm{~W} / \mathrm{sr}$ in that direction.
capacitance The electric capacitance of two parallel, charged surfaces is the charge on each surface divided by the electric potential difference (volts) between the two surfaces.
capacitor current See charging current.
capacity factor See retention factor.
capacity ratio See retention factor.
capillary electrochromatography A version of high-performance liquid chromatography in which mobile phase is driven by electroosmosis instead of a pressure gradient. Solutes are separated by partitioning between the mobile and stationary phases.
capillary electrophoresis Separation of a mixture into its components by a strong electric field imposed between the two ends of a narrow capillary tube filled with electrolyte solution. Unlike chromatography, there is no stationary phase in electrophoresis. Solutes are separated by differences in mobility.
capillary gel electrophoresis A form of capillary electrophoresis in which the tube is filled with a polymer gel that serves as a sieve for macromolecules. The largest molecules have the slowest migration through the gel.
capillary zone electrophoresis A form of capillary electrophoresis in which ionic solutes are separated because of differences in their electrophoretic mobility.
carboxylate anion Conjugate base $\left(\mathrm{RCO}_{2}^{-}\right)$of a carboxylic acid.
carboxylic acid A molecule with the general structure $\mathrm{RCO}_{2} \mathrm{H}$, where R is any group of atoms.
carcinogen A cancer-causing agent.
carrier gas Mobile phase gas in gas chromatography.
cathode Electrode at which reduction occurs. In electrophoresis, it is the negatively charged electrode.
cathodic depolarizer A molecule that is easily reduced, thereby preventing the cathode potential of an electrochemical cell from becoming very low.
cathodic wave In voltammetry, a flow of current due to reduction at the working electrode.
catholyte Solution present in the cathode chamber of an electrochemical cell.
cation A positively charged ion.
cation exchanger An ion exchanger with negatively charged groups covalently attached to the support. It can reversibly bind cations.
certified reference material Samples sold by national measurement institutes and containing known quantities of analytes to test accuracy of analytical procedures. The U.S. National Institute of Standards and Technology calls its certified materials Standard Reference Materials. chain of custody Trail followed by a sample from the time it is collected to the time it is analyzed and, possibly, archived.
characteristic The part of a logarithm at the left of the decimal point. charge balance A statement that the sum of all positive charge in solution equals the magnitude of the sum of all negative charge in solution. charge coupled device An extremely sensitive detector in which light creates electrons and holes in a semiconductor material. The electrons are attracted to regions near positive electrodes, where the electrons are "stored" until they are ready to be counted. The number of electrons in each pixel (picture element) is proportional to the number of photons striking the pixel.
charged aerosol detector Sensitive, nearly universal detector for liquid chromatography in which solvent is evaporated from eluate to leave an aerosol of fine particles of nonvolatile solute. Aerosol particles are charged by adsorption of $\mathrm{N}_{2}^{+}$ions and flow to a collector that measures total charge reaching the detector versus time.
charging current Electric current arising from charging or discharging of the electric double layer at the electrode-solution interface. Also called capacitor current or condenser current.
charring In a gravimetric analysis, the precipitate and filter paper are first dried gently. Then the filter paper is charred at intermediate temperature to destroy the paper without letting it inflame. Finally, precipitate is ignited at high temperature to convert it into its analytical form.
chelate effect The observation that a single multidentate ligand forms metal complexes that are more stable than those formed by several individual ligands with the same ligand atoms.
chelating ligand A ligand that binds to a metal through more than one atom. chemical interference In atomic spectroscopy, any chemical reaction that decreases the efficiency of atomization.
chemical ionization A gentle method of producing ions for a mass spectrometer without extensive fragmentation of the analyte molecule, M. A reagent gas such as $\mathrm{CH}_{4}$ is bombarded with electrons to make $\mathrm{CH}_{5}^{+}$, which transfers $\mathrm{H}^{+}$to M , giving $\mathrm{MH}^{+}$.
chemical oxygen demand, COD In a natural water or industrial effluent sample, the quantity of $\mathrm{O}_{2}$ equivalent to the quantity of $\mathrm{K}_{2} \mathrm{Cr}_{2} \mathrm{O}_{7}$ consumed by refluxing the sample with a standard dichromate-sulfuric acid solution containing $\mathrm{Ag}^{+}$catalyst. Because 1 mol of $\mathrm{K}_{2} \mathrm{Cr}_{2} \mathrm{O}_{7}$ consumes $6 \mathrm{e}^{-}\left(\mathrm{Cr}^{6+} \rightarrow \mathrm{Cr}^{3+}\right)$, it is equivalent to 1.5 mol of $\mathrm{O}_{2}\left(\mathrm{O} \rightarrow \mathrm{O}^{2-}\right)$. See also oxidizability.
chemiluminescence Emission of light by an excited-state product of a chemical reaction.
chiral molecule One that is not superimposable on its mirror image in any accessible conformation. Also called an optically active molecule, a chiral molecule rotates the plane of polarization of light.
chromatogram A graph showing chromatography detector response as a function of elution time or volume.
chromatograph A machine used to perform chromatography.
chromatography A technique in which molecules in a mobile phase are separated because of their different affinities for a stationary phase. The greater the affinity for the stationary phase, the longer a molecule is retained. chromophore The part of a molecule responsible for absorption of light of a particular frequency.
chronoamperometry A technique in which the potential of a working electrode in an unstirred solution is varied rapidly while the current between the working and the auxiliary electrodes is measured. Suppose that the analyte is reducible and that the potential of the working electrode is made more negative. Initially, no reduction occurs. At a certain potential, the analyte begins to be reduced and the current increases. As the potential becomes more negative, the current increases further until the concentration of analyte at the surface of the electrode is sufficiently depleted. Then the current decreases, even though the potential becomes more negative. The maximum current is proportional to the concentration of analyte in bulk solution.
chronopotentiometry A technique in which a constant current is forced to flow between two electrodes. The voltage remains fairly steady until the concentration of an electroactive species becomes depleted. Then the voltage changes rapidly as a new redox reaction assumes the burden of current flow. The elapsed time when the voltage suddenly changes is proportional to the concentration of the initial electroactive species in bulk solution.
cladding Covering; overlay. Layer surrounding the core of an optical fiber. Clark electrode One that measures the concentration of dissolved oxygen by amperometry.
coagulation With respect to gravimetric analysis, small crystallites coming together to form larger crystals.
co-chromatography See spike.
coefficient of variation The standard deviation, $s$, expressed as a percentage of the mean value $\bar{x}$ : coefficient of variation $=100 \times s / \bar{x}$. Also called relative standard deviation.
coherence Degree to which electromagnetic waves are in phase with one another. Laser light is highly coherent.
co-ion An ion with the same charge as the ion of interest.
cold trapping Splitless gas chromatography injection technique in which solute is condensed far below its boiling point in a narrow band at the start of the column.
collimated light Light in which all rays travel in parallel paths.
collimation Process of making light rays travel parallel to one another. collisionally activated dissociation Fragmentation of an ion in a mass spectrometer by high-energy collisions with gas molecules. In atmospheric pressure chemical ionization or electrospray interfaces, collisionally activated dissociation at the inlet to the mass filter can be promoted by varying the cone voltage. In tandem mass spectrometry, dissociation occurs in a
collision cell between the two mass separators. Also called collisioninduced dissociation.
collision cell Middle stage of a tandem mass spectrometer in which the precursor ion selected by the first stage is fragmented by collisions with gas molecules.
colloid A dissolved particle with a diameter in the approximate range $1-500 \mathrm{~nm}$. It is too large to be considered one molecule but too small to simply precipitate.
combination electrode A glass electrode with a concentric reference electrode built on the same body.
combustion analysis A technique in which a sample is heated in an atmosphere of $\mathrm{O}_{2}$ to oxidize it to $\mathrm{CO}_{2}$ and $\mathrm{H}_{2} \mathrm{O}$, which are collected and weighed or measured by gas chromatography. Modifications permit the simultaneous analysis of N, S, and halogens.
common ion effect Occurs when a salt is dissolved in a solution already containing one of the ions of the salt. The salt is less soluble than it would be in a solution without that extra ion. An application of Le Châtelier's principle.
complex ion Historical name for any ion containing two or more ions or molecules that are each stable by themselves; e.g., $\mathrm{CuCl}_{3}^{-}$contains $\mathrm{Cu}^{+}+3 \mathrm{Cl}^{-}$.
complexometric titration One in which the reaction between analyte and titrant involves complex formation.
composite sample A representative sample prepared from a heterogeneous material. If the material consists of distinct regions, the composite is made of portions of each region, with relative amounts proportional to the size of each region.
compound electrode An ion-selective electrode consisting of a conventional electrode surrounded by a barrier that is selectively permeable to the analyte of interest. Alternatively, the barrier region might convert external analyte into a different species, to which the inner electrode is sensitive. concentration An expression of the quantity per unit volume or unit mass of a substance. Common measures of concentration are molarity ( $\mathrm{mol} / \mathrm{L}$ ) and molality ( $\mathrm{mol} / \mathrm{kg}$ of solvent).
concentration cell A galvanic cell in which both half-reactions are the same, but the concentrations in each half-cell are not identical. The cell reaction increases the concentration of species in one half-cell and decreases the concentration in the other.
concentration polarization Occurs when an electrode reaction occurs so rapidly that the concentration of solute near the surface of the electrode is not the same as the concentration in bulk solution.
condenser current See charging current.
conditional formation constant, $K_{\mathrm{f}}^{\prime}$ Equilibrium constant for formation of a complex under a particular stated set of conditions, such as pH , ionic strength, and concentration of auxiliary complexing species. Also called effective formation constant.
conduction band Energy levels containing conduction electrons in a semiconductor.
conduction electron An electron free to move about within a solid and carry electric current. In a semiconductor, the energies of the conduction electrons are above those of the valence electrons that are localized in chemical bonds. The energy separating the valence and conduction bands is called the band gap.
conductivity, $\sigma$ Proportionality constant between electric current density, $J\left(\mathrm{~A} / \mathrm{m}^{2}\right)$, and electric field, $E(\mathrm{~V} / \mathrm{m}): J=\sigma E$. Units are $\Omega^{-1} \mathrm{~m}^{-1}$. Conductivity is the reciprocal of resistivity.
cone voltage Voltage applied between the skimmer cone and a nearby orifice through which gaseous ions flow into the mass separator of a mass spectrometer. The magnitude of the voltage can be increased to promote collisionally activated dissociation of ions prior to mass separation.
confidence interval Range of values within which there is a specified probability that the true value lies.
conjugate acid-base pair An acid and a base that differ only through the gain or loss of a single proton.
constant-current electrolysis Electrolysis in which a constant current flows between working and auxiliary electrodes. As reactants are
consumed, increasing voltage is required to keep the current flowing, so this is the least selective form of electrolysis.
constant mass In gravimetric analysis, the product is heated and cooled to room temperature in a desiccator until successive weighings are "constant." There is no standard definition of "constant mass"; but, for ordinary work, it is usually taken to be about $\pm 0.3 \mathrm{mg}$. Constancy is usually limited by the irreproducible regain of moisture during cooling and weighing.
constant-voltage electrolysis Electrolysis in which a constant voltage is maintained between working and auxiliary electrodes. This is less selective than controlled-potential electrolysis because the potential of the working electrode becomes more extreme as ohmic potential and overpotential change.
continuous-dynode electron multiplier An electron detector that works like a photomultiplier tube. An electron striking the lead-doped glass wall of a horn-shaped tube liberates several electrons which are accelerated into the horn by increasingly positive potential. After many bounces, $\sim 10^{5}$ electrons reach the narrow end of the horn for each incident electron.
control chart A graph in which successive observations of a process are recorded to determine whether the process is within specified control limits.
controlled-potential electrolysis A technique for selective reduction (or oxidation), in which the voltage between working and reference electrodes is held constant.
convection Process in which solute is carried from one place to another by bulk motion of the solution.
coprecipitation Occurs when a substance whose solubility is not exceeded precipitates along with one whose solubility is exceeded. correlation coefficient The square of the correlation coefficient, $R^{2}$, is a measure of goodness of fit of data points to a straight line. The closer $R^{2}$ is to 1 , the better the fit.
coulomb, C Amount of charge per second that flows past any point in a circuit when the current is 1 ampere. There are approximately 96485 coulombs in a mole of electrons.
coulometer A device that generates a redox reagent for quantitative reaction with analyte and measures the number of electrons required to generate the redox reagent.
coulometric titration One conducted with a constant current for a measured time.
coulometry A technique in which the quantity of analyte is determined by measuring the number of coulombs needed for complete electrolysis. counter electrode See auxiliary electrode. counterion An ion with a charge opposite that of the ion of interest. coupled equilibria Reversible chemical reactions that have a species in common. For example, the product of one reaction could be a reactant in another reaction.
critical point Critical temperature and pressure of a substance.
critical pressure Pressure above which a fluid cannot be condensed to two phases (liquid and gas), no matter how low the temperature. critical temperature Temperature above which a fluid cannot be condensed to two phases (liquid and gas), no matter how great a pressure is applied.
cross-linking Covalent linkage between different strands of a polymer. cryogenic focusing In gas chromatography, cold trapping of solutes below ambient temperature at the beginning of a column. A cryogen is a cold fluid such as liquid nitrogen used for cooling.
crystallization Process in which a substance comes out of solution slowly to form a solid with a regular arrangement of atoms.
cumulative formation constant, $\boldsymbol{\beta}_{n}$ Equilibrium constant for a reaction of the type $\mathrm{M}+n \mathrm{X} \rightleftharpoons \mathrm{MX}_{n}$. Also called overall formation constant. current, $I$ Amount of charge flowing through a circuit per unit time (A/s).
current density Electric current per unit area $\left(\mathrm{A} / \mathrm{m}^{2}\right)$.
cuvet A cell with transparent walls used to hold samples for spectrophotometric measurements.
cyclic voltammetry A polarographic technique with a triangular waveform. Both cathodic and anodic currents are observed for reversible reactions.
dalton, Da Unit of atomic mass defined as $1 / 12$ of the mass of ${ }^{12} \mathrm{C}$. dark current Small current produced by a photodetector in the absence of light.

## DART See direct analysis in real time.

data quality objectives Accuracy, precision, and sampling requirements for an analytical method.
dead volume Volume of a chromatography system (not including the column) between the point of injection and the point of detection. Also called extra-column volume.
Debye-Hückel equation Gives the activity coefficient, $\gamma$, as a function of ionic strength, $\mu$. The extended Debye-Hückel equation, applicable to ionic strengths up to about 0.1 M , is $\log \gamma=\left[-0.51 z^{2} \sqrt{\mu}\right] /[1+$ ( $\alpha \sqrt{\mu} / 305$ )], where $z$ is the ionic charge and $\alpha$ is the effective hydrated radius in picometers.
decant To pour liquid off a solid or, perhaps, a denser liquid. The denser phase is left behind.
decomposition potential In an electrolysis, that voltage at which rapid reaction first begins.
degrees of freedom In statistics, the number of observations minus the number of parameters estimated from the observations.
deionized water Water that has been passed through a cation exchanger (in the $\mathrm{H}^{+}$form) and an anion exchanger (in the $\mathrm{OH}^{-}$form) to remove ions from the solution.
deliquescent substance A hygroscopic solid that spontaneously picks up so much water from the air that the substance completely dissolves.
demasking Removal of a masking agent from the species protected by the masking agent.
density Mass per unit volume.
depolarizer A molecule that is oxidized or reduced at a modest potential. It is added to an electrolytic cell to prevent the cathode or anode potential from becoming too extreme.
derivatization Chemical alteration to attach a group to a molecule so that the molecule can be detected conveniently. Alternatively, treatment can alter volatility or solubility to allow easier separation.
desalting Removal of salts (or any small molecules) from a solution of macromolecules. Gel filtration or dialysis are used for desalting.
DESI See desorption electrospray ionization.
desiccant A drying agent.
desiccator A sealed chamber in which samples can be dried in the presence of a desiccant or by vacuum pumping or both.
desorption The release of an adsorbed substance from a surface.
desorption electrospray ionization, DESI A solvent is electrosprayed onto a surface to dissolve analyte from the surface into aerosol microdroplets, which can be analyzed with a mass spectrometer.
detection limit The smallest quantity of analyte that is "significantly different" from a blank. The detection limit is often taken as the mean signal for blanks plus three times the standard deviation of a low-concentration sample. Also called lower limit of detection.
determinant The value of the two-dimensional determinant $\left|\begin{array}{ll}a & b \\ c & d\end{array}\right|$ is
the difference $a d-b c$.
determinate error See systematic error.
deuterium arc lamp Source of broadband ultraviolet radiation. An electric discharge (a spark) in deuterium gas causes $\mathrm{D}_{2}$ molecules to dissociate and emit many wavelengths of radiation.
dialysis A technique in which solutions are placed on either side of a semipermeable membrane that allows small molecules, but not large molecules, to cross. Small molecules in the two solutions diffuse across and equilibrate between the two sides. Large molecules are retained on their original side.
dielectric constant, $\varepsilon$ The electrostatic force, $F$, between two charged particles is given by $F=k q_{1} q_{2} / \varepsilon r^{2}$, where $k$ is a constant, $q_{1}$ and $q_{2}$ are the
charges, $r$ is the separation between particles, and $\varepsilon$ is the dielectric constant of the medium. The higher the dielectric constant, the less force is exerted by one charged particle on another.
difference plot A graph of the mean fraction of protons bound to an acid versus pH . For complex formation, the difference plot gives the mean number of ligands bound to a metal versus $\mathrm{pL}(=-\log [$ ligand concentration]). Also called Bjerrum plot.
diffiraction Occurs when electromagnetic radiation passes through or is reflected from slits with a spacing comparable to the wavelength. Interference of waves from adjacent slits produces a spectrum of radiation, with each wavelength emerging at a different angle.
diffuse part of the double layer Region of solution near a charged surface in which excess counterions are attracted to the charge. The thickness of this layer is $0.3-10 \mathrm{~nm}$.
diffuse reflection Occurs when a rough surface reflects light in all directions.
diffusion Net transport of a solute from a region of high concentration to a region of low concentration caused by the random movement of molecules in a liquid or gas (or, very slowly, in a solid).
diffusion coefficient, $D$ Defined by Fick's first law of diffusion: $J=-D(d c / d x)$, where $J$ is the rate at which molecules diffuse across a plane of unit area and $d c / d x$ is the concentration gradient in the direction of diffusion.
diffusion current Current observed when the rate of electrolysis is limited by the rate of diffusion of analyte to the electrode. In polarography, diffusion current $=$ limiting current - residual current
diffusion layer Region near an electrode containing excess product or decreased reactant involved in the electrode reaction. The thickness of this layer can be hundreds of micrometers.
digestion Process in which a precipitate is left (usually warm) in the presence of mother liquor to promote particle recrystallization and growth.
Purer, more easily filterable crystals result. Also used to describe any chemical treatment in which a substance is decomposed to transform the analyte into a form suitable for analysis.
dilution factor Factor (initial volume of reagent)/(total volume of solution) used to multiply the initial concentration of reagent to find the diluted concentration.
dimer A molecule made from two identical units.
diode A semiconductor device consisting of a $p n$ junction through which current can pass in only one direction. Current flows when the $n$-type material is made negative and the $p$-type material is made positive. A voltage sufficient to overcome the activation energy for carrier movement must be supplied before any current flows. For silicon diodes, this voltage is $\sim 0.6 \mathrm{~V}$. If a sufficiently large voltage, called the breakdown voltage, is applied in the reverse direction, current will flow in the wrong direction through the diode.
diprotic acids and bases Compounds that can donate or accept two protons. direct analysis in real time, DART A DART source produces excited He or $\mathrm{N}_{2}$, which is directed at the surface of an object to be sampled in ambient atmosphere. The excited species react with ambient moisture to create protonated water clusters that react with analyte M to make $\mathrm{MH}^{+}$. The $\mathrm{MH}^{+}$is measured by mass spectrometry.
direct current polarography Classical form of polarography, in which a linear voltage ramp is applied to the working electrode.
direct titration One in which the analyte is treated with titrant and the volume of titrant required for complete reaction is measured.
dispersion A measure of the ability of a monochromator to separate wavelengths differing by $\Delta \lambda$ through the angle $\Delta \phi$. The greater the dispersion, the greater the angle separating two closely spaced wavelengths. For a prism, dispersion refers to the rate of change of refractive index with wavelength, $d n / d \lambda$.
displacement titration An EDTA titration procedure in which analyte is treated with excess MgEDTA ${ }^{2-}$ to displace $\mathrm{Mg}^{2+}: \mathrm{M}^{n+}+$ MgEDTA ${ }^{2-} \rightleftharpoons$ MEDTA ${ }^{n-4}+\mathrm{Mg}^{2+}$. The liberated $\mathrm{Mg}^{2+}$ is then titrated with EDTA. This procedure is useful if there is no suitable indicator for direct titration of $\mathrm{M}^{n+}$.
disproportionation A reaction in which an element in one oxidation state gives products containing that element in both higher and lower oxidation states; e.g., $2 \mathrm{Cu}^{+} \rightleftharpoons \mathrm{Cu}^{2+}+\mathrm{Cu}(s)$.
distribution coefficient, $D$ For a solute partitioned between two phases, the distribution coefficient is the total concentration of all forms of solute in phase 2 divided by the total concentration in phase 1 .
Donnan equilibrium Ions of the same charge as those fixed on an ionexchange resin are repelled from the resin. Thus, anions do not readily penetrate a cation-exchange resin, and cations are repelled from an anionexchange resin.
dopant When small amounts of substance B are added to substance A, we call B a dopant and say that A is doped with B. Doping is done to alter the properties of A .
Doppler effect A molecule moving toward a source of radiation experiences a higher frequency than one moving away from the source
double-focusing mass spectrometer A spectrometer that uses electric and magnetic sectors in series to obtain high resolution.
double-junction electrode An electrode with inner and outer compartments designed to minimize contact between analyte solution and the contents of the inner electrode. The outer compartment serves as a salt bridge with ions that are chemically compatible with the analyte.
double layer See electric double layer.
drift Slow change in the response of an instrument due to various causes such as changes in electrical components with temperature, variation in power-line voltage to an instrument, and aging of components within instruments. Same as $1 / f$ noise or flicker noise.
dropping-mercury electrode One that delivers fresh drops of Hg to a polarographic cell.
dry ashing Oxidation of organic matter with $\mathrm{O}_{2}$ at high temperature to leave behind inorganic components for analysis.
dwell time In chromatography, time between mixing of solvents and when they reach the start of the column.
dwell volume In chromatography, volume between the point of mixing solvents and the start of the column.
dynamic range Range of analyte concentration over which a change in concentration gives a change in detector response.
dynode A metal surface that easily emits several electrons each time it is struck by one accelerated electron in a photomultiplier tube or an electron multiplier.
$E^{\circ} \quad$ Standard reduction potential.
$E^{\circ \prime} \quad$ Effective standard reduction potential at pH 7 (or at some other specified conditions).
EDTA (ethylenediaminetetraacetic acid)
$\left(\mathrm{HO}_{2} \mathrm{CCH}_{2}\right)_{2} \mathrm{NCH}_{2} \mathrm{CH}_{2} \mathrm{~N}\left(\mathrm{CH}_{2} \mathrm{CO}_{2} \mathrm{H}\right)_{2}$, the most widely used reagent for complexometric titrations. It forms 1:1 complexes with virtually all cations with a charge of 2 or more.
effective formation constant, $\boldsymbol{K}_{\mathrm{f}}^{\prime}$ See conditional formation constant. effervescence Rapid release of gas with bubbling and hissing.
efflorescence Property by which the outer surface or entire mass of a substance turns into powder from loss of water of crystallization.
effluent See eluate.
einstein A mole of photons. The symbol of this unit is the same as its name, einstein
electric charge, $q$ Quantity of electricity, measured in coulombs. electric discharge emission spectroscopy A technique in which atomization and excitation are stimulated by an electric arc, a spark, or microwave radiation.
electric double layer Region comprising the charged surface of an electrode or a particle plus the oppositely charged region of solution adjacent to the surface. Also called double layer.
electric potential, $E$ The electric potential (in volts) at a point is the energy (in joules) needed to bring one coulomb of positive charge from infinity to that point. The potential difference between two points is the energy needed to transport one coulomb of positive charge from the negative point to the positive point.
electroactive species Any species that can be oxidized or reduced at an electrode.
electrocapillary maximum Potential at which the net charge on a mercury drop from a dropping-mercury electrode is 0 (and the surface tension of the drop is maximal).

## electrochemical cell See galvanic cell.

electrochemical detector Liquid chromatography detector that measures current when an electroactive solute emerges from the column and passes over a working electrode held at a fixed potential with respect to a reference electrode. Also called amperometric detector.
electrochemistry Use of electrical measurements on a chemical system for analytical purposes. Also refers to use of electricity to drive a chemical reaction or use of a chemical reaction to produce electricity.
electrode An electrical conductor through which electrons flow into or out of chemical species involved in a redox reaction.
electroendosmosis See electroosmosis.
electrogravimetric analysis A technique in which the mass of an electrolytic deposit is used to quantify the analyte.
electrokinetic injection In capillary electrophoresis, the use of an electric field to inject sample into the capillary. Because different species have different mobilities, the injected sample does not have the same composition as the original sample.
electrolysis Process in which the passage of electric current causes a chemical reaction to occur.
electrolyte A substance that produces ions when dissolved.
electrolytic cell A cell in which a chemical reaction that would not otherwise occur is driven by a voltage applied between two electrodes. electromagnetic spectrum The whole range of electromagnetic radiation, including visible light, radio waves, X-rays, etc.
electron capture detector Gas chromatography detector that is particularly sensitive to compounds with halogen atoms, nitro groups, and other groups with high electron affinity. Makeup gas ( $\mathrm{N}_{2}$ or $5 \% \mathrm{CH}_{4}$ in Ar ) is ionized by $\beta$-rays from ${ }^{63} \mathrm{Ni}$ to liberate electrons that produce a small, steady current. High-electron-affinity analytes capture some of the electrons and reduce the detector current.
electronic balance A weighing device that uses an electromagnetic servomotor to balance the load on the pan. The mass of the load is proportional to the current needed to balance it.
electronic transition One in which an electron is promoted from one energy level to another.
electron ionization Interaction of analyte molecules (M) with highenergy electrons in the ion source of a mass spectrometer to give the cation radical, $\mathrm{M}^{+\cdot}$, and fragments derived from $\mathrm{M}^{+}$.
electron multiplier An ion detector that works like a photomultiplier tube. Cations striking a cathode liberate electrons. A series of dynodes multiplies the number of electrons by $\sim 10^{5}$ before they reach the anode. electron-transfer dissociation Breaking of a chemical bond by the exothermic transfer of an electron from one species to another. This process is used in mass spectral sequencing of polypeptides because it cleaves peptide bonds without breaking other bonds in the molecule. electroosmosis Bulk flow of fluid in a capillary tube induced by an electric field. Mobile ions in the diffuse part of the double layer at the wall of the capillary serve as the "pump." Also called electroendosmosis.
electroosmotic flow Uniform, pluglike flow of fluid in a capillary tube under the influence of an electric field. The greater the charge on the wall of the capillary, the greater the number of counterions in the double layer and the stronger the electroosmotic flow.
electroosmotic mobility, $\mu_{\mathrm{eo}}$ Constant of proportionality between the electroosmotic speed, $u_{\mathrm{eo}}$, of a fluid in a capillary and the applied electric field, $E: u_{\mathrm{eo}}=\mu_{\mathrm{eo}} E$. Also equal to the speed of a neutral species, $u_{\mathrm{neutral}}$, divided by the electric field, $E$. See also apparent mobility.
electroosmotic velocity Speed with which solvent flows through a capillary electrophoresis column. It is measured by adding a detectable neutral molecule to the sample. Electroosmotic velocity is the distance from injector to detector divided by the time required for the neutral molecule to reach the detector.
electropherogram A graph of detector response versus time for electrophoresis.
electrophoresis Migration of ions in solution in an electric field. Cations move toward the cathode and anions move toward the anode. Ions can be separated from one another by their differing rates of migration in a strong electric field.
electrophoretic mobility, $\mu_{\mathrm{ep}}$ Constant of proportionality between the electrophoretic speed, $u_{\mathrm{ep}}$, of an ion in solution and the applied electric field, $E: u_{\mathrm{ep}}=\mu_{\mathrm{ep}} E$. See also apparent mobility.
electrospray ionization A method for interfacing liquid chromatography to mass spectrometry. A high potential applied to the liquid at the column exit creates charged droplets in a fine aerosol. Gaseous ions are derived from ions that were already in the mobile phase on the column. It is common to observe protonated bases $\left(\mathrm{BH}^{+}\right)$, ionized acids ( $\mathrm{A}^{-}$), and complexes formed between analyte, M (which could be neutral or charged), and stable ions such as $\mathrm{NH}_{4}^{+}, \mathrm{Na}^{+}, \mathrm{HCO}_{2}^{-}$, or $\mathrm{CH}_{3} \mathrm{CO}_{2}^{-}$that were already in solution.
eluate What comes out of a chromatography column. Also called effluent. eluent Solvent applied to the beginning of a chromatography column.
eluent strength, $\varepsilon^{\circ}$ A measure of the ability of a solvent to elute solutes from a chromatography column. Eluent strength is a measure of the adsorption energy of a solvent on the stationary phase in chromatography. Also called solvent strength.
eluotropic series Ranks solvents according to their ability to displace solutes from the stationary phase in adsorption chromatography.
elution Process of passing a liquid or a gas through a chromatography column.
emission spectrum A graph of luminescence intensity versus luminescence wavelength (or frequency or wavenumber), obtained with a fixed excitation wavelength.
emissivity A quotient given by the radiant emission from a real object divided by the radiant emission of a blackbody at the same temperature.
emulsion A stable dispersion of immiscible liquids, which might be made by vigorous shaking. Homogenized milk is an emulsion of cream in an aqueous phase. Emulsions usually require an emulsifying agent (a surfactant) for stability. The emulsifying agent stabilizes the interface between the two phases by its affinity for both phases.
enantiomers Mirror image isomers that cannot be superimposed on each other. Also called optical isomers.
endothermic reaction One for which $\Delta H$ is positive; heat must be supplied to reactants for them to react.
end point Point in a titration at which there is a sudden change in a physical property, such as indicator color, pH , conductivity, or absorbance. Used as a measure of the equivalence point.
energy The product force $\times$ distance.
enthalpy change, $\Delta H$ The heat absorbed or released when a reaction occurs at constant pressure.
enthalpy of hydration Heat liberated when a gaseous species is transferred to water.
entropy A measure of the "disorder" of a substance.
enzyme A protein that catalyzes a chemical reaction.
equilibrium State in which the forward and reverse rates of all reactions are equal, so the concentrations of all species remain constant.
equilibrium constant, $K \quad$ For the reaction $a \mathrm{~A}+b \mathrm{~B} \rightleftharpoons c \mathrm{C}+d \mathrm{D}$,
$K=\mathcal{A}_{\mathrm{C}}^{c} \mathcal{A}_{\mathrm{D}}^{d} / \mathcal{A}_{\mathrm{A}}^{a} \mathcal{A}_{\mathrm{B}}^{b}$, where $\mathcal{A}_{i}$ is the activity of the $i$ th species.
equimolar mixture of compounds One that contains an equal number of moles of each compound.
equivalence point Point in a titration at which the quantity of titrant is exactly sufficient for stoichiometric reaction with the analyte.
equivalent For a redox reaction, the amount of reagent that can donate or accept one mole of electrons. For an acid-base reaction, the amount of reagent that can donate or accept one mole of protons.
equivalent weight The mass of substance containing one equivalent.
error bar Graphical depiction of the uncertainty in a measurement.
evanescent wave Light that penetrates the walls of an optical fiber or waveguide in which the light travels by total internal reflection.
evaporative light-scattering detector A liquid chromatography detector that makes a fine mist of eluate and evaporates solvent from the mist in a heated zone. The remaining particles of liquid or solid solute flow past a laser beam and are detected by their ability to scatter the light.
excitation spectrum A graph of luminescence (measured at a fixed wavelength) versus excitation frequency or wavelength. It closely corresponds to an absorption spectrum because the luminescence is generally proportional to the absorbance.
excited state Any state of an atom or a molecule having more than the minimum possible energy.
exitance, $M$ Power per unit area radiating from the surface of an object. exothermic reaction One for which $\Delta H$ is negative; heat is liberated when products are formed.
extended Debye-Hückel equation See Debye-Hückel equation.
extinction coefficient See molar absorptivity.
extra-column volume See dead volume.
extracted ion chromatogram Chromatogram made by collecting consecutive full-range mass spectra, but selecting just one value of $\mathrm{m} / \mathrm{z}$ for display. Most time is spent monitoring values of $m / z$ that will not be displayed. A selected ion chromatogram provides greater signal-to-noise ratio than an extracted ion chromatogram because all of the time is taken to monitor just one or a few values of $\mathrm{m} / \mathrm{z}$ in the selected ion chromatogram. extraction Process in which a solute is transferred from one phase to another. Analyte is sometimes removed from a sample by extraction into a solvent that dissolves the analyte.
extrapolation Estimation of a value that lies beyond the range of measured data.
$F$ test For two variances, $s_{1}^{2}$ and $s_{2}^{2}$ (with $s_{1}$ chosen to be the larger of the two), the statistic $F$ is defined as $F=s_{1}^{2} / s_{2}^{2}$. To decide whether $s_{1}$ is significantly greater than $s_{2}$, we compare $F$ with the critical values in a table based on a certain confidence level. If the calculated value of $F$ is greater than the value in the table, the difference is significant.
Fajans titration A precipitation titration in which the end point is signaled by adsorption of a colored indicator on the precipitate.
false negative A conclusion that the concentration of analyte is below a certain limit when, in fact, the concentration is above the limit.
false positive A conclusion that the concentration of analyte exceeds a certain limit when, in fact, the concentration is below the limit.
farad, $F$ Unit of electrical capacitance; 1 farad of capacitance will store 1 coulomb of charge in a potential difference of 1 volt.
faradaic current That component of current in an electrochemical cell due to oxidation and reduction reactions.
Faraday constant, $F$ The number of coulombs in a mole of elementary charges, approximately $9.6485 \times 10^{4} \mathrm{C} / \mathrm{mol}$ of charge.
Faraday cup A mass spectrometric ion detector in which each arriving cation is neutralized by an electron. The current required to neutralize the ions is proportional to the number of cations arriving at the Faraday cup.
Faraday's laws Two laws stating that the extent of an electrochemical reaction is directly proportional to the quantity of electricity that has passed through the cell. The mass of substance that reacts is proportional to its formula mass and inversely proportional to the number of electrons required in its half-reaction.
ferroelectric material A solid with a permanent electric polarization (dipole) in the absence of an external electric field. The polarization results from alignment of molecules within the solid.
Fick's first law of diffusion See diffusion coefficient.
field blank A blank sample exposed to the environment at the sample collection site and transported in the same manner as other samples between the lab and the field.
field effect transistor A semiconductor device in which the electric field between gate and base governs the flow of current between source and drain.
filtrate Liquid that passes through a filter.
flame ionization detector A gas chromatography detector in which solute is burned in an $\mathrm{H}_{2}$-air flame to produce $\mathrm{CHO}^{+}$ions. The current carried through the flame by these ions is proportional to the concentration of susceptible species in the eluate.
flame photometer A device that uses flame atomic emission and a filter photometer to quantify $\mathrm{Li}, \mathrm{Na}, \mathrm{K}$, and Ca in liquid samples.
flame photometric detector Gas chromatography detector that measures optical emission from $\mathrm{S}, \mathrm{P}, \mathrm{Pb}, \mathrm{Sn}$, or other elements in a $\mathrm{H}_{2}-\mathrm{O}_{2}$ flame. flicker noise See drift.
flow adaptor An adjustable plungerlike device that may be used on either side of a chromatographic bed to support the bed and to minimize the dead space through which liquid can flow outside of the column bed.
flow injection analysis Analytical technique in which sample is injected into flowing liquid carrier containing a reagent that reacts with the analyte. Additional reagents might be added further downstream. As sample flows from injector to detector, the sample zone broadens and reacts with reagent to form a product to which the detector responds.
fluorescence Process in which a molecule emits a photon $10^{-8}$ to $10^{-4} \mathrm{~s}$ after absorbing a photon. It results from a transition between states of the same spin multiplicity (e.g., singlet $\rightarrow$ singlet).
fluorescence detector Liquid chromatography detector that uses a strong light or laser to irradiate eluate emerging from a column and detects radiant emission from fluorescent solutes.
flux In sample preparation, flux is the agent used as the medium for a fusion. In transport phenomena, flux is the quantity of whatever you like crossing each unit area in one unit of time. For example, the flux of diffusing molecules could be $\mathrm{mol} /\left(\mathrm{m}^{2} \cdot \mathrm{~s}\right)$. Heat flux would be $\mathrm{J} /\left(\mathrm{m}^{2} \cdot \mathrm{~s}\right)$.
force The product mass $\times$ acceleration.
formal concentration, $F$ The molarity of a substance if it did not change its chemical form on being dissolved. It represents the total number of moles of substance dissolved in a liter of solution, regardless of any reactions that take place when the solute is dissolved. Also called analytical concentration or formality.
formality, F See formal concentration.
formal potential Potential of a half-reaction (relative to a standard hydrogen electrode) when the formal concentrations of reactants and products are unity. Any other conditions (such as pH , ionic strength, and concentrations of ligands) also must be specified.
formation constant, $K_{\mathrm{f}}$ Equilibrium constant for the reaction of a metal with its ligands to form a metal-ligand complex. Also called stability constant. See also conditional formation constant.
formula mass, FM The mass containing one mole of the indicated chemical formula of a substance. For example, the formula mass of $\mathrm{CuSO}_{4} \cdot 5 \mathrm{H}_{2} \mathrm{O}$ is the sum of the masses of copper, sulfate, and five water molecules.
fortification Same as a spike-a deliberate addition of analyte to a sample. Fourier analysis Process of decomposing a function into an infinite series of sine and cosine terms. Because each term represents a certain frequency or wavelength, Fourier analysis decomposes a function into its component frequencies or wavelengths.
Fourier series Infinite sum of sine and cosine terms that add to give a particular function in a particular interval.
fraction of association, $\alpha$ For the reaction of a base (B) with $\mathrm{H}_{2} \mathrm{O}$, the fraction of base in the form $\mathrm{BH}^{+}$.
fraction of dissociation, $\alpha$ For the dissociation of an acid (HA), the fraction of acid in the form $\mathrm{A}^{-}$.
free energy See Gibbs free energy.
frequency, $v \quad$ The number of cycles per unit time for a repetitive event.
friction coefficient A molecule migrating through a solution is retarded by a force that is proportional to its speed. The constant of proportionality is the friction coefficient.
fugacity The activity of a gas.
fugacity coefficient Activity coefficient for a gas.
fused-core particle See superficially porous particle.
fusion Process in which an otherwise insoluble substance is dissolved in a molten salt such as $\mathrm{Na}_{2} \mathrm{CO}_{3}, \mathrm{Na}_{2} \mathrm{O}_{2}$, or KOH . Once the substance has dissolved, the melt is cooled, dissolved in aqueous solution, and analyzed.
galvanic cell One that produces electricity by means of a spontaneous chemical reaction. Also called a voltaic cell.
gas chromatography A form of chromatography in which the mobile phase is a gas.
gathering A process in which a trace constituent of a solution is intentionally coprecipitated with a major constituent.
Gaussian distribution Theoretical bell-shaped distribution of measurements when all error is random. The center of the curve is the mean, $\mu$, and the width is characterized by the standard deviation, $\sigma$. A normalized Gaussian distribution, also called the normal error curve, has an area of unity and is given by

$$
y=\frac{1}{\sigma \sqrt{2 \pi}} \mathrm{e}^{-(x-\mu)^{2} / 2 \sigma^{2}}
$$

Gaussian noise See white noise.
gel Chromatographic stationary phase particles, such as Sephadex or polyacrylamide, which are soft and pliable.
gel filtration chromatography See molecular exclusion chromatography. gel permeation chromatography See molecular exclusion chromatography. geometric mean For a series of $n$ measurements with the values $x_{i}$, geometric mean $=\sqrt[n]{x_{1} x_{2} \ldots x_{n}}$.
Gibbs free energy, $G$ The change in Gibbs free energy, $\Delta G$, for any process at constant temperature is related to the change in enthalpy, $\Delta H$, and entropy, $\Delta S$, by the equation $\Delta G=\Delta H-T \Delta S$, where $T$ is temperature in kelvins. A process is spontaneous (thermodynamically favorable) if $\Delta G$ is negative.
glass electrode One that has a thin glass membrane across which a pH dependent voltage develops. The voltage (and hence pH ) is measured by a pair of reference electrodes on either side of the membrane.
glassy carbon electrode An inert carbon electrode, impermeable to gas, and especially well suited as an anode. The isotropic structure (same in all directions) is thought to consist of tangled ribbons of graphitelike sheets, with some cross-linking.
globar An infrared radiation source made of a ceramic such as silicon carbide heated by passage of electricity.
Gooch fillter crucible A short, cup-shaped container with holes at the bottom, used for filtration and ignition of precipitates. For ignition, the crucible is made of porcelain or platinum and lined with a mat of ceramic fibers to retain the precipitate. For precipitates that do not need ignition, the crucible is made of glass and has a porous glass disk instead of holes at the bottom.
gradient elution Chromatography in which the composition of the mobile phase is progressively changed to increase the eluent strength of the solvent.
graduated cylinder A tube with volume calibrations along its length. Also called graduate.
gram-atom The amount of an element containing Avogadro's number of atoms; it is the same as a mole of the element.
Gran plot A graph such as the plot of $V_{\mathrm{b}} \cdot 10^{-\mathrm{pH}}$ versus $V_{\mathrm{b}}$ used to find the end point of a titration. $V_{\mathrm{b}}$ is the volume of base (titrant) added to an acid being titrated. The slope of the linear portion of the graph is related to the dissociation constant of the acid.
graphite furnace A graphite tube that can be heated electrically to about 2500 K to decompose and atomize a sample for atomic spectroscopy.
grating Either a reflective or a transmitting surface etched with closely spaced lines; used to disperse light into its component wavelengths. gravimetric analysis Any analytical method that relies on measuring the mass of a substance (such as a precipitate) to complete the analysis. gravimetric titration A titration in which the mass of titrant is measured, instead of the volume. Titrant concentration is conveniently
expressed as mol reagent/kg titrant solution. Gravimetric titrations can be more accurate and precise than volumetric titrations.
green chemistry Principles intended to change our behavior in a manner that will help sustain the habitability of Earth. Green chemistry seeks to design chemical products and processes to reduce the use of resources and energy and the generation of hazardous waste.
gross sample See bulk sample.
ground state State of an atom or a molecule with the minimum possible energy.
Grubbs test Statistical test used to decide whether to discard a datum that appears discrepant.
guard column In high-performance liquid chromatography, a short column packed with the same material as the main column and placed between the injector and the main column. The guard column removes impurities that might irreversibly bind to the main column and degrade it. Also called precolumn. In gas chromatography, the guard column is a length of empty, silanized capillary ahead of the chromatography column. Nonvolatile residues accumulate in the guard column.
half-cell Part of an electrochemical cell in which half of an electrochemical reaction (either the oxidation or the reduction reaction) occurs.
half-height Half of the maximum amplitude of a signal.
half-reaction Any redox reaction can be conceptually broken into two half-reactions, one involving only oxidation and one involving only reduction.
half-wave potential Potential at the midpoint of the rise in the current of a polarographic wave.
half-width Width of a signal at its half-height.
Hall-Héroult process Electrolytic production of aluminum metal from a molten solution of $\mathrm{Al}_{2} \mathrm{O}_{3}$ and cryolite $\left(\mathrm{Na}_{3} \mathrm{AlF}_{6}\right)$.
Hammett acidity function The acidity of a solvent that protonates the weak base, B , is called the Hammett acidity function, $H_{0}$, and is given by

$$
H_{0}=\mathrm{p} K_{\mathrm{a}}\left(\text { for } \mathrm{BH}^{+}\right)+\log \frac{[\mathrm{B}]}{\left[\mathrm{BH}^{+}\right]}
$$

For dilute aqueous solutions, $H_{0}$ approaches pH .
hanging-drop electrode One with a stationary drop of Hg that is used for stripping analysis.
hardness Total concentration of alkaline earth ions in natural water expressed as $\mathrm{mg} \mathrm{CaCO}_{3}$ per liter of water as if all of the alkaline earths present were $\mathrm{CaCO}_{3}$. See also permanent hardness and temporary hardness.
Heisenberg uncertainty principle Certain pairs of physical quantities cannot be known simultaneously with arbitrary accuracy. If $\delta E$ is the uncertainty in the energy difference between two atomic states and $\delta t$ is the lifetime of the excited state, their product cannot be known more accurately than $\delta E \delta t \gtrsim h /(4 \pi)$, where $h$ is Planck's constant. A similar relation holds between the position and the momentum of a particle. If position is known very accurately, then the uncertainty in momentum is large, and vice versa.
Henderson-Hasselbalch equation A logarithmic rearranged form of the acid dissociation equilibrium equation:

$$
\mathrm{pH}=\mathrm{p} K_{\mathrm{a}}+\log \frac{\left[\mathrm{A}^{-}\right]}{[\mathrm{HA}]}
$$

Henry's law The partial pressure of a gas in equilibrium with gas dissolved in a solution is proportional to the concentration of dissolved gas: $P=k$ [dissolved gas]. The constant $k$ is called the Henry's law constant. It is a function of the gas, the liquid, and the temperature. hertz, Hz Unit of frequency, $\mathrm{s}^{-1}$, also called reciprocal seconds. heterogeneous Not uniform throughout.
HETP, height equivalent to a theoretical plate The length of a chromatography column divided by the number of theoretical plates in the column.
hexadentate ligand One that binds to a metal atom through six ligand atoms.
high-performance liquid chromatography, HPLC A chromatographic technique using very small stationary phase particles and high pressure to force solvent through the column.
HILIIC See hydrophilic interaction chromatography.
hole Absence of an electron in a semiconductor. When a neighboring electron moves into the hole, a new hole is created where the electron came from. By this means, a hole can move through a solid just as an electron can move through a solid.
hollow-cathode lamp One that emits sharp atomic lines characteristic of the element from which the cathode is made.
homogeneous Having the same composition everywhere.
homogeneous precipitation A technique in which a precipitating agent is generated slowly by a reaction in homogeneous solution, effecting a slow crystallization instead of a rapid precipitation of product.
hydrated radius Effective size of an ion or a molecule plus its associated water molecules in solution.
hydrodynamic flow Motion of fluid through a tube, driven by a pressure difference. Hydrodynamic flow is usually laminar, in which there is a parabolic profile of velocity vectors, with the highest velocity at the center of the stream and zero velocity at the walls.
hydrodynamic injection In capillary electrophoresis, the use of a pressure difference between the two ends of the capillary to inject sample into the capillary. Injection is achieved by applying pressure on one end, by applying suction on one end, or by siphoning.
hydrodynamic radius Effective radius of a molecule migrating through a fluid. It is defined by the Stokes equation, in which the friction coefficient is $6 \pi \eta r$, where $\eta$ is the viscosity of the fluid and $r$ is the hydrodynamic radius of the molecule.
hydrolysis "Reaction with water." The reaction $\mathrm{B}+\mathrm{H}_{2} \mathrm{O} \rightleftharpoons \mathrm{BH}^{+}+\mathrm{OH}^{-}$ is often called hydrolysis of a base.
hydronium ion, $\mathrm{H}_{3} \mathrm{O}^{+}$What we really mean when we write $\mathrm{H}^{+}(a q)$. hydrophilic interaction chromatography Chromatographic separation of polar solutes with a hydrophilic stationary phase using mixed organicaqueous eluent. Eluent strength increases with decreasing organic solvent. Commonly called HILIC.
hydrophilic substance One that is soluble in water or attracts water to its surface.
hydrophobic interaction chromatography Chromatographic separation based on the interaction of a hydrophobic solute with a hydrophobic stationary phase.
hydrophobic substance One that is insoluble in water or repels water from its surface.
hygroscopic substance One that readily picks up water from the atmosphere.
ignition The heating to high temperature of some gravimetric precipitates to convert them into a known, constant composition that can be weighed.
immiscible liquids Two liquids that do not form a single phase when mixed together.
immunoassay An analytical measurement using antibodies.
inclusion An impurity that occupies lattice sites in a crystal.
indeterminate error See random error.
indicator A compound having a physical property (usually color) that changes abruptly near the equivalence point of a chemical reaction. indicator electrode One that develops a potential whose magnitude depends on the activity of one or more species in contact with the electrode.
indicator error Difference between the indicator end point of a titration and the true equivalence point.
indirect detection Chromatographic detection based on the absence of signal from a background species. For example, in ion chromatography, a light-absorbing ionic species can be added to the eluent. Nonabsorbing analyte replaces an equivalent amount of light-absorbing eluent when analyte emerges from the column, thereby decreasing the absorbance of eluate.
indirect titration One that is used when the analyte cannot be directly titrated. For example, analyte A may be precipitated with excess reagent R. The product is filtered, and the excess R washed away. Then AR is dissolved in a new solution, and R can be titrated.
inductively coupled plasma A high-temperature plasma that derives its energy from an oscillating radio-frequency field. It is used to atomize a sample for atomic emission spectroscopy.
inflection point One at which the derivative of the slope is $0: d^{2} y / d x^{2}=0$. That is, the slope reaches a maximum or minimum value.
injection precision See instrument precision.
inner filter effect See self-absorption.
inorganic carbon In a natural water or industrial effluent sample, the quantity of dissolved carbonate and bicarbonate.
instrument precision Reproducibility observed when the same quantity of one sample is repeatedly introduced into an instrument. Also called injection precision.
intensity Power per unit area of a beam of electromagnetic radiation $\left(\mathrm{W} / \mathrm{m}^{2}\right)$. Also called radiant power or irradiance.
intercalation Binding of a flat, aromatic molecule between the flat, hydrogen-bonded base pairs in DNA or RNA.
intercept For a straight line whose equation is $y=m x+b, b$ is the intercept. It is the value of $y$ when $x=0$.
interference A phenomenon in which the presence of one substance changes the response in the analysis of another substance.
interference filter A filter that transmits a particular band of wavelengths and reflects others. Transmitted light interferes constructively within the filter, whereas light that is reflected interferes destructively. interferogram A graph of light intensity versus retardation (or time) for the radiation emerging from an interferometer.
interferometer A device with a beamsplitter, fixed mirror, and moving mirror that breaks input light into two beams that interfere with each other. The degree of interference depends on the difference in pathlength of the two beams.
interlaboratory precision The reproducibility observed when aliquots of the same sample are analyzed by different people in different laboratories. intermediate precision Precision observed when an assay is performed by different people on different instruments on different days in the same lab. Also called ruggedness.
internal conversion A radiationless, isoenergetic, electronic transition between states of the same electron-spin multiplicity.
internal standard A known quantity of a compound other than analyte added to a solution containing an unknown quantity of analyte. The concentration of analyte is then measured relative to that of the internal standard.
interpolation Estimation of the value of a quantity that lies between two known values.
intersystem crossing A radiationless, isoenergetic, electronic transition between states of different electron-spin multiplicity.
intra-assay precision Precision observed when analyzing aliquots of a homogeneous material several times by one person on one day with the same equipment.
iodimetry Use of triiodide (or iodine) as a titrant.
iodometry A technique in which an oxidant is treated with $\mathrm{I}^{-}$to produce $\mathrm{I}_{3}^{-}$, which is then titrated (usually with thiosulfate).
ion chromatography High-performance liquid chromatography ionexchange separation of ions. See also suppressed-ion chromatography and single-column ion chromatography.
ion-exchange chromatography A technique in which solute ions are retained by oppositely charged sites in the stationary phase.
ion-exchange equilibrium An equilibrium involving replacement of a cation by a different cation or replacement of an anion by a different anion. Usually the ions in these reactions are bound by electrostatic forces. ion-exchange membrane Membrane containing covalently bound charged groups. Oppositely charged ions in solution penetrate the membrane freely, but similarly charged ions tend to be excluded from the membrane by the bound charges.
ion-exclusion chromatography A technique in which electrolytes are separated from nonelectrolytes by an ion-exchange resin.
ionic atmosphere The region of solution around an ion or a charged particle. It contains an excess of oppositely charged ions.
ionic liquid A salt that melts near or below room temperature and has a large temperature range over which it remains liquid.
ionic radius Effective size of an ion in a crystal.
ionic strength, $\mu$ Given by $\mu=\frac{1}{2} \sum_{i} c_{i} z_{i}^{2}$, where $c_{i}$ is the concentration of the $i$ th ion in solution and $z_{i}$ is the charge on that ion. The sum extends over all ions in solution, including the ions whose activity coefficients are being calculated.
ionization interference In atomic spectroscopy, a lowering of signal intensity as a result of ionization of analyte atoms.
ionization suppressor An element used in atomic spectroscopy to decrease the extent of ionization of the analyte.
ion mobility spectrometer An instrument that measures the drift time of gaseous ions migrating in an electric field against a flow of gas. The "spectrum" of detector current versus drift time is really an electropherogram of a gas.
ionophore A molecule with a hydrophobic outside and a polar inside that can engulf an ion and carry the ion through a hydrophobic phase (such as a cell membrane).
ion pair A closely associated anion and cation, held together by electrostatic attraction. In solvents less polar than water, ions are usually found as ion pairs.
ion-pair chromatography Separation of ions on reversed-phase highperformance liquid chromatography column by adding to the eluent a hydrophobic counterion that pairs with analyte ion and is attracted to stationary phase.
ion-selective electrode One whose potential is selectively dependent on the concentration of one particular ion in solution.
ion spray See electrospray ionization.
irradiance Power per unit area $\left(\mathrm{W} / \mathrm{m}^{2}\right)$ of a beam of electromagnetic radiation. Also called radiant power or intensity.
isobaric interference In mass spectrometry, overlap of two peaks with nearly the same mass. For example, ${ }^{41} \mathrm{~K}^{+}$and ${ }^{40} \mathrm{ArH}^{+}$differ by 0.01 atomic mass unit and appear as a single peak unless the spectrometer resolution is great enough to separate them.
isocratic elution Chromatography using a single solvent for the mobile phase.
isoelectric buffer A neutral, polyprotic acid occasionally used as a lowconductivity "buffer" for capillary zone electrophoresis. For example, a solution of pure aspartic acid ( $\mathrm{p} K_{1}=1.99, \mathrm{p} K_{2}=3.90, \mathrm{p} K_{3}=10.00$ ) has $\mathrm{pH}=\frac{1}{2}\left(\mathrm{p} K_{1}+\mathrm{p} K_{2}\right)=2.94$. Calling pure aspartic acid a "buffer" is an oxymoron, because the buffer capacity is a minimum at pH 2.94 and increases to maxima at pH 1.99 and 3.90 . However, as the pH drifts away from 2.94, the solution gains significant buffer capacity. When electrophoresis is conducted in a background electrolyte of aspartic acid, the pH stays near 2.94 and conductivity remains very low, permitting a high electric field to be used, thus enabling rapid separations.
isoelectric focusing A technique in which a sample containing polyprotic molecules is subjected to a strong electric field in a medium with a pH gradient. Each species migrates until it reaches the region of its isoelectric pH . In that region, the molecule has no net charge, ceases to migrate, and remains focused in a narrow band.
isoelectric point That pH at which the average charge of a polyprotic species is 0 . Same as isoelectric $p H$.
isoionic point The pH of a pure solution of a neutral, polyprotic molecule. The only ions present are $\mathrm{H}^{+}, \mathrm{OH}^{-}$, and those derived from the polyprotic species. Same as isoionic pH .
isosbestic point A wavelength at which the absorbance spectra of two species cross each other. The appearance of isosbestic points in a solution in which a chemical reaction is occurring is evidence that there are only two components present, with a constant total concentration.
isotherm Graph of $C_{\mathrm{s}}$ (mass transfer in stationary phase) versus $C_{\mathrm{m}}$ (mass transfer in the mobile phase) at a given temperature.
isotope ratio mass spectrometry A mass spectrometric technique designed to provide accurate measurements of the ratio of different ions of a selected element. The instrument has one detector dedicated to each isotope.

## Job's method See method of continuous variation.

Johnson noise A form of white noise arising from random fluctuations of electrons in an electronic device. Lowering the temperature lowers the Johnson noise. Also called Nyquist noise.
Jones reductor A column packed with zinc amalgam. An oxidized analyte is passed through to reduce the analyte, which is then titrated with an oxidizing agent.
joule, J SI unit of energy. One joule is expended when a force of 1 N acts over a distance of 1 m . This energy is equivalent to that required to raise 102 g (about $\frac{1}{4}$ pound) by 1 m at sea level.
Joule heating Heat produced in an electric circuit by the flow of electricity. Power ( $\mathrm{J} / \mathrm{s}$ ) $=I^{2} R$, where $I$ is the current (A) and $R$ is the resistance (ohms).
junction potential An electric potential that exists at the junction (interface) between two different electrolyte solutions or substances. It arises in solutions as a result of unequal rates of diffusion of different ions.

Karl Fischer titration A sensitive technique for measuring traces of water, based on the reaction of $\mathrm{H}_{2} \mathrm{O}$ with an amine, $\mathrm{I}_{2}, \mathrm{SO}_{2}$, and an alcohol. kelvin, $K \quad$ Absolute unit of temperature defined such that the temperature of water at its triple point (where water, ice, and water vapor are at equilibrium) is 273.16 K and the absolute zero of temperature is 0 K .
kilogram, kg SI unit of mass equal to the mass of a particular $\mathrm{Pt}-\mathrm{Ir}$ cylinder kept at the International Bureau of Weights and Measures, Sèvres, France.
Kjeldahl nitrogen analysis Procedure for the analysis of nitrogen in organic compounds. The compound is digested with boiling $\mathrm{H}_{2} \mathrm{SO}_{4}$ to convert nitrogen into $\mathrm{NH}_{4}^{+}$, which is treated with base and distilled as $\mathrm{NH}_{3}$ into a standard acid solution. The moles of acid consumed equal the moles of $\mathrm{NH}_{3}$ liberated from the compound.
Kovats index See retention index.
laboratory sample Portion of bulk sample taken to the lab for analysis. Must have the same composition as the bulk sample.
laminar flow Motion with a parabolic velocity profile of fluid through a tube. Motion is fastest at the center and zero at the walls.
laser Source of intense, coherent monochromatic radiation. Light is produced by stimulated emission of radiation from a medium in which an excited state has been pumped to a high population. Coherence means that all light exiting the laser has the same phase.
laser-induced breakdown spectroscopy Semiquantitative measurement of elements in a surface by vaporizing a small patch with a short laser pulse and measuring atomic emission from the plasma above the surface. Latimer diagram One that shows the reduction potentials connecting a series of species containing an element in different oxidation states.
law of mass action For the chemical reaction $a \mathrm{~A}+b \mathrm{~B} \rightleftharpoons c \mathrm{C}+d \mathrm{D}$, the condition at equilibrium is $K=\mathcal{A}_{\mathrm{C}}^{c} \mathcal{A}_{\mathrm{D}}^{d} / \mathcal{A}_{\mathrm{A}}^{a} \mathcal{A}_{\mathrm{B}}^{b}$, where $\mathrm{A}_{i}$ is the activity of the $i$ th species. The law is usually used in approximate form, in which activities are replaced by concentrations.
least squares Process of fitting a mathematical function to a set of measured points by minimizing the sum of the squares of the distances from the points to the curve.
Le Châtelier's principle If a system at equilibrium is disturbed, the direction in which it proceeds back to equilibrium is such that the disturbance is partly offset.
leveling effect The strongest acid that can exist in solution is the protonated form of the solvent. A stronger acid will donate its proton to the solvent and be leveled to the acid strength of the protonated solvent. Similarly, the strongest base that can exist in a solvent is the deprotonated form of the solvent.

Lewis acid One that can form a chemical bond by sharing a pair of electrons donated by another species.
Lewis base One that can form a chemical bond by sharing a pair of its electrons with another species.
ligand An atom or a group attached to a central atom in a molecule. The term is often used to mean any group attached to anything else of interest.
limiting current In a polarographic experiment, the current that is reached at the plateau of a polarographic wave. See also diffusion current. limit of quantitation The minimum signal that can be measured "accurately," often taken as the mean signal for blanks plus 10 times the standard deviation of a low-concentration sample.
linear flow rate In chromatography, the distance per unit time traveled by the mobile phase.
linear interpolation A form of interpolation in which the variation in some quantity is assumed to be linear. For example, to find the value of $b$ when $a=32.4$ in the following table,

$$
\begin{array}{llcl}
a: & 32 & 32.4 & 33 \\
b: & 12.85 & x & 17.96
\end{array}
$$

you can set up the proportion

$$
\frac{32.4-32}{33-32}=\frac{x-12.85}{17.96-12.85}
$$

which gives $x=14.89$.
linear quadrupole ion-trap mass spectrometer An instrument that separates gaseous ions by trapping them in stable trajectories inside a linear quadrupole by use of radio-frequency fields. Ions can be expelled from the trap in order of increasing $m / z$ for mass spectrometry.
linearity A measure of how well data in a graph follow a straight line, showing that response is proportional to the quantity of analyte.
linear range Concentration range over which the change in detector response is proportional to the change in analyte concentration.
linear response The case in which the analytical signal is directly proportional to the concentration of analyte.
linear-solvent-strength model In liquid chromatography, a model in which the retention factor $k$ is related to mobile phase composition $\Phi$ by the empirical equation, $\log k \approx \log k_{\mathrm{w}}-S \Phi$, where $\log k_{\mathrm{w}}$ and $S$ are constants.
linear voltage ramp The linearly increasing potential that is applied to the working electrode in polarography.
line noise Noise concentrated at discrete frequencies that come from sources external to an intended measuring system. Common sources include radiation emanating from the $60-\mathrm{Hz}$ power line, vacuum-pump motors, and radio-frequency devices. Same as whistle noise.
lipid bilayer Double layer formed by molecules containing hydrophilic headgroup and hydrophobic tail. The tails of the two layers associate with each other and the headgroups face the aqueous solvent.
liquid-based ion-selective electrode One that has a hydrophobic membrane separating an inner reference electrode from the analyte solution. The membrane is saturated with a liquid ion exchanger dissolved in a nonpolar solvent. The ion-exchange equilibrium of analyte between the liquid ion exchanger and the aqueous solution gives rise to the electrode potential.
liquid chromatography A form of chromatography in which the mobile phase is a liquid.
liquid-liquid extraction Extraction of a solute from one liquid phase to another liquid phase.
liter, $L$ Common unit of volume equal to exactly $1000 \mathrm{~cm}^{3}$.
logarithm The base 10 logarithm of $n$ is $a$ if $10^{a}=n$ (which means $\log n=$ a). The natural logarithm of $n$ is $a$ if $\mathrm{e}^{a}=n$ (which means $\ln n=a$ ). The number $\mathrm{e}(=2.71828 \ldots)$ is called the base of the natural logarithm.
longitudinal diffusion Diffusion of solute molecules parallel to the direction of travel through a chromatography column.
lot Entire material that is to be analyzed. Examples are a bottle of reagent, a lake, or a truckload of gravel.
lower limit of detection See detection limit.
lower limit of quantitation Smallest amount of analyte that can be measured with reasonable accuracy. Usually taken as 10 times the standard deviation of a low-concentration sample. Also called quantitation limit. luminescence Any emission of light by a molecule.
L'vov platform Platform on which sample is placed in a graphite-tube furnace for atomic spectroscopy to prevent sample vaporization before the walls reach constant temperature.
magnetic sector mass spectrometer A device that separates gaseous ions that have the same kinetic energy by passing them through a magnetic field perpendicular to their velocity. Trajectories of ions with a certain mass-to-charge ratio are bent exactly enough to reach the detector. Other ions are deflected too much or too little.
makeup gas Gas added to the exit stream from a gas chromatography column for the purpose of changing flow rate or gas composition to optimize detection of analyte.

## MALDI See matrix-assisted laser desorption/ionization.

mantissa The part of a logarithm to the right of the decimal point.
masking Process of adding a chemical substance (a masking agent) to a sample to prevent one or more components from interfering in a chemical analysis.
masking agent A reagent that selectively reacts with one (or more) component(s) of a solution to prevent the component(s) from interfering in a chemical analysis.
mass balance A statement that the sum of the moles of any element in all of its forms in a solution must equal the moles of that element delivered to the solution.
mass chromatogram See selected ion chromatogram.
mass spectrometer An instrument that converts gaseous molecules into ions, accelerates them in an electric field, separates them according to their mass-to-charge ratio, and detects the amount of each species.
mass spectrometry A technique in which gaseous molecules are ionized, accelerated by an electric field, and then separated according to their mass.
mass spectrometry-mass spectrometry, MS-MS See selected reaction monitoring.
mass spectrum In mass spectrometry, a graph showing the relative abundance of each ion as a function of its mass-to-charge ratio.
mass titration One in which the mass of titrant, instead of the volume, is measured.
mass-to-charge ratio, $\mathrm{m} / \mathrm{z}$ The mass of an ion in daltons divided by the charge of the ion measured in multiples of the elementary charge. For ${ }^{23} \mathrm{Na}^{+}$, for example, $m / z \approx 23 / 1=23$.
matrix The medium containing analyte. For many analyses, it is important that standards be prepared in the same matrix as the unknown.
matrix-assisted laser desorption/ionization, MALDI A gentle technique for introducing predominantly singly charged, intact macromolecular ions into the gas phase. An intimate solid mixture of analyte plus a large excess of a small, ultraviolet-absorbing molecule is irradiated by a pulse from an ultraviolet laser. The small molecule (the matrix) absorbs the radiation, becomes ionized, evaporates, and expands in a supersonic jet that carries analyte into the gas phase. Matrix ions apparently transfer charge to the analyte.
matrix effect A change in analytical signal caused by anything in the sample other than analyte.
matrix modifier Substance added to sample for atomic spectroscopy to make the matrix more volatile or the analyte less volatile so that the matrix evaporates before analyte does.
mean The sum of a set of results divided by the number of values in the set. Also called average.
mean activity coefficient For the salt (cation) $)_{m}(\text { anion })_{n}$, the mean activity coefficient, $\gamma_{ \pm}$, is related to the individual ion activity coefficients ( $\gamma_{+}$ and $\gamma_{-}$) by the equation $\gamma_{ \pm}=\left(\gamma_{+}^{m} \gamma_{-}^{n}\right)^{1 /(m+n)}$.
mechanical balance A balance having a beam that pivots on a fulcrum. Standard masses are used to measure the mass of an unknown.
median For a set of data, that value above and below which there are equal numbers of data.
mediator In electrolysis, a molecule that carries electrons between the electrode and the intended analyte. Used when the analyte cannot react directly at the electrode or when analyte concentration is so low that other reagents react instead. Mediator is recycled indefinitely by oxidation or reduction at the counter electrode.
memory effect Interference in a later analysis caused by substances retained in the instrument or apparatus from an earlier analysis.
meniscus Curved surface of a liquid.
mesh size The number of openings per linear inch in a standard screen used to sort particles. A 100/200 mesh particle passes through a 100 mesh screen but not through a 200 mesh screen.
metal ion buffer Consists of a metal-ligand complex plus excess free ligand. The two serve to fix the concentration of free metal ion through the reaction $\mathrm{M}+n \mathrm{~L} \rightleftharpoons \mathrm{ML}_{n}$.
metal ion indicator A compound that changes color when it binds to a metal ion.
meter, $m$ SI unit of length defined as the distance that light travels in a vacuum during $\frac{1}{299792458}$ of a second.
method blank A sample without deliberately added analyte. The method blank is taken through all steps of a chemical analysis, including sample preparation.
method of continuous variation Procedure for finding the stoichiometry of a complex by preparing a series of solutions with different metal-to-ligand ratios. The ratio at which the extreme response (such as spectrophotometric absorbance) occurs corresponds to the stoichiometry of the complex. Also called Job's method.
method of least squares Process of fitting a mathematical function to a set of measured points by minimizing the sum of the squares of the distances from the points to the curve.
method validation Process of proving that an analytical method is acceptable for its intended purpose.
micellar electrokinetic capillary chromatography A form of capillary electrophoresis in which a micelle-forming surfactant is present. Migration times of solutes depend on the fraction of time spent in the micelles.
micelle An aggregate of molecules with ionic headgroups and long, nonpolar tails. The inside of the micelle resembles hydrocarbon solvent, whereas the outside interacts strongly with aqueous solution.
microelectrode An electrode with a diameter on the order of $10 \mu \mathrm{~m}$ (or less). Microelectrodes fit into small places, such as living cells. Their small current gives rise to little ohmic loss, so they can be used in resistive, nonaqueous media. Small double-layer capacitance allows their voltage to be changed rapidly, permitting short-lived species to be studied.
microequilibrium constant An equilibrium constant that describes the reaction of a chemically distinct site in a molecule. For example, a base may be protonated at two distinct sites, each of which has a different equilibrium constant.
microporous particles Chromatographic stationary phase consisting of porous particles $1.5-10 \mu \mathrm{~m}$ in diameter, with high efficiency and high capacity for solute.
migration Electrostatically induced motion of ions in a solution under the influence of an electric field.
miscible liquids Two liquids that form a single phase when mixed in any ratio.
mobile phase In chromatography, the phase that travels through the column.
mobility The terminal velocity that an ion reaches in a field of $1 \mathrm{~V} / \mathrm{m}$. Velocity $=$ mobility $\times$ field. See also apparent mobility and electrophoretic mobility.
modulation amplitude In polarography, the magnitude of the voltage pulse applied to the working electrode.
Mohr titration Argentometric titration conducted in the presence of chromate. The end point is signaled by the formation of red $\mathrm{Ag}_{2} \mathrm{CrO}_{4}(s)$.
molality, $m \quad$ A measure of concentration equal to the number of moles of solute per kilogram of solvent.
molar absorptivity, $\varepsilon$ Constant of proportionality in Beer's law: $A=\varepsilon b c$, where $A$ is absorbance, $b$ is pathlength, and $c$ is the molarity of the absorbing species. Also called extinction coefficient.
molarity, M A measure of concentration equal to the number of moles of solute per liter of solution.
mole, mol SI unit for the amount of substance that contains as many molecules as there are atoms in 12 g of ${ }^{12} \mathrm{C}$. There are approximately $6.022 \times 10^{23}$ molecules per mole.
molecular exclusion chromatography A technique in which the stationary phase has a porous structure into which small molecules can enter but large molecules cannot. Molecules are separated by size, with larger molecules moving faster than smaller ones. Also called size exclusion, gel filtration, or gel permeation chromatography.
molecular ion, $\mathbf{M}^{+\cdot}$ In mass spectrometry, an ion that has not lost or gained any atoms during ionization.
molecularly imprinted polymer A polymer synthesized in the presence of a template molecule. After the template is removed, the polymer has a void with the right shape to hold the template, and polymer functional groups are positioned correctly to bind to template functional groups.
molecular mass The number of grams of a substance that contains Avogadro's number of molecules.
molecular orbital Describes the distribution of an electron within a molecule.
molecular sieve A solid particle with pores the size of small molecules. Zeolites (sodium aluminosilicates) are a common type.
mole fraction The number of moles of a substance in a mixture divided by the total number of moles of all components present.
monochromatic light Light with a very narrow range of wavelengths ("one color").
monochromator A device (usually a prism, grating, or filter) that dis-
perses light into its component wavelengths and selects a narrow band of wavelengths to pass through the exit slit.
monodentate ligand One that binds to a metal ion through only one atom.
monolithic column Chromatographic column in which polymerization is conducted inside the column to fill the column with porous stationary phase. Monolithic columns allow faster flow rates because the pore structure is maintained at high pressure.
monoprotic acids and bases Compounds that can donate or accept one proton.
mortar and pestle A mortar is a hard ceramic or steel vessel in which a solid sample is ground with a hard tool called a pestle.
mother liquor Solution from which a substance has crystallized or precipitated.
MS $^{n}$ Successive cycles of selected reaction monitoring. The product ion from one cycle becomes the precursor ion for the next cycle. This experiment can be conducted in a single three-dimensional quadrupole ion-trap mass spectrometer under software control.
mull A fine dispersion of a solid in an oil.
multidentate ligand One that binds to a metal ion through more than one atom.
$\mathrm{m} / \mathrm{z}$ See mass-to-charge ratio.
natural logarithm The natural logarithm (ln) of $a$ is $b$ if $\mathrm{e}^{b}=a$, where $\mathrm{e}=2.71828 \ldots$ See also logarithm.
nebulization Process of breaking a liquid into a mist of fine droplets.
nebulizer In atomic spectroscopy, this device breaks the liquid sample into a mist of fine droplets.
needle valve A valve with a tapered plunger that fits into a small orifice to constrict flow.
nephelometry A technique in which the intensity of light scattered at $90^{\circ}$ by a suspension is measured to determine the concentration of suspended
particles. In a precipitation titration, the scattering increases until the equivalence point is reached, and then remains constant.

Nernst equation Relates the voltage of a cell, $E$, to the activities of reactants and products:

$$
E=E^{\circ}-\frac{R T}{n F} \ln Q
$$

where $R$ is the gas constant, $T$ is temperature in kelvins, $F$ is the Faraday constant, $Q$ is the reaction quotient, and $n$ is the number of electrons transferred in the balanced reaction. $E^{\circ}$ is the cell voltage when all activities are unity.
neutralization Process in which a stoichiometric equivalent of acid is added to a base (or vice versa).
neutron-activation analysis A technique in which radiation is observed from a sample bombarded by slow neutrons. The radiation gives both qualitative and quantitative information about the sample composition.
newton, $\mathbf{N}$ SI unit of force. One newton will accelerate a mass of 1 kg by $1 \mathrm{~m} / \mathrm{s}^{2}$.
nitrogen chemiluminescence detector Gas chromatography detector in which combustion of eluate at $1800^{\circ} \mathrm{C}$ converts nitrogen into NO , which reacts with $\mathrm{O}_{3}$ to create a chemiluminescent product. Response to N is $10^{7}$ times greater than response to C .
nitrogen-phosphorus detector See alkali flame detector.
nitrogen rule A compound with an odd number of nitrogen atoms-in addition to $\mathrm{C}, \mathrm{H}$, halogens, $\mathrm{O}, \mathrm{S}, \mathrm{Si}$, and P -will have an odd nominal mass. A compound with an even number of nitrogen atoms $(0,2,4, \ldots)$ will have an even nominal mass.
noise Signals originating from sources other than those intended to be measured. See also line noise and white noise.
nominal mass Integer mass of the species with the most abundant isotope of each of the constituent atoms. For $\mathrm{C}, \mathrm{H}$, and Br , the most abundant isotopes are ${ }^{12} \mathrm{C},{ }^{1} \mathrm{H}$, and ${ }^{79} \mathrm{Br}$. Therefore, the nominal mass of $\mathrm{C}_{2} \mathrm{H}_{5} \mathrm{Br}$ is $(2 \times 12)+(5 \times 1)+(1 \times 79)=108$.
nonelectrolyte A substance that does not dissociate into ions when dissolved.
nonpolarizable electrode One whose potential remains nearly constant, even when current flows; e.g., a saturated calomel electrode.
nonpolar substance A substance, such as a hydrocarbon, with little charge separation within the molecule and no net ionic charge. Nonpolar substances interact with other substances by weak van der Waals forces and are generally not soluble in water.
normal error curve See Gaussian distribution.
normal hydrogen electrode, N.H.E. Same as standard hydrogen electrode.
normality $n$ times the molarity of a redox reagent, where $n$ is the number of electrons donated or accepted by that species in a particular chemical reaction. For acids and bases, it is also $n$ times the molarity, but $n$ is the number of protons donated or accepted by the species.
normal-phase chromatography A chromatographic separation utilizing a polar stationary phase and a less polar mobile phase.
nucleation Process whereby molecules in solution come together randomly to form small crystalline aggregates that can grow into larger crystals.
null hypothesis In statistics, the supposition that two quantities do not differ from each other or that two methods do not give different results. Nyquist noise See Johnson noise.
occlusion An impurity that becomes trapped (sometimes with solvent) in a pocket within a growing crystal.
ohm, $\Omega$ SI unit of electrical resistance. A current of 1 A flows across a potential difference of 1 V if the resistance of the circuit is $1 \Omega$.
ohmic potential Voltage required to overcome the electrical resistance of an electrochemical cell.
Ohm's law States that the current, $I$, in a circuit is proportional to voltage, $E$, and inversely proportional to resistance, $R: I=E / R$.
Ohm's law plot In capillary electrophoresis, a graph of current versus applied voltage. The graph deviates from a straight line when Joule heating becomes significant.
on-column injection Technique used in gas chromatography to place a thermally unstable sample directly on the column without excessive heating in an injection port. Solute is condensed at the start of the column by low temperature, and then the temperature is raised to initiate chromatography. 1/f noise See drift.
open tubular column In chromatography, a capillary column whose walls are coated with stationary phase.
optical density, OD See absorbance.
optical fiber Fiber that carries light by total internal reflection because the transparent core has a higher refractive index than the surrounding cladding. optical isomers See enantiomers.
optode A sensor based on an optical fiber. Also called optrode. orbitrap mass spectrometer A device that traps ions in stable orbits around a central electrode. Ions oscillate from one end of the trap to the other, inducing image currents in the outer electrodes. Fourier analysis of the image currents gives $\mathrm{m} / \mathrm{z}$ for the oscillating ions.
order of magnitude A power of 10 .
ordinate Vertical (y) axis of a graph.
osmolarity An expression of concentration that gives the total number of particles (ions and molecules) per liter of solution. For nonelectrolytes such as glucose, the osmolarity equals the molarity. For the strong electrolyte $\mathrm{CaCl}_{2}$, the osmolarity is three times the molarity, because each mole of $\mathrm{CaCl}_{2}$ provides 3 mol of ions $\left(\mathrm{Ca}^{2+}+2 \mathrm{Cl}^{-}\right)$.
outlier A datum that lies far from the other data in a set of measurements.
overall formation constant, $\beta_{n}$ Same as cumulative formation constant. overpotential Voltage required to overcome the activation energy for a reaction at an electrode. The electrode potential is above that expected from the equilibrium potential, concentration polarization, and ohmic potential. Overpotential is 0 for a reversible reaction.
oxidant See oxidizing agent.
oxidation A loss of electrons or a raising of the oxidation state.
oxidation number See oxidation state.
oxidation state A bookkeeping device used to tell how many electrons have been gained or lost by a neutral atom when it forms a compound. Also called oxidation number.
oxidizability In a natural water or industrial effluent sample, the quantity of $\mathrm{O}_{2}$ equivalent to the quantity of $\mathrm{KMnO}_{4}$ consumed by refluxing the sample with standard permanganate. Each $\mathrm{KMnO}_{4}$ consumes five electrons and is chemically equivalent to 1.25 mol of $\mathrm{O}_{2}$. See also chemical oxygen demand.
oxidizing agent A substance that takes electrons in a chemical reaction. Also called oxidant.
packed column A chromatography column filled with stationary phase particles.
parallax Apparent displacement of an object when the observer changes position. Occurs when the scale of an instrument is viewed from a position that is not perpendicular to the scale. The apparent reading is not the true reading.
particle growth Process in which molecules become attached to a crystal to form a larger crystal.
partition chromatography A technique in which separation is achieved by equilibration of solute between two phases.
partition coefficient, $K$ The equilibrium constant for the reaction in which a solute is partitioned between two phases: solute (in phase 1 ) $\rightleftharpoons$ solute (in phase 2).
partition ratio See retention factor.
parts per billion, ppb An expression of concentration denoting nanograms $\left(10^{-9} \mathrm{~g}\right)$ of solute per gram of solution.
parts per million, ppm An expression of concentration denoting micrograms $\left(10^{-6} \mathrm{~g}\right)$ of solute per gram of solution.
pascal, Pa SI unit of pressure equal to $1 \mathrm{~N} / \mathrm{m}^{2}$. There are $10^{5} \mathrm{~Pa}$ in 1 bar and 101325 Pa in 1 atm .
pellicular particles A type of stationary phase used in liquid chromatography. Contains a thin layer of liquid coated on a spherical bead. It has high efficiency (low plate height) but low capacity.
peptization Occurs when washing some ionic precipitates with distilled water causes the ions that neutralize the charges of individual particles to be washed away. The particles then repel one another, disintegrate, and pass through the filter with the wash liquid.
performance test sample In a series of analytical measurements, a performance test sample is inserted to see whether the procedure gives correct results when the analyst does not know the right answer. The performance test sample is formulated by someone other than the analyst to contain a known concentration of analyte. Also called a quality control sample or blind sample.
permanent hardness Component of water hardness not due to dissolved alkaline earth bicarbonates. This hardness remains in the water after boiling. See also hardness.
p function The negative logarithm (base 10) of a quantity: $\mathrm{pX}=-\log \mathrm{X}$. $\mathrm{pH} \quad$ Defined as $\mathrm{pH}=-\log \mathcal{A}_{\mathrm{H}^{+}}$where $\mathcal{A}_{\mathrm{H}^{+}}$is the activity of $\mathrm{H}^{+}$. In most approximate applications, the pH is taken as $-\log \left[\mathrm{H}^{+}\right]$.
phase transfer agent A compound such as a crown ether or a salt of a hydrophobic ion used to extract an ionic species from water into an organic solvent.
pH meter A potentiometer that can measure voltage when extremely little current is flowing. It is used with a glass electrode to measure pH .
pH of zero charge The pH at which the net charge on the surface of a solid is zero.
phospholipid A molecule with a phosphate-containing polar headgroup and long hydrocarbon (lipid) tail.
phosphorescence Emission of light during a transition between states of different spin multiplicity (e.g., triplet $\rightarrow$ singlet). Phosphorescence is slower than fluorescence, with emission occurring $\sim 10^{-4}$ to $10^{2} \mathrm{~s}$ after absorption of a photon.
photochemistry Chemical reaction initiated by absorption of a photon. photoconductive detector A detector whose conductivity changes when light is absorbed by the detector material.
photodiode array An array of semiconductor diodes used to detect light. The array is normally used to detect light that has been spread into its component wavelengths. One small band of wavelengths falls on each detector.
photoionization detector A gas chromatography detector that uses vacuum ultraviolet radiation to ionize aromatic and unsaturated compounds; it has little response to saturated hydrocarbons or halocarbons. Electrons produced by the ionization are collected and measured. photomultiplier tube One in which the cathode emits electrons when struck by light. The electrons then strike a series of dynodes (plates that are positive with respect to the cathode), and more electrons are released each time a dynode is struck. As a result, more than $10^{6}$ electrons may reach the anode for every photon striking the cathode.
photon A "particle" of light with energy $h \nu$, where $h$ is Planck's constant and $v$ is the frequency of the light.
phototube A vacuum tube with a photoemissive cathode. The electric current flowing between the cathode and the anode is proportional to the intensity of light striking the cathode.
photovoltaic detector A photodetector with a junction across which the voltage changes when light is absorbed by the detector material.
pH-stat A device that maintains a constant pH in a solution by continually injecting (or electrochemically generating) acid or base to counteract pH changes.
piezoelectric crystal A crystal that deforms when an electric field is applied.
piezoelectric effect Development of electric charge on the surface of certain crystals when subjected to pressure. Conversely, application of an electric field deforms the crystal.
pipet A glass tube calibrated to deliver a fixed or variable volume of liquid.
$\mathrm{p} K$ The negative logarithm (base 10) of an equilibrium constant:
$\mathrm{p} K=-\log K$.
Planck distribution Equation giving the spectral distribution of blackbody radiation:

$$
M_{\lambda}=\frac{2 \pi h c^{2}}{\lambda^{5}}\left(\frac{1}{\mathrm{e}^{h c / \lambda k T}-1}\right)
$$

where $h$ is Planck's constant, $c$ is the speed of light, $\lambda$ is the wavelength of light, $k$ is Boltzmann's constant, and $T$ is temperature in kelvins. $M_{\lambda}$ is the power (watts) per square meter of surface per meter of wavelength radiating from the surface. The integral $\int_{\lambda_{1}}^{\lambda_{2}} \mathbf{M}_{\lambda} d \lambda$ gives the power emitted per unit area in the wavelength interval from $\lambda_{1}$ to $\lambda_{2}$.
Planck's constant Fundamental constant of nature equal to the energy of light divided by its frequency: $h=E / v \approx 6.626 \times 10^{-34} \mathrm{~J} \cdot \mathrm{~s}$. plane polarized light Light whose electric field oscillates in one plane. plasma A gas that is hot enough to contain free ions and electrons, as well as neutral molecules.
plasmon A collective oscillation of the free electrons in a metal.
plate height, $H$ Length of a chromatography column divided by the number of theoretical plates in the column. Calculated as the variance, $\sigma^{2}$, of the analyte band divided by the distance, $x$, it has traveled: $H=\sigma^{2} / x$. polarizability Proportionality constant relating the induced dipole to the strength of the electric field. When a molecule is placed in an electric field, a dipole is induced in the molecule by attraction of the electrons toward the positive pole and attraction of the nuclei toward the negative pole. polarizable electrode One whose potential can change readily when a small current flows. Examples are Pt or Ag wires used as indicator electrodes.
polarogram A graph showing the relation between current and potential during a polarographic experiment.
polarograph An instrument used to obtain and record a polarogram.
polarographic wave $S$-shaped increase in current during a redox reaction in polarography.
polarography A voltammetry experiment using a dropping-mercury electrode.
polar substance A substance, such as an alcohol, that has positive and negative regions that attract neighboring molecules by electrostatic forces. Polar substances tend to be soluble in water and insoluble in nonpolar substances, such as hydrocarbons.
polychromatic light Light of many wavelengths ("many colors").
polychromator A device that spreads light into its component wavelengths and directs each small band of wavelengths to a different region where it is detected by a photodiode array.
polyprotic acid or base Compound that can donate or accept more than one proton.
population inversion A necessary condition for laser operation in which the population of an excited energy level is greater than that of a lower energy level.
porous-layer column Gas chromatography column containing an adsorptive solid phase coated on the inside surface of its wall.
postprecipitation Adsorption of otherwise soluble impurities on the surface of a precipitate after the precipitation is over.
potential See electric potential.
potential difference See electric potential.
potentiometer A device that measures electric potential by balancing it with a known potential of the opposite sign. A potentiometer measures the same quantity as that measured by a voltmeter, but the potentiometer is designed to draw much less current from the circuit being measured. potentiometry An analytical method in which an electric potential difference (a voltage) of a cell is measured.
potentiostat An electronic device that maintains a constant voltage between a pair of electrodes.
power Energy expended (work done) per unit time. SI units are $\mathrm{J} / \mathrm{s}=$ watts, W.
ppb, parts per billion An expression of concentration denoting nanograms $\left(10^{-9} \mathrm{~g}\right)$ of solute per gram of solution.
ppm, parts per million An expression of concentration denoting micrograms $\left(10^{-6} \mathrm{~g}\right)$ of solute per gram of solution.
precipitant A substance that precipitates a species from solution. precipitation Occurs when a substance leaves solution rapidly (to form either microcrystalline or amorphous solid).
precipitation titration One in which the analyte forms a precipitate with the titrant.
precision How well replicate measurements agree with each other. precolumn See guard column.
preconcentration Process of concentrating trace components of a mixture prior to their analysis.
precursor ion In tandem mass spectrometry (selected reaction monitoring), the ion selected by the first mass separator for fragmentation in the collision cell.
premix burner In atomic spectroscopy, one in which the sample is nebulized and simultaneously mixed with fuel and oxidant before being fed into the flame.
preoxidation Process of oxidizing analyte prior to titrating it with a reducing agent.
preparative chromatography Chromatography of large quantities of material conducted for the purpose of isolating pure material.
prereduction Process of reducing an analyte to a lower oxidation state prior to performing a titration with an oxidizing agent.
pressure Force per unit area, commonly measured in pascals ( $\mathrm{N} / \mathrm{m}$ ) or bars. pressure broadening In spectroscopy, line broadening due to collisions between molecules.
primary standard A reagent that is pure enough and stable enough to be used directly after weighing. The entire mass is considered to be pure reagent. prism A transparent, triangular solid. Each wavelength of light passing through the prism is bent (refracted) at a different angle.
product The species created in a chemical reaction. Products appear on the right side of the chemical equation.
product ion In tandem mass spectrometry (selected reaction monitoring), the fragment ion from the collision cell selected by the final mass separator for passage through to the detector.
protic solvent One with an acidic hydrogen atom.
protocol In quality assurance, written directions stating what must be documented and how the documentation is to be done.
proton The ion $\mathrm{H}^{+}$.
proton acceptor A Brønsted-Lowry base: a molecule that combines with $\mathrm{H}^{+}$.
protonated molecule In mass spectrometry, the ion $\mathrm{MH}^{+}$resulting from addition of $\mathrm{H}^{+}$to the analyte.
proton donor A Brønsted-Lowry acid: a molecule that can provide $\mathrm{H}^{+}$ to another molecule.
purge To force a fluid (usually gas) to flow through a substance or a chamber, usually to extract something from the substance being purged or to replace the fluid in the chamber with the purging fluid.
purge and trap A method for removing volatile analytes from liquids or solids, concentrating the analytes, and introducing them into a gas chromatograph. A carrier gas bubbled through a liquid or solid extracts volatile analytes, which are then trapped in a tube containing adsorbent. After analyte has been collected, the adsorbent tube is heated and purged to desorb the analytes, which are collected by cold trapping at the start of a gas chromatography column.
pyroelectric effect Variation with temperature in the electric polarization of a ferroelectric material.
pyrolysis Thermal decomposition of a substance.
$Q$ test Statistical test used to decide whether to discard a datum that appears discrepant.
quadrupole ion-trap mass spectrometer See three-dimensional iontrap mass spectrometer and linear quadrupole ion-trap mass spectrometer. qualitative analysis Process of determining the identity of the constituents of a substance.
quality assurance Quantitative indications that demonstrate whether data requirements have been met. Also refers to the broader process that includes quality control, quality assessment, and documentation of procedures and results designed to ensure adequate data quality.
quality control Active measures taken to ensure the required accuracy and precision of a chemical analysis.
quality control sample See performance test sample.
quantitation limit See lower limit of quantitation.
quantitative analysis Process of measuring how much of a constituent is present in a substance.
quantitative transfer Transfer of the entire contents from one vessel to another. This process is usually accomplished by rinsing the first vessel several times with fresh liquid and pouring each rinse into the receiving vessel.
quantum yield In photochemistry, the fraction of absorbed photons that produce a particular result. For example, if a molecule can isomerize from a cis to a trans isomer when light is absorbed, the quantum yield for isomerization is the number of molecules that isomerize divided by the number that absorb photons. Quantum yield is in the range 0 to 1 .
quaternary ammonium ion A cation containing four substituents attached to a nitrogen atom; e.g., $\left(\mathrm{CH}_{3} \mathrm{CH}_{2}\right)_{4} \mathrm{~N}^{+}$, the tetraethylammonium ion.
quenching Process in which emission from an excited molecule is decreased by energy transfer to another molecule called a quencher.
radian, rad SI unit of plane angle. There are $2 \pi$ radians in a complete circle.
radiant power Power per unit area $\left(\mathrm{W} / \mathrm{m}^{2}\right)$ of a beam of electromagnetic radiation. Also called irradiance or intensity.
Raleigh scattering Scattering of light in all directions by molecules or particles that are much smaller than the wavelength of the light. The wavelength of scattered light is the same as that of incident light. The intensity of scattered light increases as $1 / \lambda^{4}$, where $\lambda$ is the wavelength.
Raman scattering Scattering of light in which the wavelength of scattered light is changed from that of incident light by an energy corresponding to vibrational energy of the molecule responsible for scattering. In Stokes Raman scattering, the molecule gains vibrational energy and scattered light has less energy than incident light. In anti-Stokes Raman scattering, an excited molecule loses vibrational energy and scattered light has more energy than incident light.
random error A type of error, which can be either positive or negative and cannot be eliminated, based on the ultimate limitations on a physical measurement. Also called indeterminate error.
random heterogeneous material A material in which there are differences in composition with no pattern or predictability and on a fine scale. When you collect a portion of the material for analysis, you obtain some of each of the different compositions.
random sample Bulk sample constructed by taking portions of the entire lot at random.
range The difference between the highest and lowest values in a set of data. Also called spread. With respect to an analytical method, range is the concentration interval over which linearity, accuracy, and precision are all acceptable.
raw data Individual values of a measured quantity, such as peak areas from a chromatogram or volumes from a buret.
reactant The species consumed in a chemical reaction. It appears on the left side of a chemical equation.
reaction quotient, $Q$ Expression having the same form as the equilibrium constant for a reaction. However, the reaction quotient is evaluated for a particular set of existing activities (concentrations), which are generally not the equilibrium values. At equilibrium, $Q=K$.
reagent blank A solution prepared from all of the reagents, but no analyte. The blank measures the response of the analytical method to impurities in the reagents or any other effects caused by any component other than the analyte. The reagent blank, unlike the method blank, is not subjected to all sample preparation steps before analysis.
reagent gas In a chemical ionization source for mass spectrometry, reagent gas (normally methane, isobutane, or ammonia at $\sim 1 \mathrm{mbar}$ ) is converted into strongly proton donating species such as $\mathrm{CH}_{5}^{+}$by a process beginning with electron ionization. Protonated reagent gas reacts with analyte to create protonated analyte.
reagent grade chemical A high-purity chemical generally suitable for use in quantitative analysis and meeting purity requirements set by organizations such as the American Chemical Society.
reciprocal centimeter, $\mathrm{cm}^{-1}$ The most common unit of wavenumber, $1 / \lambda$, where $\lambda$ is wavelength in cm .
reconstructed total ion chromatogram In chromatography, a graph of the sum of intensities of all ions detected at all masses (above a selected cutoff) versus time.
redox couple A pair of reagents related by electron transfer; e.g., $\mathrm{Fe}^{3+} \mid \mathrm{Fe}^{2+}$ or $\mathrm{MnO}_{4}^{-} \mid \mathrm{Mn}^{2+}$.
redox indicator A compound used to find the end point of a redox titration because its various oxidation states have different colors. The standard potential of the indicator must be such that its color changes near the equivalence point of the titration.
redox reaction A chemical reaction in which electrons are transferred from one element to another.
redox titration One in which the reaction between analyte and titrant is an oxidation-reduction reaction.
reduced plate height In chromatography, the quotient plate height/d, where the numerator is the height equivalent to a theoretical plate and the denominator is the diameter of stationary phase particles.
reducing agent A substance that donates electrons in a chemical reaction. Also called reductant.
reductant See reducing agent.
reduction A gain of electrons or a lowering of the oxidation state. reference electrode One that maintains a constant potential against which the potential of another half-cell may be measured.
reflectance Fraction of incident radiant power reflected by an object.
refraction Bending of light when it passes between media with different refractive indexes.
refractive index, $n$ The speed of light in any medium is $c / n$, where $c$ is the speed of light in vacuum and $n$ is the refractive index of the medium. The refractive index also measures the angle at which a light ray is bent when it passes from one medium into another. Snell's law states that $n_{1} \sin \theta_{1}=n_{2} \sin \theta_{2}$, where $n_{i}$ is the refractive index for each medium and $\theta_{i}$ is the angle of the ray with respect to the normal between the two media. refractive index detector Liquid chromatography detector that measures the change in refractive index of eluate as solutes emerge from the column.
relative retention, $\alpha$ In chromatography, the ratio of adjusted retention times for two components. If component 1 has an adjusted retention time of $t_{\mathrm{r} 1}^{\prime}$ and component 2 has an adjusted retention time of $t_{\mathrm{r} 2}^{\prime}\left(>t_{\mathrm{r} 1}^{\prime}\right)$, the relative retention is $\alpha=t_{\mathrm{r} 2}^{\prime} / \mathrm{t}_{\mathrm{r} 1}^{\prime}$. Also called separation factor. See also unadjusted relative retention, $\gamma$.
relative standard deviation See coefficient of variation.
relative supersaturation Defined as $(Q-S) / S$, where $S$ is the concentration of solute in a saturated solution and $Q$ is the concentration in a particular supersaturated solution.
relative uncertainty Uncertainty of a quantity divided by the value of the quantity. It is usually expressed as a percentage of the measured quantity.
releasing agent In atomic spectroscopy, a substance that prevents chemical interference.
replicate measurements Repeated measurements of the same quantity. reporting limit Concentration below which regulations dictate that an analyte is reported as "not detected." The reporting limit is typically set 5 to 10 times higher than the detection limit.
reprecipitation Sometimes a gravimetric precipitate can be freed of impurities only by redissolving it in fresh solvent and reprecipitating it. The impurities are present at lower concentration during the second precipitation and are less likely to coprecipitate.
residual current The small current that is observed prior to the decomposition potential in an electrolysis.
resin Small, hard particles of an ion exchanger, such as polystyrene with ionic substituents.
resistance, $R \quad$ A measure of the retarding force opposing the flow of electric current. SI unit is ohm, $\Omega$.
resistivity, $\rho$ A measure of the ability of a material to retard the flow of electric current. $J=E / \rho$, where $J$ is the current density $\left(\mathrm{A} / \mathrm{m}^{2}\right)$ and $E$ is electric field $(\mathrm{V} / \mathrm{m})$. Units of resistivity are $\mathrm{V} \cdot \mathrm{m} / \mathrm{A}=\mathrm{ohm} \cdot \mathrm{m}=\Omega \cdot \mathrm{m}$. The resistance, $R$, of a conductor with a given length and cross-sectional area is given by $R=\rho \cdot$ length/area. Resistivity is the reciprocal of conductivity.
resolution How close two bands in a spectrum or a chromatogram can be to each other and still be seen as two peaks. In chromatography, it is defined as the difference in retention times of adjacent peaks divided by their width. In mass spectrometry, resolution is the smallest difference in $\mathrm{m} / \mathrm{z}$ values that can be detected as separate peaks and should be reported with the $\mathrm{m} / \mathrm{z}$, value where it is measured.
resolving power In mass spectrometry, resolving power can be defined as $m / \Delta m$, where $\Delta m$ is the separation of two peaks when the overlap at the base is $10 \%$ of the peak height and $m$ is the smaller of the two $m / z$ values. Alternatively, resolving power can be taken as $m / m_{1 / 2}$, where $m_{1 / 2}$ is the width of a peak at half the maximum height. In this case, the dip between two barely resolved peaks is $8 \%$ below the peak heights.
response factor, $F$ Relative response of a detector to analyte (X) and internal standard $(\mathrm{S})$ : $($ signal from X$) /[\mathrm{X}]=F($ signal from S$) /[\mathrm{S}]$. Once you have measured $F$ with a standard mixture, you can use it to find [X] in an unknown if you know $[\mathrm{S}]$ and the quotient (signal from X$) /($ signal from $S$ ).
results What we ultimately report after applying statistics to treated data. retardation, $\delta$ Difference in pathlength between light striking the stationary and moving mirrors of an interferometer.
retention factor, $k$ In chromatography, the adjusted retention time for a peak divided by the time for the mobile phase to travel through the column. Retention factor is also equal to the ratio of the time spent by the solute in the stationary phase to the time spent in the mobile phase. Also called capacity factor; capacity ratio, and partition ratio.
retention gap In gas chromatography, a 3- to 10-m length of empty, silanized capillary ahead of the chromatography column. The retention gap improves the peak shape of solutes that elute close to solvent when large volumes of solvent are injected or when the solvent has a very different polarity from that of the stationary phase.
retention index, $I$ In gas chromatography, the Kovats retention index is a logarithmic scale that relates the retention time of a compound to those of linear alkanes. Pentane would be given an index of 500 , hexane 600 , heptane 700 , and so on.
retention ratio In chromatography, the time required for solvent to pass through the column divided by the time required for solute to pass through the column.
retention time, $t_{\mathrm{r}}$ The time, measured from injection, needed for a solute to be eluted from a chromatography column.
retention volume, $V_{r}$ The volume of solvent needed to elute a solute from a chromatography column.
reversed-phase chromatography A technique in which the stationary phase is less polar than the mobile phase.
rings + double bonds formula The number of rings + double bonds in a molecule with the formula $\mathrm{C}_{c} \mathrm{H}_{h} \mathrm{~N}_{n} \mathrm{O}_{x}$ is $c-h / 2+n / 2+1$, where $c$ includes all Group 14 atoms ( $\mathrm{C}, \mathrm{Si}, \mathrm{Ge}, \mathrm{Sn}, \mathrm{Pb}$, which all make four bonds), $h$ includes $\mathrm{H}+$ halogens (which make one bond), and $n$ is the number of Group 15 atoms ( $\mathrm{N}, \mathrm{P}, \mathrm{As}, \mathrm{Sb}, \mathrm{Bi}$, which make three bonds). Group 16 atoms (which make two bonds) do not affect the result.
robustness Ability of an analytical method to be unaffected by small, deliberate changes in operating parameters.
root-mean-square (rms) noise Standard deviation of the noise in a region where the signal is flat:

$$
\text { rms noise }=\sqrt{\frac{\sum_{i}\left(A_{i}-\bar{A}\right)^{2}}{n}}
$$

where $A_{i}$ is the measured signal for the $i$ th data point, $\bar{A}$ is the mean signal, and $n$ is the number of data points.
rotating disk electrode A motor-driven electrode with a smooth flat face in contact with the solution. Rapid convection created by rotation brings fresh analyte to the surface of the electrode. A Pt electrode is especially suitable for studying anodic processes, in which a mercury electrode would be too easily oxidized.
rotational transition Occurs when a molecule changes its rotation energy. rubber policeman A glass rod with a flattened piece of rubber on the tip. The rubber is used to scrape solid particles from glass surfaces in gravimetric analysis.
ruggedness See intermediate precision.
run buffer See background electrolyte.
salt An ionic solid.
salt bridge A conducting ionic medium in contact with two electrolyte solutions. It allows ions to flow without allowing immediate diffusion of one electrolyte solution into the other.
sample cleanup Removal of portions of the sample that do not contain analyte and may interfere with analysis.
sample preparation Transforming a sample into a state that is suitable for analysis. This process can include concentrating a dilute analyte and removing or masking interfering species.
sampling The process of collecting a representative sample for analysis. sampling variance The square of the standard deviation arising from heterogeneity of the sample, not from the analytical procedure. For inhomogeneous materials, it is necessary to take larger portions or more portions to reduce the uncertainty of composition due to variation from one region to another. Total variance is the sum of variances from sampling and from analysis.
saturated calomel electrode, S.C.E. A calomel electrode saturated with KCl . The electrode half-reaction is $\mathrm{Hg}_{2} \mathrm{Cl}_{2}(s)+2 \mathrm{e}^{-} \rightleftharpoons 2 \mathrm{Hg}(l)+2 \mathrm{Cl}^{-}$. saturated solution One that contains the maximum amount of a compound that can dissolve at equilibrium.
Scatchard plot A graph used to find the equilibrium constant for a reaction such as $\mathrm{X}+\mathrm{P} \rightleftharpoons \mathrm{PX}$. It is a graph of $[\mathrm{PX}] /[\mathrm{X}]$ versus $[\mathrm{PX}]$ or any functions proportional to these quantities. The magnitude of the slope of the graph is the equilibrium constant.
S.C.E. See saturated calomel electrode.
schlieren Streaks in a liquid mixture observed before the two phases have mixed. Streaks arise from regions that refract light differently.
Schottky noise See white noise.
second, s SI unit of time equal to the duration of 9192631770 periods of the radiation corresponding to the transition between two hyperfine levels of the ground state of ${ }^{133} \mathrm{Cs}$.
segregated heterogeneous material A material in which differences in composition are on a large scale. Different regions have obviously different composition.
selected ion chromatogram A graph of detector response versus time when a mass spectrometer monitors just one or a few species of selected mass-to-charge ratio, $m / z$, emerging from a chromatograph. Also called mass chromatogram.
selected ion monitoring Use of a mass spectrometer to monitor species with just one or a few mass-to-charge ratios, $\mathrm{m} / \mathrm{z}$.
selected reaction monitoring A technique in which the precursor ion selected by one mass separator passes through a collision cell in which the precursor breaks into several fragment ions (product ions). A second mass separator then selects one (or a few) of these ions for detection. Selected reaction monitoring improves chromatographic signal-to-noise ratio because it is insensitive to almost everything other than the intended analyte. Also called mass spectrometry-mass spectrometry $(M S-M S)$ or tandem mass spectrometry.
selectivity See specificity.
selectivity coefficient With respect to an ion-selective electrode, a measure of the relative response of the electrode to two different ions. In ion-exchange chromatography, the selectivity coefficient is the equilibrium constant for displacement of one ion by another from the resin.
self-absorption In a luminescence measurement, a high concentration of analyte molecules can absorb excitation energy from excited analyte. Also called inner filter effect. If the absorbed energy is dissipated as heat instead of light, fluorescence does not increase in proportion to analyte concentration. Analyte concentration can be so high that fluorescence decreases with increasing concentration. In flame emission atomic spectroscopy, there is a lower concentration of excited-state atoms in the cool, outer part of the flame than in the hot, inner flame. The cool atoms can absorb emission from the hot ones and thereby decrease the observed signal.
semiconductor A material whose conductivity $\left(10^{-7}\right.$ to $\left.10^{4} \Omega^{-1} \cdot \mathrm{~m}^{-1}\right)$ is intermediate between that of good conductors $\left(10^{8} \Omega^{-1} \cdot \mathrm{~m}^{-1}\right)$ and that of insulators $\left(10^{-20}\right.$ to $\left.10^{-12} \Omega^{-1} \cdot \mathrm{~m}^{-1}\right)$.
semipermeable membrane A thin layer of material that allows some substances, but not others, to pass across the material. A dialysis membrane allows small molecules to pass, but not large molecules.
sensitivity Capability of responding reliably and measurably to changes in analyte concentration. In quantitative terms, sensitivity is the amount of instrument response per unit change in concentration of analyte.
separation factor See relative retention.
separator column Ion-exchange column used to separate analyte species in ion chromatography.
septum A disk, usually made of silicone rubber, covering the injection port of a gas chromatograph. The sample is injected by syringe through the septum. sequential injection analysis Analytical technique related to flow injection. Sample and reagents are taken into a holding coil through a multiport valve. After a suitable reaction time, flow is reversed and the zones of reagent, product, and sample are pushed through a detector to measure the amount of product. Flow is not continuous, so sequential injection consumes less reagents than does flow injection.
shot noise A form of white noise (Gaussian noise) arising from the quantized nature of charge carriers and photons. At low signal levels, shot noise arises from random variation in the small number of photons reaching a detector or the small number of electrons and holes generated in a semiconductor. Also called Schottky noise.
SI units International system of units based on the meter, kilogram, second, ampere, kelvin, candela, mole, radian, and steradian.
sieving In electrophoresis, the separation of macromolecules by migration through a polymer gel. Movement of the smallest molecules is fastest and that of the largest is slowest.
signal averaging Improvement of a signal by averaging successive scans. The signal increases in proportion to the number of scans accumulated. The noise increases in proportion to the square root of the number of scans. Therefore, the signal-to-noise ratio improves in proportion to the square root of the number of scans collected.
signal-to-noise ratio The height of a signal divided by the noise in the baseline around the signal. Noise is commonly expressed as root-meansquare noise. The higher the signal-to-noise ratio, the less uncertainty there is in the signal.
significant figure The number of significant digits in a quantity is the minimum number of digits needed to express the quantity in scientific notation without loss of precision. In experimental data, the first uncertain figure is the last significant figure.
silanization Treatment of a chromatographic solid support or glass column with hydrophobic silicon compounds that bind to the most reactive $\mathrm{Si}-\mathrm{OH}$ groups. It reduces irreversible adsorption and tailing of polar solutes.
silver-silver chloride electrode A common reference electrode containing a silver wire coated with AgCl paste and dipped in a solution saturated with AgCl and (usually) KCl . The half-reaction is $\mathrm{AgCl}(s)+\mathrm{e}^{-} \rightleftharpoons$ $\mathrm{Ag}(s)+\mathrm{Cl}^{-}$.
single-column ion chromatography Separation of ions on a low-capacity ion-exchange column, using low-ionic-strength eluent.
single-electrode potential Voltage measured when the electrode of interest is connected to the positive terminal of a potentiometer and a standard hydrogen electrode is connected to the negative terminal.
singlet state One in which all electron spins are paired.
size exclusion chromatography See molecular exclusion chromatography. skimmer cone voltage See cone voltage.
slope For a straight line whose equation is $y=m x+b$, the value of $m$ is the slope. It is the ratio $\Delta y / \Delta x$ for any segment of the line.
slurry A suspension of a solid in a solvent.
Smith-Hieftje background correction In atomic absorption spectroscopy, a method of distinguishing analyte signal from background signal, based on applying a periodic pulse of high current to the hollowcathode lamp to distort the lamp signal. Signal detected during the current pulse is subtracted from signal detected without the pulse to obtain the corrected response.
smoothing Use of a mathematical procedure or electrical filtering to improve the quality of a signal.
Snell's law Relates angle of refraction, $\theta_{2}$, to angle of incidence, $\theta_{1}$, for light passing from a medium with refractive index $n_{1}$ to a medium of refractive index $n_{2}: n_{1} \sin \theta_{1}=n_{2} \sin \theta_{2}$. Angles are measured with respect to the normal to the surface between the two media.
sodium error Systematic error that occurs when a glass pH electrode is placed in a strongly basic solution containing very little $\mathrm{H}^{+}$and a high concentration of $\mathrm{Na}^{+}$. The electrode begins to respond to $\mathrm{Na}^{+}$as if it were $\mathrm{H}^{+}$, so the pH reading is lower than the actual pH . Also called alkaline error.
solid-phase extraction Preconcentration procedure in which a solution is passed through a short column of chromatographic stationary phase, such as $\mathrm{C}_{18}$ on silica. Trace solutes adsorbed on the column can be eluted with a small volume of solvent of high eluent strength.
solid-phase microextraction Extraction of compounds from liquids or gases into a coated fiber dispensed from a syringe needle. After extraction, the fiber is withdrawn into the needle and the needle is inserted through the septum of a chromatograph. The fiber is extended inside the injection port and adsorbed solutes are desorbed by heating (for gas chromatography) or solvent (for liquid chromatography).
solid-state ion-selective electrode An ion-selective electrode that has a solid membrane made of an inorganic salt crystal. Ion-exchange equilibria between the solution and the surface of the crystal account for the electrode potential.
solid-supported liquid-liquid extraction A form of liquid-liquid extraction in which the liquid to be extracted is applied to a porous solid which retains the liquid. The second liquid is then passed through the porous solid to extract solute from the first liquid.
solubility product, $K_{\text {sp }}$ Equilibrium constant for the dissociation of a solid salt to give its ions in solution. For the reaction $\mathrm{M}_{m} \mathrm{~N}_{n}(s) \rightleftharpoons$ $m \mathrm{M}^{n+}+n \mathrm{~N}^{m-}, K_{\mathrm{sp}}=\mathcal{A}_{\mathrm{M}^{n+}}^{m} \mathcal{A}_{\mathrm{N}^{m-}}^{n}$ where $\mathcal{A}$ is the activity of each species.
solute A minor component of a solution.
solution A homogeneous mixture of two or more substances.
solvation Interaction of solvent molecules with solute. Solvent molecules orient themselves around solute to minimize the energy through dipole and van der Waals forces.
solvent Major constituent of a solution.
solvent extraction A method in which a chemical species is transferred from one liquid phase to another. It is used to separate components of a mixture.
solvent strength See eluent strength.
solvent trapping Splitless gas chromatography injection technique in which solvent is condensed near its boiling point at the start of the column. Solutes dissolve in a narrow band in the condensed solvent.
speciation Describes the distribution of an element or compound among different chemical forms.
species Chemists refer to any element, compound, or ion of interest as a species. The word species is both singular and plural.
specific adsorption Process in which molecules are held tightly to a surface by van der Waals or electrostatic forces.
specifications In quality assurance, specifications are written statements describing how good analytical results need to be and what precautions are required in an analytical method.
specific gravity A dimensionless quantity equal to the mass of a substance divided by the mass of an equal volume of water at $4^{\circ} \mathrm{C}$. Specific gravity is virtually identical with density in $\mathrm{g} / \mathrm{mL}$.
specificity Capability of an analytical method to distinguish analyte from other species in the sample. Also called selectivity.
spectral interference In atomic spectroscopy, any physical process that affects light intensity at the analytical wavelength. Created by substances that absorb, scatter, or emit light of the analytical wavelength.
spectrophotometer A device used to measure absorption of light. It includes a source of light, a wavelength selector (monochromator), and an electrical means of detecting light.
spectrophotometric analysis Any method in which light absorption, emission, reflection, or scattering is used to measure chemical concentrations.
spectrophotometric titration One in which absorption of light is used to monitor the progress of the titration reaction and to find the equivalence point. spectrophotometry In a broad sense, any method using light to measure chemical concentrations.
specular reflection Reflection of light at an angle equal to the angle of incidence.
spike Addition of a known compound (usually at a known concentration) to an unknown. In isotope dilution mass spectrometry, the spike is the added, unusual isotope. Spike is a noun and a verb. In co-chromatography, spiking is the simultaneous chromatography of a known compound with an unknown. If a known and an unknown have the same retention time on several columns, they are probably identical. Also called fortification. spike recovery The fraction of a spike eventually found by chemical analysis.
split injection Technique used in capillary gas chromatography to inject a small fraction of sample onto the column; the rest of the sample is blown out to waste.
splitless injection Technique used in capillary gas chromatography for trace analysis and quantitative analysis. The entire sample in a low-boiling solvent is directed to the column, where the sample is concentrated by solvent trapping (condensing the solvent below its boiling point) or cold trapping (condensing solutes far below their boiling range). The column is then warmed to initiate separation.
spontaneous process One that is energetically favorable. It will eventually occur, but thermodynamics makes no prediction about how long it will take. spread See range.
square wave voltammetry A form of voltammetry (measurement of current versus potential in an electrochemical cell) in which the potential waveform consists of a square wave superimposed on a voltage staircase. The technique is faster and more sensitive than voltammetry with other waveforms.
stability constant See formation constant.
stacking In electrophoresis, the process of concentrating ions into a narrow band at the interface of electrolytes of low conductivity and high conductivity. Stacking occurs because the electric field in low-conductivity electrolyte is stronger than the field in high-conductivity electrolyte. Ions in the low-conductivity region migrate rapidly until they reach the interface, where the electric field is much smaller.
standard addition A technique in which an analytical signal due to an unknown is first measured. Then a known quantity of analyte is added, and the increase in signal is recorded. From the response, it is possible to calculate what quantity of analyte was in the unknown.
standard curve A graph showing the response of an analytical technique to known quantities of analyte.
standard deviation A statistic measuring how closely data are clustered about the mean value. For a finite set of data, the standard deviation, $s$, is computed from the formula

$$
s=\sqrt{\frac{\sum_{i}\left(x_{i}-\bar{x}\right)^{2}}{n-1}}=\sqrt{\frac{\sum_{i}\left(x_{i}^{2}\right)}{n-1}-\frac{\left(\sum_{i} x_{i}\right)^{2}}{n(n-1)}}
$$

where $n$ is the number of results, $x_{i}$ is an individual result, and $\bar{x}$ is the mean result. For a large number of measurements, $s$ approaches $\sigma$, the true standard deviation of the population, and $\bar{x}$ approaches $\mu$, the true population mean.
standard deviation of the mean, $\sigma_{n}$ The standard deviation of a set of measurements $(\sigma)$ divided by the square root of the number of measurements $(n)$ in the set: $\sigma / \sqrt{n}$.
standard hydrogen electrode, S.H.E. One that contains $\mathrm{H}_{2}(g)$ bubbling over a catalytic Pt surface immersed in aqueous $\mathrm{H}^{+}$. The activities of $\mathrm{H}_{2}$ and $\mathrm{H}^{+}$are both unity in the hypothetical standard electrode. The reaction is $\mathrm{H}^{+}+\mathrm{e}^{-} \rightleftharpoons \frac{1}{2} \mathrm{H}_{2}(g)$. Also called normal hydrogen electrode (N.H.E.). standardization Process of determining the concentration of a reagent by reaction with a known quantity of a second reagent.
standard operating procedure A written procedure that must be rigorously followed to ensure the quality of a chemical analysis.
standard reduction potential, $E^{\circ}$ The voltage that would be measured when a hypothetical cell containing the desired half-reaction (with all species present at unit activity) is connected to a standard hydrogen electrode anode.
Standard Reference Material Same as certified reference material. standard solution A solution whose composition is known by virtue of the way that it was made from a reagent of known purity or by virtue of its reaction with a known quantity of a standard reagent.
standard state The standard state of a solute is 1 M and the standard state of a gas is 1 bar. Pure solids and liquids are considered to be in their standard states. In equilibrium constants, dimensionless concentrations are expressed as a ratio of the concentration of each species to its concentration in its standard state.
stationary phase In chromatography, the phase that does not move through the column.
stepwise formation constant, $K_{n}$ Equilibrium constant for a reaction of the type $\mathrm{ML}_{n-1}+\mathrm{L} \rightleftharpoons \mathrm{ML}_{n}$.
steradian, sr Unit of solid angle. There are $4 \pi$ steradians in a complete sphere.
stimulated emission Emission of a photon induced by the passage of another photon of the same wavelength.
stir-bar sorptive extraction Sample preparation method similar to solid-phase microextraction, except the sorptive layer is coated on the outside of a stirring bar. Coating volume is greater than the fiber volume in solid-phase microextraction, so it provides $\sim 10^{2}$ times greater sensitivity for traces of analyte. Analyte is removed from the coating by thermal desorption for chromatography.
stoichiometry Ratios of substances participating in a chemical reaction. Stokes equation The friction coefficient for a molecule migrating through solution is $6 \pi \eta r$, where $\eta$ is the viscosity of the fluid and $r$ is the hydrodynamic radius (equivalent spherical radius) of the molecule.
stray light In spectrophotometry, light reaching the detector that is not part of the narrow set of wavelengths expected from the monochromator.
stripping analysis A sensitive polarographic technique in which analyte is concentrated from dilute solution by reduction into a drop (or a film) of Hg . It is then analyzed polarographically during an anodic redissolution process. Some analytes can be oxidatively concentrated onto an electrode other than Hg and stripped in a reductive process.
strong acids and bases Those that are completely dissociated (to $\mathrm{H}^{+}$or $\mathrm{OH}^{-}$) in water.
strong electrolyte One that mostly dissociates into ions in solution.
Student's $t$ A statistical tool used to express confidence intervals and to compare results from different experiments.
sulfur chemiluminescence detector Gas chromatography detector for the element sulfur. Exhaust from a flame ionization detector is mixed with $\mathrm{O}_{3}$ to form an excited state of $\mathrm{SO}_{2}$ that emits light, which is detected. Response to S is $10^{7}$ times greater than response to C .
superconductor A material that loses all electrical resistance when cooled below a critical temperature.
supercritical fluid A fluid whose temperature is above its critical temperature and whose pressure is above its critical pressure. It has properties of both a liquid and a gas.
supercritical fluid chromatography Chromatography using supercritical fluid as the mobile phase. Capable of highly efficient separations of nonvolatile solutes and able to use detectors suitable for gas or liquid.
supercritical fluid extraction Extraction of compounds (usually from solids) with a supercritical fluid solvent.
superficially porous particle A stationary phase particle for liquid chromatography containing a thin, porous outer layer and a dense, nonporous core. Mass transfer is faster in the superfically porous particle than in a fully porous particle of the same diameter. Also called fused-core particle. supernatant liquid Liquid remaining above the solid after a precipitation. Also called supernate.
supersaturated solution One that contains more dissolved solute than would be present at equilibrium.
support-coated column Open tubular gas chromatography column in which the stationary phase is coated on solid support particles attached to the inside wall of the column.
supporting electrolyte An unreactive salt added in high concentration to solutions for voltammetric measurements (such as polarography). The supporting electrolyte carries most of the ion-migration current and therefore decreases the coulombic migration (drift of ions in the electric field) of electroactive species to a negligible level. The electrolyte also decreases the resistance of the solution.
suppressed-ion chromatography Separation of ions by using an ionexchange column followed by a suppressor (membrane or column) to remove ionic eluent.
suppressor In ion chromatography, a device that transforms ionic eluent into a nonionic form.
surface plasmon resonance A sensitive means to measure the binding of molecules to a thin gold layer on the underside of a prism. Light directed through the prism is reflected from the gold surface. There is one narrow range of angles at which reflection is nearly 0 because the gold absorbs the light to set up oscillations (called plasmons) of the electron cloud in the metal. When a thin layer of material (such as protein or DNA) binds to the side of the gold away from the prism, the electrical properties of the gold are changed and the reflectivity changes.
surfactant A molecule with an ionic or polar headgroup and a long, nonpolar tail. Surfactants aggregate in aqueous solution to form micelles. Surfactants derive their name from the fact that they accumulate at boundaries between polar and nonpolar phases and modify the surface tension, which is the free energy of formation of the surface. Soaps are surfactants.
sweeping In capillary electrophoresis, migration of a collector species such as a micelle or chelator to concentrate analyte into a narrow region at the front of the migrating collector species.
syringe A device having a calibrated barrel into which liquid is sucked by a plunger. The liquid is expelled through a needle by pushing on the plunger.
systematic error Error due to procedural or instrumental factors that cause a measurement to be consistently too large or too small. The error can, in principle, be discovered and corrected. Also called determinate error. systematic treatment of equilibrium A method that uses the charge balance, mass balance(s), and equilibria to completely specify a system's composition.
$t$ test Statistical test used to decide whether the results of two experiments are within experimental uncertainty of each other. The uncertainty must be specified to within a certain probability.
tailing Asymmetric chromatographic band in which the later part elutes very slowly. It often results from adsorption of a solute onto a few active sites on the stationary phase.
tandem mass spectrometry See selected reaction monitoring.
tare As a noun, tare is the mass of an empty vessel used to receive a substance to be weighed. As a verb, tare means setting the balance reading to 0 when an empty vessel or weighing paper is placed on the pan.
temperature programming Raising the temperature of a gas chromatography column during a separation to reduce the retention time of late-eluting components.
temporary hardness Component of water hardness due to dissolved alkaline earth bicarbonates. It is temporary because boiling causes precipitation of the carbonates.
test portion Part of the laboratory sample used for one analysis. Also called aliquot.
theoretical plate An imaginary construct in chromatography denoting a segment of a column in which one equilibration of solute occurs between stationary and mobile phases. The number of theoretical plates on a column with Gaussian bandshapes is defined as $N=t_{\mathrm{r}}^{2} / \sigma^{2}$, where $t_{\mathrm{r}}$ is the retention time of a peak and $\sigma$ is the standard deviation of the band. See also plate height.
thermal conductivity, $\kappa$ Rate at which a substance transports heat (energy per unit time per unit area) through a temperature gradient (degrees per unit distance). Energy flow $\left[\mathrm{J} /\left(\mathrm{s} \cdot \mathrm{m}^{2}\right)\right]=-\kappa(d T / d x)$, where $\kappa$ is the thermal conductivity $[\mathrm{W} /(\mathrm{m} \cdot \mathrm{K})]$ and $d T / d x$ is the temperature gradient $(\mathrm{K} / \mathrm{m})$.
thermal conductivity detector A device that detects substances eluted from a gas chromatography column by measuring changes in the thermal conductivity of the gas stream.
thermal desorption A sample preparation technique used in gas chromatography to release volatile substances from a solid sample by heating. thermistor A device whose electrical resistance changes markedly with changes in temperature.
thermocouple An electrical junction across which a temperaturedependent voltage exists. Thermocouples are calibrated for measurement of temperature and usually consist of two dissimilar metals in contact with each other.
thermogravimetric analysis A technique in which the mass of a substance is measured as the substance is heated. Changes in mass indicate decomposition of the substance, often to well-defined products.
thermometric titration One in which the temperature is measured to determine the end point. Most titration reactions are exothermic, so the temperature rises during the reaction and suddenly stops rising when the equivalence point is reached.
thin-layer chromatography Liquid chromatography in which the stationary phase is coated on a flat glass or plastic plate. Solute is spotted near the bottom of the plate. The bottom edge of the plate is placed in contact with solvent, which creeps up the plate by capillary action.
three-dimensional quadrupole ion-trap mass spectrometer An instrument that separates gaseous ions by trapping them in stable threedimensional trajectories inside a metal chamber to which a radiofrequency electric field is applied. Application of an oscillating electric
field between the ends of the chamber destabilizes the trajectories of ions with a particular mass-to-charge ratio, expelling them from the cavity and into a detector.
time-of-flight mass spectrometer Ions of different mass accelerated through the same electric field have different velocities: The lighter ions move faster than the heavier ions. The time-of-flight spectrometer finds the mass-to-charge ratio by measuring the time that each group of ions requires to travel a fixed distance to the detector.
titer A measure of concentration, usually defined as how many milligrams of reagent B will react with 1 mL of reagent A . One milliliter of $\mathrm{AgNO}_{3}$ solution with a titer of $1.28 \mathrm{mg} \mathrm{NaCl} / \mathrm{mL}$ will be consumed by 1.28 mg NaCl in the reaction $\mathrm{Ag}^{+}+\mathrm{Cl}^{-} \rightarrow \mathrm{AgCl}(s)$. The same solution of $\mathrm{AgNO}_{3}$ has a titer of 0.993 mg of $\mathrm{KH}_{2} \mathrm{PO}_{4} / \mathrm{mL}$, because 1 mL of AgNO solution will be consumed by $0.993 \mathrm{mg} \mathrm{KH} \mathrm{KO}_{2}$ to precipitate $\mathrm{Ag}_{3} \mathrm{PO}_{4}$. titrant Substance added to the analyte in a titration.
titration A procedure in which one substance (titrant) is carefully added to another (analyte) until complete reaction has occurred. The quantity of titrant required for complete reaction tells how much analyte is present.
titration curve A graph showing how the concentration of a reactant or a physical property of the solution varies as one reactant (the titrant) is added to another (the analyte).
titration error Difference between the observed end point and the true equivalence point in a titration.
tolerance Manufacturer's stated uncertainty in the accuracy of a device such as a buret or volumetric flask. A $100-\mathrm{mL}$ flask with a tolerance of $\pm 0.08 \mathrm{~mL}$ may contain 99.92 to 100.08 mL and be within tolerance.
total carbon In a natural water or industrial effluent sample, the quantity of $\mathrm{CO}_{2}$ produced when the sample is completely oxidized by oxygen at $900^{\circ} \mathrm{C}$ in the presence of a catalyst.
total ion chromatogram A graph of detector response versus time when a mass spectrometer monitors all ions above a selected $\mathrm{m} / \mathrm{z}$ ratio emerging from a chromatograph.
total organic carbon In a natural water or industrial effluent sample, the quantity of $\mathrm{CO}_{2}$ produced when the sample is first acidified and purged to remove carbonate and bicarbonate and then completely oxidized by oxygen at $900^{\circ} \mathrm{C}$ in the presence of a catalyst.
total oxygen demand In a natural water or industrial effluent sample, the quantity of $\mathrm{O}_{2}$ required for complete oxidation of species in the water at $900^{\circ} \mathrm{C}$ in the presence of a catalyst.
trace analysis Chemical analysis of very low levels of analyte, typically ppm and lower.
transition range For an acid-base indicator, the pH range over which the color change occurs. For a redox indicator, the potential range over which the color change occurs.
transmission quadrupole mass spectrometer A mass spectrometer that separates ions by passing them between four metallic cylinders to which are applied direct current and oscillating electric fields. Resonant ions with the right mass-to-charge ratio pass through the chamber to the detector while nonresonant ions are deflected into the cylinders and are lost.
transmittance, $T$ Defined as $T=P / P_{0}$, where $P_{0}$ is the radiant power of light striking the sample on one side and $P$ is the radiant power of light emerging from the other side of the sample.
treated data Concentrations or amounts of analyte found from raw data with a calibration curve or some other calibration method.
triple point The one temperature and pressure at which the solid, liquid, and gaseous forms of a substance are in equilibrium with one another.
triplet state An electronic state in which there are two unpaired electrons.
tungsten lamp An ordinary light bulb in which electricity passing through a tungsten filament heats the wire and causes it to emit visible light.
turbidimetry A technique in which the decrease in intensity of light traveling through a turbid solution (a solution containing suspended particles) is measured. The greater the concentration of suspended particles, the less light is transmitted. See diagram under nephelometry.
turbidity Light-scattering property associated with suspended particles in a liquid. A turbid solution appears cloudy.
turbidity coefficient The transmittance of a turbid solution is given by $P / P_{0}=\mathrm{e}^{-\tau b}$, where $P$ is the transmitted radiant power, $P_{0}$ is the incident radiant power, $b$ is the pathlength, and $\tau$ is the turbidity coefficient.
ultraviolet detector Liquid chromatography detector that measures ultraviolet absorbance of solutes emerging from the column.
unadjusted relative retention, $\gamma$ For components A and B separated by chromatography or electrophoresis, the unadjusted relative retention $\gamma$ is the quotient of linear velocities or unadjusted retention times: $\gamma=u_{\mathrm{A}} / u_{\mathrm{B}}=$ $t_{\mathrm{B}} / t_{\mathrm{A}}$, where $u$ is linear velocity and $t$ is retention time.
underpotential deposition Reduction of $\mathrm{M}^{n+}$ to make an atomic monolayer of M on the surface of another material, such as gold. If the reduction potential to make the monolayer on gold is less negative than the potential required to reduce $\mathrm{M}^{n+}$ onto bulk metal M , we say that underpotential deposition occurs.
upconversion A process in which a higher energy photon is created by the combination of energy of several lower energy photons.
use objectives In quality assurance, use objectives are a written statement of how results will be used. Use objectives are required before specifications can be written for the method.
valence band Energy levels containing valence electrons in a semiconductor. The electrons in these levels are localized in chemical bonds.
van Deemter equation Describes the dependence of chromatographic plate height, $H$, on linear flow rate, $u_{\mathrm{x}}: H=A+B / u_{\mathrm{x}}+C u_{\mathrm{x}}$. The constant A depends on band-broadening processes such as multiple flow paths that are independent of flow rate. B depends on the rate of diffusion of solute in the mobile phase. C depends on the rate of mass transfer between the stationary and mobile phases.
variance, $\sigma^{2}$ The square of the standard deviation.
vibrational transition Occurs when a molecule changes its vibrational energy.
viscosity Resistance to flow in a fluid.
void volume, $V_{0} \quad$ Volume of the mobile phase outside the gel particles in a molecular exclusion chromatography column.
volatile Easily vaporized.
volatilization Selective removal of a component from a mixture by transforming the component into a volatile (low-boiling) species and removing it by heating, pumping, or bubbling a gas through the mixture.
Volhard titration Titration of $\mathrm{Ag}^{+}$with $\mathrm{SCN}^{-}$in the presence of $\mathrm{Fe}^{3+}$. Formation of red $\mathrm{Fe}(\mathrm{SCN})^{2+}$ marks the end point.
volt, $\mathbf{V}$ Unit of electric potential difference. If the potential difference between two points is one volt, then one joule of energy is required to move one coulomb of charge between the two points.
voltaic cell See galvanic cell.
voltammetry An analytical method in which the relation between current and voltage is observed during an electrochemical reaction.
voltammogram A graph of current versus electrode potential in an electrochemical cell.
voltmeter Device for measuring electric potential difference. See also potentiometer.
volume flow rate In chromatography, the volume of mobile phase per unit time eluted from the column.
volume percent, vol\% Defined as (volume of solute/volume of solution) $\times 100$.
volumetric analysis A technique in which the volume of material needed to react with the analyte is measured.
volumetric flask One having a tall, thin neck with a calibration mark. When the liquid level is at the calibration mark, the flask contains its specified volume of liquid at a specified temperature.

Walden reductor A column packed with silver and eluted with HCl . Analyte is reduced during passage through the column. The reduced product is titrated with an oxidizing agent.
wall-coated column Hollow chromatographic column in which the stationary phase is coated on the inside surface of the wall.
watt, W SI unit of power equal to an energy flow of one joule per second. When an electric current of one ampere flows through a potential difference of one volt, the power is one watt.
waveguide A thin layer or hollow structure in which electromagnetic radiation is totally reflected.
wavelength, $\lambda$ Distance between consecutive crests of a wave.
wavenumber, $\tilde{v}$ Reciprocal of the wavelength, $1 / \lambda$, usually expressed in units of $\mathrm{cm}^{-1}$.
weak acids and bases Those whose dissociation constants are not large. weak electrolyte One that only partly dissociates into ions when it dissolves.
weighing paper Paper on which to place a solid reagent on a balance. Weighing paper has a very smooth surface, from which solids fall easily for transfer to a vessel.
weight percent, wt \% (Mass of solute/mass of solution) $\times 100$.
weight/volume percent [(Mass of solute, g$) /($ volume of solution, mL$)] \times 100$.
Weston cell A stable voltage source based on the reaction
$\mathrm{Cd}(s)+\mathrm{HgSO}_{4}(a q) \rightleftharpoons \mathrm{CdSO}_{4}(a q)+\mathrm{Hg}(l)$. It was formerly used to standardize a potentiometer.
wet ashing Destruction of organic matter in a sample by a liquid reagent (such as boiling aqueous $\mathrm{HClO}_{4}$ ) prior to analysis of an inorganic component. whistle noise See line noise.
white light Light comprising all wavelengths.
white noise Random noise, also called Gaussian noise, due to random movement of charge carriers in an electric circuit (called thermal noise, Johnson noise, or Nyquist noise) or from random arrival of photons or charge carriers to a detector (called shot noise or Schottky noise).
width at half-height, $w_{1 / 2}$ Width of a signal at half of its maximum height. Also called half-width.
work Energy required or released when an object is moved from one point to another. Units of work are joules, J.
working electrode One at which the reaction of interest occurs.
$y$-intercept The value of $y$ at which a line crosses the $y$-axis.
Zeeman background correction Technique used in atomic spectroscopy in which analyte signals are shifted outside the detector monochromator range by applying a strong magnetic field to the sample. Signal that remains is the background.
Zeeman effect Shifting of atomic energy levels in a magnetic field. zwitterion A molecule with a positive charge localized at one position and a negative charge localized at another position.

If $a$ is the base $10 \operatorname{logarithm}$ of $n(a=\log n)$, then $n=10^{a}$. On a calculator, you find the logarithm of a number by pressing the "log" button. If you know $a=\log n$ and you wish to find $n$, use the "antilog" button or raise 10 to the power $a$ :

$$
\begin{gathered}
a=\log n \\
10^{a}=10^{\log n}=n(\Rightarrow n=\operatorname{antilog} a)
\end{gathered}
$$

Natural logarithms (ln) are based on the number e (=2.718 281 ...) instead of 10 :

$$
\begin{gathered}
b=\ln n \\
\mathrm{e}^{b}=\mathrm{e}^{\ln n}=n
\end{gathered}
$$

On a calculator, you find the $\ln$ of $n$ with the "ln" button. To find $n$ when you know $b=\ln n$, use the $\mathrm{e}^{x}$ key.

Here are some useful properties to know:
$\log (a \cdot b)=\log a+\log b \quad \log 10^{a}=a$
$\log \left(\frac{a}{b}\right)=\log a-\log b \quad \quad a^{b} \cdot a^{c}=a^{(b+c)}$
$\log \left(a^{b}\right)=b \log a \quad \frac{a^{b}}{a^{c}}=a^{(b-c)}$

## Problems

Test yourself by simplifying each expression as much as possible:
(a) $\mathrm{e}^{\ln a}$
(e) $\mathrm{e}^{-\ln a^{3}}$
(i) $\log \left(10^{a^{2}-b}\right)$
(b) $10^{\log a}$
(f) $\mathrm{e}^{\ln a^{-3}}$
(j) $\underset{(a+\ln b)}{\log }\left(20^{3}\right)$
(c) $\log 10^{a}$
(g) $\log \left(10^{1 / a^{3}}\right)$
(k) $\mathrm{e}^{(a+\ln b)}$
(l) $10^{[(\log 3)-(4 \log 2)]}$

Solving a logarithmic equation: In working with the Nernst and Henderson-Hasselbalch equations, we will need to solve equations such as

$$
a=b-c \log \frac{d}{g x}
$$

for the variable, $x$. First isolate the log term:

$$
\log \frac{d}{g x}=\frac{(b-a)}{c}
$$

Then raise 10 to the value of each side of the equation:

$$
10^{\log (d / g x)}=10^{(b-a) / c}
$$

But $10^{\log (d / g x)}$ is just $d / g x$, so

$$
\frac{d}{g x}=10^{(b-a) / c} \Rightarrow x=\frac{d}{g 10^{(b-a) / c}}
$$

Converting between $\ln x$ and $\log x$ : The relation between them is derived by writing $x=10^{\log x}$ and taking $\ln$ of both sides:

$$
\ln x=\ln \left(10^{\log x}\right)=(\log x)(\ln 10)
$$

because $\ln a^{b}=b \ln a$.

## Answers

(a) $a$
(d) $1 / a$
(b) $a$
(e) $1 / a^{3}$
(g) $1 / a^{3}$
(j) $b^{2}+\log \left(2 a^{3}\right)$
(c) $a$
(f) $1 / a^{3}$
(h) $-a^{2}$
(k) $b \mathrm{e}^{a}$
(i) $a^{2}-b$
(l) $3 / 16$
(c)

The general form of the equation of a straight line is

$$
y=m x+b
$$

where $m=$ slope $=\frac{\Delta y}{\Delta x}=\frac{y_{2}-y_{1}}{x_{2}-x_{1}}$
$b=$ intercept on $y$-axis
The meanings of slope and intercept are illustrated in Figure B-1.

$$
\text { Slope }=m=\frac{\Delta y}{\Delta x}
$$

FIGURE B-1 Parameters of a straight line.
If you know two points $\left[\left(x_{1}, y_{1}\right)\right.$ and $\left.\left(x_{2}, y_{2}\right)\right]$ that lie on the line, you can generate the equation of the line by noting that the slope is the same for every pair of points on the line. Calling some general point on the line $(x, y)$, we can write

$$
\begin{equation*}
\frac{y-y_{1}}{x-x_{1}}=\frac{y_{2}-y_{1}}{x_{2}-x_{1}}=m \tag{B-1}
\end{equation*}
$$

which can be rearranged to the form

$$
\begin{aligned}
y-y_{1} & =\left(\frac{y_{2}-y_{1}}{x_{2}-x_{1}}\right)\left(x-x_{1}\right) \\
y & =\underbrace{\left(\frac{y_{2}-y_{1}}{x_{2}-x_{1}}\right)}_{m} x+\underbrace{y_{1}-\left(\frac{y_{2}-y_{1}}{x_{2}-x_{1}}\right) x_{1}}_{b}
\end{aligned}
$$

When you have a series of experimental points that should lie on a line, the best line is generally obtained by the method of least squares, described in Chapter 4. This method gives the slope and the intercept directly. If, instead, you wish to draw the "best" line by eye, you can derive the equation of the line by selecting two points that lie on the line and applying Equation B-1.

FIGURE B-2 A linear graph in which one axis is a logarithmic function.
Sometimes you are presented with a linear plot in which $x$ or $y$ or both are nonlinear functions. An example is shown in Figure B-2, in which the potential of an electrode is expressed as a function of the activity of analyte. Given that the slope is 29.6 mV and the line passes through the point ( $\mathcal{A}=10^{-4}, E=-10.2$ ), find the equation of the line. To do this, first note that the $y$-axis is linear but the $x$-axis is logarithmic. That is, the function $E$ versus $\mathcal{A}$ is not linear, but $E$ versus $\log \mathcal{A}$ is linear. The form of the straight line should therefore be

To find $b$, we can use the coordinates of the one known point in Equation B-1:

$$
\frac{y-y_{1}}{x-x_{1}}=\frac{E-E_{1}}{\log \mathcal{A}-\log \mathcal{A}_{1}}=\frac{E-(-10.2)}{\log \mathcal{A}-\log \left(10^{-4}\right)}=m=29.6
$$

or

$$
\begin{gathered}
E+10.2=29.6 \log \mathcal{A}+(29.6)(4) \\
E(\mathrm{mV})=29.6(\mathrm{mV}) \log \mathcal{A}+108.2(\mathrm{mV})
\end{gathered}
$$

The rules for propagation of uncertainty in Table 3-1 are special cases of a general formula. Suppose you wish to calculate the function, $F$, of several experimental quantities, $x, y, z, \ldots$ If the errors $\left(e_{x}, e_{y}, e_{z}, \ldots\right)$ in $x, y, z, \ldots$ are small, random, and independent of one another, then the uncertainty, $e_{F}$, in the function $F$ is approximately:*

$$
\begin{equation*}
e_{F}=\sqrt{\left(\frac{\partial F}{\partial x}\right)^{2} e_{x}^{2}+\left(\frac{\partial F}{\partial y}\right)^{2} e_{y}^{2}+\left(\frac{\partial F}{\partial z}\right)^{2} e_{z}^{2}+\ldots} \tag{C-1}
\end{equation*}
$$

The quantities in parentheses are partial derivatives, which are calculated in the same manner as ordinary derivatives, except that all but one variable are treated as constants. For example, if $F=3 x y^{2}$, then $\partial F / \partial x=3 y^{2}$ and $\partial F / \partial y=(3 x)(2 y)=6 x y$.

As an example of using Equation C-1, let's find the uncertainty in the function

$$
F=x^{y}=(2.00 \pm 0.02)^{3.00 \pm 0.09}
$$

The partial derivatives are

$$
\frac{\partial F}{\partial x}=y x^{y-1} \quad \frac{\partial F}{\partial y}=x^{y} \ln x
$$

Putting these quantities into Equation C-1 gives

$$
\begin{aligned}
e_{F} & =\sqrt{\left(y x^{y-1}\right)^{2} e_{x}^{2}+\left(x^{y} \ln x\right)^{2} e_{y}^{2}} \\
& =\sqrt{y^{2} x^{2 y-2} e_{x}^{2}+x^{2 y}(\ln x)^{2} e_{y}^{2}} \\
& =\sqrt{y^{2} x^{2 y}\left(\frac{e_{x}}{x}\right)^{2}+x^{2 y}(\ln x)^{2} e_{y}^{2}}
\end{aligned}
$$

Multiplying and dividing the second term by $y^{2}$ allows us to rearrange to a more pleasant form:

$$
e_{F}=\sqrt{y^{2} x^{2 y}\left(\frac{e_{x}}{x}\right)^{2}+y^{2} x^{2 y}(\ln x)^{2}\left(\frac{e_{y}}{y}\right)^{2}}
$$

Removing $\sqrt{y^{2} x^{2 y}}=y F$ from both terms gives

$$
e_{F}=y F \sqrt{\left(\frac{e_{x}}{x}\right)^{2}+(\ln x)^{2}\left(\frac{e_{y}}{y}\right)^{2}}
$$

Now for the number crunching. Disregarding uncertainties for a moment, we know that $F=2.00^{3.00}=8.00 \pm$ ? The uncertainty is obtained from the equation above:

$$
e_{F}=3.00 \cdot 8.00 \sqrt{\left(\frac{0.02}{2.00}\right)^{2}+(\ln 2.00)^{2}\left(\frac{0.09}{3.00}\right)^{2}}=0.55
$$

Reasonable answers are $F=8.0_{0} \pm 0.5_{5}$ or $8.0 \pm 0.6$.

[^17] R. de Levie, J. Chem. Ed. 2000, 77, 534.

## Exercises

C-1. Verify the following calculations.
(a) $2.36^{4.39 \pm 0.08}=43.4 \pm 3.0$
(b) $(2.36 \pm 0.06)^{4.39 \pm 0.08}=43.4 \pm 5.7$

C-2. For $F=\sin (2 \pi x y)$, show that

$$
e_{F}=2 \pi x y \cos (2 \pi x y) \sqrt{\left(\frac{e_{x}}{x}\right)^{2}+\left(\frac{e_{y}}{y}\right)^{2}}
$$

## Covariance in Propagation of Uncertainty

Equation C-1 presumes that errors in $x, y$, and $z$ are independent of one another. A common case in which this is not true is when we use the leastsquares slope and intercept to compute a new quantity, such as the value of $x$ from an observed value of $y$. In general, uncertainties in the slope and intercept are correlated, so they are not independent errors.

Let's restrict our attention to a function, $F$, of the two experimental parameters, $m$ and $b$, whose uncertainties are $s_{m}$ and $s_{b}$. If the uncertainties are correlated, the equation for propagation of uncertainty is ${ }^{\dagger}$

$$
e_{F}=\sqrt{\underbrace{\left(\frac{\partial F}{\partial m}\right)^{2} s_{m}^{2}+\left(\frac{\partial F}{\partial b}\right)^{2} s_{b}^{2}}_{\begin{array}{c}
\text { Variance terms from }  \tag{C-2}\\
\text { Equation C-1 }
\end{array}}+\underbrace{2\left(\frac{\partial F}{\partial m}\right)\left(\frac{\partial F}{\partial b}\right) s_{m b}}_{\begin{array}{c}
\text { Covariance accounts for } \\
\text { correlation of } m \text { and } b
\end{array}}}
$$

The last term in Equation C-2 reflects the fact that uncertainties in $m$ and $b$ are not independent of each other. The quantity $s_{m b}$ is called the covariance and it can be positive or negative.

In linear least-squares analysis, the variance and covariance are ${ }^{\ddagger}$
Variance:

$$
s_{m}^{2}=\frac{s_{y}^{2} n}{D} \quad s_{b}^{2}=\frac{s_{y}^{2} \sum\left(x_{i}^{2}\right)}{D}
$$

(Equations 4-21 and 4-22)

Covariance:

$$
\begin{equation*}
s_{m b}=\frac{-s_{y}^{2} \sum\left(x_{i}\right)}{D} \tag{C-3}
\end{equation*}
$$

where $s_{y}^{2}$ is the square of Equation 4-20, $D$ is given by Equation 4-18, and $n$ is the number of data points.

[^18]For the line $y=m x+b$, the $x$-intercept occurs when $y=0$, or $x=-b / m$. Let's designate the $x$-intercept as the function $F=-b / m$. Find the $x$-intercept and its uncertainty for the least-squares line in Figure 4-11.
Solution The following quantities are computed in Section 4-7:

$$
\begin{array}{llll}
m=0.61538 & s_{m}^{2}=0.0029586 & s_{y}^{2}=0.038462 & \sum\left(x_{i}\right)=14 \\
b=1.34615 & s_{b}^{2}=0.045859 & D=52 &
\end{array}
$$

The covariance in Equation C-3 is therefore

$$
s_{m b}=\frac{-s_{y}^{2} \sum\left(x_{i}\right)}{D}=\frac{-(0.038462)(14)}{52}=-0.010355
$$

The $x$-intercept is just $F=-b / m=-(1.34615) /(0.61538)=-2.1875$.
To find the uncertainty in $F$, we use Equation C-2. The derivatives in C-2 are

$$
\begin{gathered}
\frac{\partial F}{\partial m}=\frac{\partial(-b / m)}{\partial m}=\frac{b}{m^{2}}=\frac{1.34615}{0.61538^{2}}=3.5547 \\
\frac{\partial F}{\partial b}=\frac{\partial(-b / m)}{\partial b}=\frac{-1}{m}=\frac{-1}{0.61538}=-1.6250
\end{gathered}
$$

Now we can evaluate the uncertainty with Equation C-2:

$$
\begin{aligned}
e_{F} & =\sqrt{\left(\frac{\partial F}{\partial m}\right)^{2} s_{m}^{2}+\left(\frac{\partial F}{\partial b}\right)^{2} s_{b}^{2}+2\left(\frac{\partial F}{\partial m}\right)\left(\frac{\partial F}{\partial b}\right) s_{m b}} \\
& =\sqrt{\begin{array}{l}
(3.5547)^{2}(0.0029586)+ \\
(-1.6250)^{2}(0.045859)+ \\
2(3.5547)(-1.6250)(-0.010355)
\end{array}} \\
& =0.52736
\end{aligned}
$$

The final answer can now be written with a reasonable number of digits:

$$
F=-2.1875 \pm 0.52736=-2.1_{9} \pm 0.5_{3}
$$

If we had used Equation C-1 and ignored the covariance term in Equation C-2, we would have computed an uncertainty of $\pm 0.4_{0}$.

To learn how to compute variance and covariance and to see how to include weighting factors in least-squares curve fitting, see J. Tellinghuisen, "Understanding Least Squares Through Monte Carlo Calculations," J. Chem. Ed. 2005, 82, 157.

The oxidation number, or oxidation state, is a bookkeeping device used to keep track of the number of electrons formally associated with a particular element. The oxidation number is meant to tell how many electrons have been lost or gained by a neutral atom when it forms a compound. Because oxidation numbers have no real physical meaning, they are somewhat arbitrary, and not all chemists will assign the same oxidation number to a given element in an unusual compound. However, there are some ground rules that provide a useful start.

1. The oxidation number of an element by itself-e.g., $\mathrm{Cu}(s)$ or $\mathrm{Cl}_{2}(g)$-is 0 .
2. The oxidation number of H is almost always +1 , except in metal hydrides-e.g., NaH -in which H is -1 .
3. The oxidation number of oxygen is almost always -2 . The only common exceptions are peroxides, in which two oxygen atoms are connected and each has an oxidation number of -1 . Two examples are hydrogen peroxide $(\mathrm{H}-\mathrm{O}-\mathrm{O}-\mathrm{H})$ and its anion $\left(\mathrm{H}-\mathrm{O}-\mathrm{O}^{-}\right)$. The oxidation number of oxygen in gaseous $\mathrm{O}_{2}$ is, of course, 0 .
4. The alkali metals ( $\mathrm{Li}, \mathrm{Na}, \mathrm{K}, \mathrm{Rb}, \mathrm{Cs}, \mathrm{Fr}$ ) almost always have an oxidation number of +1 . The alkaline earth metals ( $\mathrm{Be}, \mathrm{Mg}, \mathrm{Ca}, \mathrm{Sr}$, $\mathrm{Ba}, \mathrm{Ra}$ ) are almost always in the +2 oxidation state.
5. The halogens ( $\mathrm{F}, \mathrm{Cl}, \mathrm{Br}, \mathrm{I}$ ) are usually in the -1 oxidation state. Exceptions occur when two different halogens are bound to each other or when a halogen is bound to more than one atom. When different halogens are bound to each other, we assign the oxidation number -1 to the more electronegative halogen.

The sum of the oxidation numbers of each atom in a molecule must equal the charge of the molecule. In $\mathrm{H}_{2} \mathrm{O}$, for example, we have

$$
\begin{array}{ll}
2 \text { hydrogen }=2(+1) & =+2 \\
\text { oxygen } & =\frac{-2}{0} \\
\text { net charge }
\end{array}
$$

In $\mathrm{SO}_{4}^{2-}$, sulfur must have an oxidation number of +6 so that the sum of the oxidation numbers will be -2 :

$$
\begin{array}{lll}
\text { oxygen }=4(-2) & = & -8 \\
\text { sulfur } & =\frac{+6}{-2} \\
\text { net charge }
\end{array}
$$

In benzene $\left(\mathrm{C}_{6} \mathrm{H}_{6}\right)$, the oxidation number of each carbon must be -1 if hydrogen is assigned the number +1 . In cyclohexane $\left(\mathrm{C}_{6} \mathrm{H}_{12}\right)$, the oxidation number of each carbon must be -2 , for the same reason. The carbons in benzene are in a higher oxidation state than those in cyclohexane.

The oxidation number of iodine in $\mathrm{ICl}_{2}^{-}$is +1 . This is unusual, because halogens are usually -1 . However, because chlorine is more electronegative than iodine, we assign Cl as -1 , thereby forcing I to be +1 .

The oxidation number of As in $\mathrm{As}_{2} \mathrm{~S}_{3}$ is +3 , and the value for S is -2 . This is arbitrary but reasonable. Because $S$ is more electronegative than As, we make $S$ negative and As positive; and, because $S$ is in the same family as oxygen, which is usually -2 , we assign $S$ as -2 , thus leaving As as +3 .

The oxidation number of S in $\mathrm{S}_{4} \mathrm{O}_{6}^{2-}$ (tetrathionate) is +2.5 . The fractional oxidation state comes about because six O atoms contribute -12 . Because the charge is -2 , the four S atoms must contribute +10 . The average oxidation number of S must be $+\frac{10}{4}=2.5$.

The oxidation number of Fe in $\mathrm{K}_{3} \mathrm{Fe}(\mathrm{CN})_{6}$ is +3 . To make this assignment, we first recognize cyanide $\left(\mathrm{CN}^{-}\right)$as a common ion that carries a charge of -1 . Six cyanide ions give -6 , and three potassium ions $\left(\mathrm{K}^{+}\right)$ give +3 . Therefore, Fe should have an oxidation number of +3 for the whole formula to be neutral. In this approach, it is not necessary to assign
individual oxidation numbers to carbon and nitrogen, as long as we recognize that the charge of CN is -1 .

## Problems

Answers are given at the end of this appendix.
D-1. Write the oxidation state of the boldface atom in each of the following species.
(a) AgBr
(p) $\mathbf{N}_{2}$
(b) $\mathrm{S}_{2} \mathrm{O}_{3}^{2-}$
(q) $\mathrm{NH}_{4}^{+}$
(c) $\mathrm{SeF}_{6}$
(r) $\mathrm{N}_{2} \mathrm{H}_{5}^{+}$
(d) $\mathrm{HS}_{2} \mathrm{O}_{3}^{-}$
(s) $\mathrm{HAsO}_{3}^{2-}$
(e) $\mathrm{HO}_{2}$
(t) $\mathbf{C o}_{2}(\mathrm{CO})_{8}(\mathrm{CO}$ group is neutral)
(f) NO
(u) $\left(\mathrm{CH}_{3}\right)_{4} \mathrm{Li}_{4}$
(g) $\mathbf{C r}^{3+}$
(v) $\mathrm{P}_{4} \mathrm{O}_{10}$
(h) $\mathrm{MnO}_{2}$
(w) $\mathrm{C}_{2} \mathrm{H}_{6} \mathrm{O}$ (ethanol, $\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{OH}$ )
(i) $\mathbf{P b}(\mathrm{OH})_{3}^{-}$
(x) $\mathrm{VO}\left(\mathrm{SO}_{4}\right)$
(y) $\mathrm{Fe}_{3} \mathrm{O}_{4}$
(j)
(k)
$\mathrm{ClO}^{-}$
(z) $\mathrm{C}_{3} \mathrm{H}_{3}^{+}$
(l) $\mathrm{K}_{4} \mathrm{Fe}(\mathrm{CN})_{6}$
(m) $\mathrm{ClO}_{2}$
(n) $\mathrm{ClO}_{2}^{-}$
(o) $\mathbf{M n}(\mathrm{CN})_{6}^{4-}$
Structure:

D-2. Identify the oxidizing agent and the reducing agent on the left side of each of the following reactions.
(a) $\mathrm{Cr}_{2} \mathrm{O}_{7}^{2-}+3 \mathrm{Sn}^{2+}+14 \mathrm{H}^{+} \rightarrow 2 \mathrm{Cr}^{3+}+3 \mathrm{Sn}^{4+}+7 \mathrm{H}_{2} \mathrm{O}$
(b) $4 \mathrm{I}^{-}+\mathrm{O}_{2}+4 \mathrm{H}^{+} \rightarrow 2 \mathrm{I}_{2}+2 \mathrm{H}_{2} \mathrm{O}$
(c) $5 \mathrm{CH}_{3} \stackrel{\|}{\mathrm{CH}}+2 \mathrm{MnO}_{4}^{-}+6 \mathrm{H}^{+} \rightarrow 5 \mathrm{CH}_{3} \stackrel{\|}{\mathrm{COH}}+2 \mathrm{Mn}^{2+}+3 \mathrm{H}_{2} \mathrm{O}$
(d) $\mathrm{HOCH}_{2} \mathrm{CHOHCH}_{2} \mathrm{OH}+2 \mathrm{IO}_{4}^{-} \rightarrow$

$$
\text { Glycerol } \quad 2 \mathrm{H}_{2} \mathrm{C}=\mathrm{O}+\mathrm{HCO}_{2} \mathrm{H}+2 \mathrm{IO}_{3}^{-}+\mathrm{H}_{2} \mathrm{O}
$$

Formaldehyde Formic acid
(e) $\mathrm{C}_{8} \mathrm{H}_{8}+2 \mathrm{Na} \rightarrow \mathrm{C}_{8} \mathrm{H}_{8}^{2-}+2 \mathrm{Na}^{+}$
$\mathrm{C}_{8} \mathrm{H}_{8}$ is cyclooctatetraene with the structure
(f) $\mathrm{I}_{2}+\mathrm{OH}^{-} \rightarrow \mathrm{HOI}+\mathrm{I}^{-}$

Hypoiodous
acid

## Balancing Redox Reactions

To balance a reaction involving oxidation and reduction, we must first identify which element is oxidized and which is reduced. We then break the net reaction into two imaginary half-reactions, one of which involves only oxidation and the other only reduction. Although free electrons never appear in a balanced net reaction, they do appear in balanced half-reactions. If we are dealing with aqueous solutions, we proceed to balance each half-reaction, using $\mathrm{H}_{2} \mathrm{O}$ and either $\mathrm{H}^{+}$or $\mathrm{OH}^{-}$, as necessary. A reaction is balanced when the number of atoms of each element is the same on both sides and the net charge is the same on both sides.*

[^19]
## Acidic Solutions

Here are the steps we will follow:

1. Assign oxidation numbers to the elements that are oxidized or reduced.
2. Break the reaction into two half-reactions, one involving oxidation and the other reduction.
3. For each half-reaction, balance the number of atoms that are oxidized or reduced.
4. Balance the electrons to account for the change in oxidation number by adding electrons to one side of each half-reaction.
5. Balance oxygen atoms by adding $\mathrm{H}_{2} \mathrm{O}$ to one side of each halfreaction.
6. Balance the H atoms by adding $\mathrm{H}^{+}$to one side of each half-reaction.
7. Multiply each half-reaction by the number of electrons in the other half-reaction so that the number of electrons on each side of the total reaction will cancel. Then add the two half-reactions and simplify to the smallest integral coefficients.

## EXAMPLE Balancing a Redox Equation

Balance the following equation using $\mathrm{H}^{+}$, but not $\mathrm{OH}^{-}$:

$$
\begin{array}{ccc}
\mathrm{Fe}^{2+} & +\mathrm{MnO}_{4}^{-} & \mathrm{Fe}^{3+} \\
+2 & +\mathrm{Mn}^{2+} \\
+7 & +3 & +2
\end{array}
$$

## Solution

1. Assign oxidation numbers. They are assigned for Fe and Mn in each species in the above reaction.
2. Break the reaction into two half-reactions.

3. Balance the atoms that are oxidized or reduced. Because there is only one Fe or Mn in each species on each side of the equation, the atoms of Fe and Mn are already balanced.
4. Balance electrons. Electrons are added to account for the change in each oxidation state.

$$
\begin{aligned}
\mathrm{Fe}^{2+} & \rightleftharpoons \mathrm{Fe}^{3+}+\mathrm{e}^{-} \\
\mathrm{MnO}_{4}^{-}+5 \mathrm{e}^{-} & \rightleftharpoons \mathrm{Mn}^{2+}
\end{aligned}
$$

In the second case, we need $5 \mathrm{e}^{-}$on the left side to take Mn from +7 to +2 .
5. Balance oxygen atoms. There are no oxygen atoms in the Fe half-reaction. There are four oxygen atoms on the left side of the Mn reaction, so we add four molecules of $\mathrm{H}_{2} \mathrm{O}$ to the right side:

$$
\mathrm{MnO}_{4}^{-}+5 \mathrm{e}^{-} \rightleftharpoons \mathrm{Mn}^{2+}+4 \mathrm{H}_{2} \mathrm{O}
$$

6. Balance hydrogen atoms. The Fe equation is already balanced. The Mn equation needs $8 \mathrm{H}^{+}$on the left.

$$
\mathrm{MnO}_{4}^{-}+5 \mathrm{e}^{-}+8 \mathrm{H}^{+} \rightarrow \mathrm{Mn}^{2+}+4 \mathrm{H}_{2} \mathrm{O}
$$

At this point, each half-reaction must be completely balanced (the same number of atoms and charge on each side) or you have made a mistake.
7. Multiply and add the reactions. We multiply the Fe equation by 5 and the Mn equation by 1 and add:

$$
\begin{aligned}
5 \mathrm{Fe}^{2+} & \rightleftharpoons 5 \mathrm{Fe}^{3+}+5 \mathrm{e}^{-} \\
\mathrm{MnO}_{4}^{-}+5 \mathrm{e}^{-}+8 \mathrm{H}^{+} & \rightleftharpoons \mathrm{Mn}^{2+}+4 \mathrm{H}_{2} \mathrm{O} \\
5 \mathrm{Fe}^{2+}+\mathrm{MnO}_{4}^{-}+8 \mathrm{H}^{+} & \rightleftharpoons 5 \mathrm{Fe}^{3+}+\mathrm{Mn}^{2+}+4 \mathrm{H}_{2} \mathrm{O}
\end{aligned}
$$

The total charge on each side is +17 , and we find the same number of atoms of each element on each side. The equation is balanced.

## EXAMPLE A Reverse Disproportionation

Now try the next reaction, which represents the reverse of a disproportionation. (In a disproportionation, an element in one oxidation state reacts to give the same element in higher and lower oxidation states.)

$\quad$| $\mathrm{I}_{2}$ |
| :---: |
| 0 |
| 0 |
| Iodine |
| Iodate |

Io

Solution

1. The oxidation numbers are assigned above. Note that chlorine has an oxidation number of -1 on both sides of the equation. Only iodine is involved in electron transfer.
2. Oxidation half-reaction: $\quad \mathrm{I}_{2} \rightleftharpoons \mathrm{ICl}_{2}^{-}$

$$
\text { Reduction half-reaction: } \begin{array}{ll}
\mathrm{IO}_{3}^{-} \\
+5
\end{array} \rightleftharpoons \underset{+1}{\mathrm{ICl}_{2}^{-}}
$$

3. We need to balance I atoms in the first reaction and add $\mathrm{Cl}^{-}$to each reaction to balance Cl .

$$
\begin{gathered}
\mathrm{I}_{2}+4 \mathrm{Cl}^{-} \rightleftharpoons 2 \mathrm{ICl}_{2}^{-} \\
\mathrm{IO}_{3}^{-}+2 \mathrm{Cl}^{-} \rightleftharpoons \mathrm{ICl}_{2}^{-}
\end{gathered}
$$

4. Now add electrons to each.

$$
\begin{gathered}
\mathrm{I}_{2}+4 \mathrm{Cl}^{-} \rightleftharpoons 2 \mathrm{ICl}_{2}^{-}+2 \mathrm{e}^{-} \\
\mathrm{IO}_{3}^{-}+2 \mathrm{Cl}^{-}+4 \mathrm{e}^{-} \rightleftharpoons \mathrm{ICl}_{2}^{-}
\end{gathered}
$$

The first reaction needs $2 \mathrm{e}^{-}$because there are two I atoms, each of which changes from 0 to +1 .
5. The second reaction needs $3 \mathrm{H}_{2} \mathrm{O}$ on the right side to balance oxygen atoms.

$$
\mathrm{IO}_{3}^{-}+2 \mathrm{Cl}^{-}+4 \mathrm{e}^{-} \rightleftharpoons \mathrm{ICl}_{2}^{-}+3 \mathrm{H}_{2} \mathrm{O}
$$

6. The first reaction is balanced, but the second needs $6 \mathrm{H}^{+}$on the left.

$$
\mathrm{IO}_{3}^{-}+2 \mathrm{Cl}^{-}+4 \mathrm{e}^{-}+6 \mathrm{H}^{+} \rightleftharpoons \mathrm{ICl}_{2}^{-}+3 \mathrm{H}_{2} \mathrm{O}
$$

As a check, the charge on each side of this half-reaction is -1 , and all atoms are balanced.
7. Multiply and add.

$$
\begin{array}{ll}
2\left(\mathrm{I}_{2}+4 \mathrm{Cl}^{-}\right. & \left.\rightleftharpoons 2 \mathrm{ICl}_{2}^{-}+2 \mathrm{e}^{-}\right) \\
\mathrm{IO}_{3}^{-}+2 \mathrm{Cl}^{-}+4 \mathrm{e}^{-}+6 \mathrm{H}^{+} & \rightleftharpoons \mathrm{ICl}_{2}^{-}+3 \mathrm{H}_{2} \mathrm{O} \\
\hline 2 \mathrm{I}_{2}+\mathrm{IO}_{3}^{-}+10 \mathrm{Cl}^{-}+6 \mathrm{H}^{+} & \rightleftharpoons \mathrm{ICl}_{2}^{-}+3 \mathrm{H}_{2} \mathrm{O} \tag{D-1}
\end{array}
$$

We multiplied the first reaction by 2 so that there would be the same number of electrons in each half-reaction. You could have multiplied the first reaction by 4 and the second by 2 , but then all coefficients would simply be doubled. We customarily write the smallest coefficients.

## Basic Solutions

The method many people prefer for basic solutions is to balance the equation first with $\mathrm{H}^{+}$. The answer can then be converted into one in which $\mathrm{OH}^{-}$is used instead. This is done by adding to each side of the equation a number of hydroxide ions equal to the number of $\mathrm{H}^{+}$ions appearing in the equation. For example, to balance Equation D-1 with $\mathrm{OH}^{-}$instead of $\mathrm{H}^{+}$, proceed as follows:

$$
\begin{aligned}
& 2 \mathrm{I}_{2}+\mathrm{IO}_{3}^{-}+10 \mathrm{Cl}^{-}+6 \mathrm{H}^{+} \rightleftharpoons 5 \mathrm{ICl}_{2}+3 \mathrm{H}_{2} \mathrm{O} \\
& \frac{+6 \mathrm{OH}^{-}}{2 \mathrm{I}_{2}+\mathrm{IO}_{3}^{-}+10 \mathrm{Cl}^{-} \underbrace{}_{\begin{array}{c}
6 \mathrm{H}_{2} \mathrm{O} \\
\Downarrow \\
+6 \mathrm{H}^{+}+6 \mathrm{OH}^{-}
\end{array}} \stackrel{6 \mathrm{OH}^{-}}{3 \mathrm{H}_{2} \mathrm{O}}+3 \mathrm{H}_{2} \mathrm{O}+6 \mathrm{OH}^{-}}
\end{aligned}
$$

Realizing that $6 \mathrm{H}^{+}+6 \mathrm{OH}^{-}=6 \mathrm{H}_{2} \mathrm{O}$, and canceling $3 \mathrm{H}_{2} \mathrm{O}$ on each side, gives the final result:

$$
2 \mathrm{I}_{2}+\mathrm{IO}_{3}^{-}+10 \mathrm{Cl}^{-}+3 \mathrm{H}_{2} \mathrm{O} \rightleftharpoons 5 \mathrm{ICl}_{2}+6 \mathrm{OH}^{-}
$$

## Problems

D-3. Balance the following reactions by using $\mathrm{H}^{+}$but not $\mathrm{OH}^{-}$.
(a) $\mathrm{Fe}^{3+}+\mathrm{Hg}_{2}^{2+} \rightleftharpoons \mathrm{Fe}^{2+}+\mathrm{Hg}^{2+}$
(b) $\mathrm{Ag}+\mathrm{NO}_{3}^{-} \rightleftharpoons \mathrm{Ag}^{+}+\mathrm{NO}$
(c) $\mathrm{VO}^{2+}+\mathrm{Sn}^{2+} \rightleftharpoons \mathrm{V}^{3+}+\mathrm{Sn}^{4+}$
(d) $\mathrm{SeO}_{4}^{2-}+\mathrm{Hg}+\mathrm{Cl}^{-} \rightleftharpoons \mathrm{SeO}_{3}^{2-}+\mathrm{Hg}_{2} \mathrm{Cl}_{2}$
(e) $\mathrm{CuS}+\mathrm{NO}_{3}^{-} \rightleftharpoons \mathrm{Cu}^{2+}+\mathrm{SO}_{4}^{2-}+\mathrm{NO}$
(f) $\mathrm{S}_{2} \mathrm{O}_{3}^{2-}+\mathrm{I}_{2} \rightleftharpoons \mathrm{I}^{-}+\mathrm{S}_{4} \mathrm{O}_{6}^{2-}$
(g) $\mathrm{ClO}_{3}^{-}+\mathrm{As}_{2} \mathrm{~S}_{3} \rightleftharpoons \mathrm{Cl}^{-}+\mathrm{H}_{2} \mathrm{AsO}_{4}^{-}+\mathrm{SO}_{4}^{2-}$
(h) $\mathrm{Cr}_{2} \mathrm{O}_{7}^{2-}+\mathrm{CH}_{3} \stackrel{\|}{\mathrm{C}} \rightleftharpoons \mathrm{CH}_{3} \mathrm{COH}+\mathrm{Cr}^{3+}$
(i) $\mathrm{MnO}_{4}^{2-} \rightleftharpoons \mathrm{MnO}_{2}+\mathrm{MnO}_{4}^{-}$
(j) $\mathrm{Hg}_{2} \mathrm{SO}_{4}+\mathrm{Ca}^{2+}+\mathrm{S}_{8} \rightleftharpoons \mathrm{Hg}_{2}^{2+}+\mathrm{CaS}_{2} \mathrm{O}_{3}$
(k) $\mathrm{ClO}_{3}^{-} \rightleftharpoons \mathrm{Cl}_{2}+\mathrm{O}_{2}$

D-4. Balance the following equations by using $\mathrm{OH}^{-}$but not $\mathrm{H}^{+}$.
(a) $\mathrm{PbO}_{2}+\mathrm{Cl}^{-} \rightleftharpoons \mathrm{ClO}^{-}+\mathrm{Pb}(\mathrm{OH})_{3}^{-}$
(b) $\mathrm{HNO}_{2}+\mathrm{SbO}^{+} \rightleftharpoons \mathrm{NO}+\mathrm{Sb}_{2} \mathrm{O}_{5}$
(c) $\mathrm{Ag}_{2} \mathrm{~S}+\mathrm{CN}^{-}+\mathrm{O}_{2} \rightleftharpoons \mathrm{~S}+\mathrm{Ag}(\mathrm{CN})_{2}^{-}+\mathrm{OH}^{-}$
(d) $\mathrm{HO}_{2}^{-}+\mathrm{Cr}(\mathrm{OH})_{3}^{-} \rightleftharpoons \mathrm{CrO}_{4}^{2-}+\mathrm{OH}^{-}$
(e) $\mathrm{ClO}_{2}+\mathrm{OH}^{-} \rightleftharpoons \mathrm{ClO}_{2}^{-}+\mathrm{ClO}_{3}^{-}$
(f) $\mathrm{WO}_{3}^{-}+\mathrm{O}_{2} \rightleftharpoons \mathrm{HW}_{6} \mathrm{O}_{21}^{5-}+\mathrm{OH}^{-}$
(g) $\mathrm{Mn}_{2} \mathrm{O}_{3}+\mathrm{CN}^{-} \rightleftharpoons \mathrm{Mn}(\mathrm{CN})_{6}^{4-}+(\mathrm{CN})_{2}$
(h) $\mathrm{Cu}^{2+}+\mathrm{H}_{2} \rightleftharpoons \mathrm{Cu}+\mathrm{H}_{2} \mathrm{O}$
(i) $\mathrm{BH}_{4}^{-}+\mathrm{H}_{2} \mathrm{O} \rightleftharpoons \mathrm{H}_{3} \mathrm{BO}_{3}+\mathrm{H}_{2}$
(j) $\mathrm{Mn}_{2} \mathrm{O}_{3}+\mathrm{Hg}+\mathrm{CN}^{-} \rightleftharpoons \mathrm{Mn}(\mathrm{CN})_{6}^{4-}+\mathrm{Hg}(\mathrm{CN})_{2}$
(k) $\mathrm{MnO}_{4}^{-}+\stackrel{\mathrm{O}}{\mathrm{HCCH}_{2} \mathrm{CH}_{2} \mathrm{OH}} \rightleftharpoons \mathrm{CH}_{2}\left(\mathrm{CO}_{2}^{-}\right)_{2}+\mathrm{MnO}_{2}$
(l) $\mathrm{K}_{3} \mathrm{~V}_{5} \mathrm{O}_{14}+\mathrm{HOCH}_{2} \mathrm{CHOHCH}_{2} \mathrm{OH} \rightleftharpoons \mathrm{VO}(\mathrm{OH})_{2}+\mathrm{HCO}_{2}^{-}+\mathrm{K}^{+}$

D-2. Oxidizing agent Reducing agent
(a) $\mathrm{Cr}_{2} \mathrm{O}_{7}^{2-} \quad \mathrm{Sn}^{2+}$
(b) $\mathrm{O}_{2}$
(c) $\mathrm{MnO}_{4}^{-}$
$\mathrm{I}^{-}$
(d) $\mathrm{IO}_{4}^{-} \quad$ Glycerol
(e) $\mathrm{C}_{8} \mathrm{H}_{8} \quad \mathrm{Na}$
(f) $\mathrm{I}_{2} \quad \mathrm{I}_{2}$

Reaction (f) is called a disproportionation, because an element in one oxidation state is transformed into two different oxidation states-one higher and one lower than the original oxidation state.
D-3. (a) $2 \mathrm{Fe}^{3+}+\mathrm{Hg}_{2}^{2+} \rightleftharpoons 2 \mathrm{Fe}^{2+}+2 \mathrm{Hg}^{2+}$
(b) $3 \mathrm{Ag}+\mathrm{NO}_{3}^{-}+4 \mathrm{H}^{+} \rightleftharpoons 3 \mathrm{Ag}^{+}+\mathrm{NO}+2 \mathrm{H}_{2} \mathrm{O}$
(c) $4 \mathrm{H}^{+}+2 \mathrm{VO}^{2+}+\mathrm{Sn}^{2+} \rightleftharpoons 2 \mathrm{~V}^{3+}+\mathrm{Sn}^{4+}+2 \mathrm{H}_{2} \mathrm{O}$
(d) $2 \mathrm{Hg}+2 \mathrm{Cl}^{-}+\mathrm{SeO}_{4}^{2-}+2 \mathrm{H}^{+} \rightleftharpoons \mathrm{Hg}_{2} \mathrm{Cl}_{2}+\mathrm{SeO}_{3}^{2-}+\mathrm{H}_{2} \mathrm{O}$
(e) $3 \mathrm{CuS}+8 \mathrm{NO}_{3}^{-}+8 \mathrm{H}^{+} \rightleftharpoons 3 \mathrm{Cu}^{2+}+3 \mathrm{SO}_{4}^{2-}+8 \mathrm{NO}+4 \mathrm{H}_{2} \mathrm{O}$
(f) $2 \mathrm{~S}_{2} \mathrm{O}_{3}^{2-}+\mathrm{I}_{2} \rightleftharpoons \mathrm{~S}_{4} \mathrm{O}_{6}^{2-}+2 \mathrm{I}^{-}$
(g) $14 \mathrm{ClO}_{3}^{-}+3 \mathrm{As}_{2} \mathrm{~S}_{3}+18 \mathrm{H}_{2} \mathrm{O} \rightleftharpoons$

$$
14 \mathrm{Cl}^{-}+6 \mathrm{H}_{2} \mathrm{AsO}_{4}^{-}+9 \mathrm{SO}_{4}^{2-}+24 \mathrm{H}^{+}
$$

(h) $\mathrm{Cr}_{2} \mathrm{O}_{7}^{2-}+3 \mathrm{CH}_{3} \mathrm{CHO}+8 \mathrm{H}^{+} \rightleftharpoons 2 \mathrm{Cr}^{3+}+3 \mathrm{CH}_{3} \mathrm{CO}_{2} \mathrm{H}+4 \mathrm{H}_{2} \mathrm{O}$
(i) $4 \mathrm{H}^{+}+3 \mathrm{MnO}_{4}^{2-} \rightleftharpoons \mathrm{MnO}_{2}+2 \mathrm{MnO}_{4}^{-}+2 \mathrm{H}_{2} \mathrm{O}$
(j) $2 \mathrm{Hg}_{2} \mathrm{SO}_{4}+3 \mathrm{Ca}^{2+}+\frac{1}{2} \mathrm{~S}_{8}+\mathrm{H}_{2} \mathrm{O} \rightleftharpoons 2 \mathrm{Hg}_{2}^{2+}+3 \mathrm{CaS}_{2} \mathrm{O}_{3}+2 \mathrm{H}^{+}$
(k) $2 \mathrm{H}^{+}+2 \mathrm{ClO}_{3}^{-} \rightleftharpoons \mathrm{Cl}_{2}+\frac{5}{2} \mathrm{O}_{2}+\mathrm{H}_{2} \mathrm{O}$

The balanced half-reaction for $\mathrm{As}_{2} \mathrm{~S}_{3}$ in $(\mathbf{g})$ is

$$
\underset{+3-2}{\mathrm{As}_{2} \mathrm{~S}_{3}+20 \mathrm{H}_{2} \mathrm{O}} \underset{+3-2}{2 \mathrm{H}_{2} \mathrm{AsO}_{4}^{-}}+\underset{+6}{3 \mathrm{SO}_{4}^{2-}}+28 \mathrm{e}^{-}+36 \mathrm{H}^{+}
$$

Because $\mathrm{As}_{2} \mathrm{~S}_{3}$ is a single compound, we must consider the $\mathrm{As}_{2} \mathrm{~S}_{3} \rightarrow$ $\mathrm{H}_{2} \mathrm{AsO}_{4}^{-}$and $\mathrm{As}_{2} \mathrm{~S}_{3} \rightarrow \mathrm{SO}_{4}^{2-}$ reactions together. The net change in oxidation number for the two As atoms is $2(5-3)=+4$. The net change in oxidation number for the three S atoms is $3[6-(-2)]=+24$. Therefore, $24+4=$ $28 \mathrm{e}^{-}$are involved in the half-reaction.
D-4. (a) $\mathrm{H}_{2} \mathrm{O}+\mathrm{OH}^{-}+\mathrm{PbO}_{2}+\mathrm{Cl}^{-} \rightleftharpoons \mathrm{Pb}(\mathrm{OH})_{3}^{-}+\mathrm{ClO}^{-}$
(b) $4 \mathrm{HNO}_{2}+2 \mathrm{SbO}^{-}+2 \mathrm{OH}^{-} \rightleftharpoons 4 \mathrm{NO}+\mathrm{Sb}_{2} \mathrm{O}_{5}+3 \mathrm{H}_{2} \mathrm{O}$
(c) $\mathrm{Ag}_{2} \mathrm{~S}+4 \mathrm{CN}^{-}+\frac{1}{2} \mathrm{O}_{2}+\mathrm{H}_{2} \mathrm{O} \rightleftharpoons \mathrm{S}+2 \mathrm{Ag}(\mathrm{CN})_{2}^{-}+2 \mathrm{OH}^{-}$
(d) $2 \mathrm{HO}_{2}^{-}+\mathrm{Cr}(\mathrm{OH})_{3}^{-\frac{1}{2}} \rightleftharpoons \mathrm{CrO}_{4}^{2-}+\mathrm{OH}^{-}+2 \mathrm{H}_{2} \mathrm{O}$
(e) $2 \mathrm{ClO}_{2}+2 \mathrm{OH}^{-} \rightleftharpoons \mathrm{ClO}_{2}^{-}+\mathrm{ClO}_{3}^{-}+\mathrm{H}_{2} \mathrm{O}$
(f) $12 \mathrm{WO}_{3}^{-}+3 \mathrm{O}_{2}+2 \mathrm{H}_{2} \mathrm{O} \rightleftharpoons 2 \mathrm{HW}_{6} \mathrm{O}_{21}^{5-}+2 \mathrm{OH}^{-}$
(g) $\mathrm{Mn}_{2} \mathrm{O}_{3}+14 \mathrm{CN}^{-}+3 \mathrm{H}_{2} \mathrm{O} \rightleftharpoons 2 \mathrm{Mn}(\mathrm{CN})_{6}^{4-}+(\mathrm{CN})_{2}+6 \mathrm{OH}^{-}$
(h) $\mathrm{Cu}^{2+}+\mathrm{H}_{2}+2 \mathrm{OH}^{-} \rightleftharpoons \mathrm{Cu}+2 \mathrm{H}_{2} \mathrm{O}$
(i) $\mathrm{BH}_{4}^{-}+4 \mathrm{H}_{2} \mathrm{O} \rightleftharpoons \mathrm{H}_{3} \mathrm{BO}_{3}+4 \mathrm{H}_{2}+\mathrm{OH}^{-}$
(j) $3 \mathrm{H}_{2} \mathrm{O}+\mathrm{Mn}_{2} \mathrm{O}_{3}+\mathrm{Hg}+14 \mathrm{CN}^{-} \rightleftharpoons$

$$
2 \mathrm{Mn}(\mathrm{CN})_{6}^{4-}+\mathrm{Hg}(\mathrm{CN})_{2}+6 \mathrm{OH}^{-}
$$

(k) $\stackrel{\stackrel{\mathrm{O}}{\|}}{2 \mathrm{MnO}_{4}^{-}}+\stackrel{\mathrm{HCCH}_{2} \mathrm{CH}_{2} \mathrm{OH}}{\rightleftharpoons} 2 \mathrm{MnO}_{2}+2 \mathrm{H}_{2} \mathrm{O}+\mathrm{CH}_{2}\left(\mathrm{CO}_{2}^{-}\right)_{2}$

For (k), the organic half-reaction is $8 \mathrm{OH}^{-}+\mathrm{C}_{3} \mathrm{H}_{6} \mathrm{O}_{2} \rightleftharpoons$

$$
\mathrm{C}_{3} \mathrm{H}_{2} \mathrm{O}_{4}^{2-}+6 \mathrm{e}^{-}+6 \mathrm{H}_{2} \mathrm{O} .
$$

(l) $32 \mathrm{H}_{2} \mathrm{O}+8 \mathrm{~K}_{3} \mathrm{~V}_{5} \mathrm{O}_{14}+5 \mathrm{HOCH}_{2} \mathrm{CHOHCH}_{2} \mathrm{OH} \rightleftharpoons$ $40 \mathrm{VO}(\mathrm{OH})_{2}+15 \mathrm{HCO}_{2}^{-}+9 \mathrm{OH}^{-}+24 \mathrm{~K}^{+}$
For (l), the two half-reactions are $\mathrm{K}_{3} \mathrm{~V}_{5} \mathrm{O}_{14}+9 \mathrm{H}_{2} \mathrm{O}+5 \mathrm{e}^{-} \rightleftharpoons$ $5 \mathrm{VO}(\mathrm{OH})_{2}+8 \mathrm{OH}^{-}+3 \mathrm{~K}^{+}$and $\mathrm{C}_{3} \mathrm{H}_{8} \mathrm{O}_{3}+11 \mathrm{OH}^{-} \rightleftharpoons 3 \mathrm{HCO}_{2}^{-}+$ $8 \mathrm{e}^{-}+8 \mathrm{H}_{2} \mathrm{O}$.

The normality, N , of a redox reagent is $n$ times the molarity, where $n$ is the number of electrons donated or accepted by that species in a chemical reaction.

$$
\begin{equation*}
\mathrm{N}=n \mathrm{M} \tag{E-1}
\end{equation*}
$$

For example, in the half-reaction

$$
\begin{equation*}
\mathrm{MnO}_{4}^{-}+8 \mathrm{H}^{+}+5 \mathrm{e}^{-} \rightleftharpoons \mathrm{Mn}^{2+}+4 \mathrm{H}_{2} \mathrm{O} \tag{E-2}
\end{equation*}
$$

the normality of permanganate ion is five times its molarity, because each $\mathrm{MnO}_{4}^{-}$accepts $5 \mathrm{e}^{-}$. If the molarity of permanganate is 0.1 M , the normality for the reaction

$$
\begin{equation*}
\mathrm{MnO}_{4}^{-}+5 \mathrm{Fe}^{2+}+8 \mathrm{H}^{+} \rightleftharpoons \mathrm{Mn}^{2+}+5 \mathrm{Fe}^{3+}+4 \mathrm{H}_{2} \mathrm{O} \tag{E-3}
\end{equation*}
$$

is $5 \times 0.1=0.5 \mathrm{~N}$ (read " 0.5 normal"). In this reaction, each $\mathrm{Fe}^{2+}$ ion donates one electron. The normality of ferrous ion equals the molarity of ferrous ion, even though it takes five ferrous ions to balance the reaction.

In the half-reaction

$$
\begin{equation*}
\mathrm{MnO}_{4}^{-}+4 \mathrm{H}^{+}+3 \mathrm{e}^{-} \rightleftharpoons \mathrm{MnO}_{2}+2 \mathrm{H}_{2} \mathrm{O} \tag{E-4}
\end{equation*}
$$

each $\mathrm{MnO}_{4}^{-}$ion accepts only three electrons. The normality of permanganate for this reaction is equal to three times the molarity of permanganate. A 0.06 N permanganate solution for this reaction contains $0.02 \mathrm{M} \mathrm{MnO}_{4}^{-}$.

The normality of a solution is a statement of the moles of "reacting units" per liter. One mole of reacting units is called one equivalent. Therefore, the units of normality are equivalents per liter (equiv/L). For redox reagents, one equivalent is the amount of substance that can donate or accept one mole of electrons. It is possible to speak of equivalents only with respect to a particular half-reaction. For example, in Reaction E-2, there are five equivalents per mole of $\mathrm{MnO}_{4}^{-}$; but, in Reaction E-4, there are only three equivalents per mole of $\mathrm{MnO}_{4}^{-}$. The mass of substance containing one equivalent is called the equivalent mass. The formula mass of $\mathrm{KMnO}_{4}$ is 158.033 9. The equivalent mass of $\mathrm{KMnO}_{4}$ for Reaction E-2 is $158.0339 / 5=31.6068$ g/equiv. The equivalent mass of $\mathrm{KMnO}_{4}$ for Reaction E-4 is $158.0339 / 3=52.6780$ g/equiv.

## EXAMPLE Finding Normality

Find the normality of a solution containing 6.34 g of ascorbic acid in 250.0 mL if the relevant half-reaction is

Solution The formula mass of ascorbic acid $\left(\mathrm{C}_{6} \mathrm{H}_{8} \mathrm{O}_{6}\right)$ is 176.124. In 6.34 g , there are $(6.34 \mathrm{~g}) /(176.124 \mathrm{~g} / \mathrm{mol})=3.60 \times 10^{-2} \mathrm{~mol}$. Because each mole contains 2 equivalents in this example, $6.34 \mathrm{~g}=(2$ equiv/mot $)$ $\left(3.60 \times 10^{-2}\right.$ mot $)=7.20 \times 10^{-2}$ equivalent. The normality is $\left(7.20 \times 10^{-2}\right.$ equiv) $/(0.2500 \mathrm{~L})=0.288 \mathrm{~N}$.

## EXAMPLE Using Normality

How many grams of potassium oxalate should be dissolved in 500.0 mL to make a 0.100 N solution for titration of $\mathrm{MnO}_{4}^{-}$?

$$
5 \mathrm{H}_{2} \mathrm{C}_{2} \mathrm{O}_{4}+2 \mathrm{MnO}_{4}^{-}+6 \mathrm{H}^{+} \rightleftharpoons 2 \mathrm{Mn}^{2+}+10 \mathrm{CO}_{2}+8 \mathrm{H}_{2} \mathrm{O} \quad(\mathrm{E}-5)
$$

Solution It is first necessary to write the oxalic acid half-reaction:

$$
\mathrm{H}_{2} \mathrm{C}_{2} \mathrm{O}_{4} \rightleftharpoons 2 \mathrm{CO}_{2}+2 \mathrm{H}^{+}+2 \mathrm{e}^{-}
$$

It is apparent that there are two equivalents per mole of oxalic acid. Hence, a 0.100 N solution will be 0.0500 M :

$$
\frac{0.100 \text { equiv/L }}{2 \text { equiv/ } / \mathrm{mol}}=0.0500 \mathrm{~mol} / \mathrm{L}=0.0500 \mathrm{M}
$$

Therefore, we must dissolve $(0.0500 \mathrm{~mol} / \mathrm{L})(0.5000 \mathrm{~L})=0.0250 \mathrm{~mol}$ in 500.0 mL . Because the formula mass of $\mathrm{K}_{2} \mathrm{C}_{2} \mathrm{O}_{4}$ is 166.216 , we should use $(0.0250 \mathrm{~mol}) \times(166.216 \mathrm{~g} / \mathrm{mol})=4.15 \mathrm{~g}$ of potassium oxalate.

The utility of normality in volumetric analysis lies in the equation

$$
\begin{equation*}
\mathrm{N}_{1} V_{1}=\mathrm{N}_{2} V_{2} \tag{E-6}
\end{equation*}
$$

where $\mathrm{N}_{1}$ is the normality of reagent $1, V_{1}$ is the volume of reagent $1, \mathrm{~N}_{2}$ is the normality of reagent 2 , and $V_{2}$ is the volume of reagent $2 . V_{1}$ and $V_{2}$ may be expressed in any units, as long as the same units are used for both.

## EXAMPLE Finding Normality

A solution containing 25.0 mL of oxalic acid required 13.78 mL of $0.04162 \mathrm{~N} \mathrm{KMnO}_{4}$ for titration, according to Reaction E-5. Find the normality and molarity of the oxalic acid.

Solution Setting up Equation E-6, we write

$$
\begin{aligned}
\mathrm{N}_{1}(25.0 \mathrm{~mL}) & =(0.04162 \mathrm{~N})(13.78 \mathrm{~mL}) \\
\mathrm{N}_{1} & =0.02294 \text { equiv/L }
\end{aligned}
$$

Because there are two equivalents per mole of oxalic acid in Reaction E-5,

$$
\mathrm{M}=\frac{\mathrm{N}}{n}=\frac{0.02294}{2}=0.01147 \mathrm{M}
$$

Normality is sometimes used in acid-base or ion-exchange chemistry. With respect to acids and bases, the equivalent mass of a reagent is the amount that can donate or accept 1 mole of $\mathrm{H}^{+}$. With respect to ion exchange, the equivalent mass is the mass of reagent containing 1 mole of charge.

*The designations $\alpha$, $\beta$, or $\gamma$ after some formulas refer to particular crystalline forms (which are customarily identified by Greek letters). Data for salts except oxalates are taken mainly from A. E. Martell and R. M. Smith, Critical Stability Constants, Vol. 4 (New York: Plenum Press, 1976). Data for oxalates are from L. G. Sillén and A. E. Martell, Stability Constants of Metal-Ion Complexes, Supplement No. 1 (London: The Chemical Society, Special Publication No. 25, 1971). Another source: R. M. H. Verbeeck et al., Inorg. Chem. 1984, 23, 1922.

Conditions are $25^{\circ} \mathrm{C}$ and zero ionic strength unless otherwise indicated: (a) $19^{\circ} \mathrm{C}$; (b) $20^{\circ} \mathrm{C}$; (c) $38^{\circ} \mathrm{C}$; (d) 0.1 M ; (e) 0.2 M ; (f) 0.5 M ; (g) 1 M; (h) 3 M; (i) 4 M; (j) 5 M.

*Each acid is written in its protonated form. The acidic protons are indicated in bold type.
${ }^{\dagger} p K_{a}$ values refer to $25^{\circ} \mathrm{C}$ unless otherwise indicated. Values in parentheses are considered to be less reliable. Data are from A. E. Martell, R. M. Smith, and R. J. Motekaitis, NIST Database 46 (Gaithersburg, MD: National Institute of Standards and Technology, 2001).
${ }^{\ddagger}$ The accurate way to calculate $K_{b}$ for the conjugate base is $p K_{b}=13.995-p K_{a}$ and $K_{b}=10^{-p K_{b}}$.
${ }^{\S}$ See marginal note on page 166 for distinction between $p K_{a}$ at $\mu=0$ and at $\mu=0.1 \mathrm{M}$.

*All species are aqueous unless otherwise indicated. The reference state for amalgams is an infinitely dilute solution of the element in $H g$. The temperature coefficient, $d E^{\circ} / d T$ allows us to calculate the standard potential, $E^{\circ}(T)$, at temperature $T: E^{\circ}(T)=E^{\circ}+\left(d E^{\circ} / d T\right) \Delta T$, where $\Delta T$ is $T-298.15 \mathrm{~K}$. Note the units $m V / K$ for $d E^{\circ} / d T$. Once you know $E^{\circ}$ for a net cell reaction at temperature $T$, you can find the equilibrium constant, $K$, for the reaction from the formula $K=10^{\text {nFE }}{ }^{\circ} /$ RT In 10 , where $n$ is the number of electrons in each half-reaction, $F$ is the Faraday constant, and $R$ is the gas constant.
sources: The most authoritative source is S. G. Bratsch, J. Phys. Chem. Ref. Data 1989, 18, 1. Additional data come from L. G. Sillén and A. E. Martell, Stability Constants of Metal-Ion Complexes (London: The Chemical Society, Special Publications Nos. 17 and 25. 1964 and 1971); G. Milazzo and S. Caroli, Tables of Standard Electrode Potentials (New York: Wiley, 1978); T. Mussini, P. Longhi, and S. Rondinini, Pure Appl. Chem. 1985, 57, 169. Another good source is A. J. Bard, R. Parsons, and J. Jordan. Standard Potentials in Aqueous Solution (New York: Marcel Dekker, 1985). Reduction potentials for 1200 free radical reactions are given by P. Wardman, J. Phys. Chem. Ref. Data 1989, 18, 1637.

*The overall (cumulative) formation constant, $\beta_{n}$, is the equilibrium constant for the reaction $M+n L \rightleftharpoons M L_{n}: \beta_{n}=\left[M L_{n}\right] /\left([M][L]^{n}\right)$.
$\beta_{n}$ is related to stepwise formation constants $\left(K_{i}\right)$ by $\beta_{n}=K_{1} K_{2} \ldots K_{n}$ (Box 6-2). $\beta_{n m}$ is the cumulative formation constant for the reaction $m M+n L \rightleftharpoons M_{m} L_{n}: \beta_{n m}=\left[M_{m} L_{n}\right] /\left([M]^{m}[L]^{n}\right)$. The subscript $n$ refers to the ligand and $m$ refers to the metal. Data from L. G. Sillén and A. E. Martell, Stability Constants of Metal-Ion Complexes (London: The Chemical Society. Special Publications No. 17 and 25, 1964 and 1971); and A. E. Martell, R. M. Smith, and R. J. Motekaitis, NIST Critical Stability Constants of Metal Complexes Database 46 (Gaithersburg, MD: National Institute of Standards and Technology, 2001).

source: A. E. Martell, R. M. Smith, and R. J. Motekaitis, NIST Critical Stability Constants of Metal Complexes Database 46 (Gaithersburg, MD: National Institute of Standards and Technology, 2001).

The table in this appendix recommends primary standards for many elements. An elemental assay standard must contain a known amount of the desired element. A matrix matching standard must contain extremely low concentrations of undesired impurities, such as the analyte. If you want to prepare 10 ppm Fe in $10 \%$ aqueous NaCl , the NaCl must not contain significant Fe impurity, because the impurity would then have a higher concentration than the deliberately added Fe.

Rather than using compounds in the table, many people purchase certified solutions whose concentrations are traceable to standards from the National Institute of Standards and Technology (NIST or other national institutes of standards). By NIST traceable, we mean that the solution has been prepared from a standard material certified by NIST or that it has been compared with an NIST standard by a reliable analytical procedure.

Manufacturers frequently indicate elemental purity by some number of 9 s . This deceptive nomenclature is based on the measurement of certain impurities. For example, $99.999 \%$ (five 9 s ) pure Al is certified to contain $\leq 0.001 \%$ metallic impurities, based on the analysis of other metals present. However, $\mathrm{C}, \mathrm{H}, \mathrm{N}$, and O are not measured. The Al might contain $0.1 \% \mathrm{Al}_{2} \mathrm{O}_{3}$ and still be "five 9 s pure." For the most accurate work, the dissolved gas content in solid elements may also be a source of error.

Carbonates, oxides, and other compounds may not possess the expected stoichiometry. For example, $\mathrm{TbO}_{2}$ will have a high Tb content if some $\mathrm{Tb}_{4} \mathrm{O}_{7}$ is present. Ignition in an $\mathrm{O}_{2}$ atmosphere may be helpful, but the final stoichiometry is never guaranteed. Carbonates may contain traces of bicarbonate, oxide, and hydroxide. Firing in a $\mathrm{CO}_{2}$ atmosphere may improve
the stoichiometry. Sulfates may contain some $\mathrm{HSO}_{4}^{-}$. Some chemical analysis may be required to ensure that you know what you are really working with.

Most metal standards dissolve in 6 M HCl or $\mathrm{HNO}_{3}$ or a mixture of the two, possibly with heating. Frothing accompanies dissolution of metals or carbonates in acid, so vessels should be loosely covered by a watchglass or Teflon lid to prevent loss of material. Concentrated $\mathrm{HNO}_{3}(16 \mathrm{M})$ may passivate some metals, forming an insoluble oxide coat that prevents dissolution. If you have a choice between using a bulk element or a powder as standards, the bulk form is preferred because it has a smaller surface area on which oxides can form and impurities can be adsorbed. After a pure metal to be used as a standard is cut, it should be etched ("pickled") in a dilute solution of the acid in which it will be dissolved to remove surface oxides and contamination from the cutter. The metal is then washed well with water and dried in a vacuum desiccator.

Dilute solutions of metals are best prepared in Teflon or plastic vessels, because glass is an ion exchanger that can replace analyte species. Specially cleaned glass vials are commercially available for trace organic analysis. Volumetric dilutions are rarely more accurate than $0.1 \%$, so gravimetric dilutions are required for greater accuracy. Of course, weights should be corrected for buoyancy with Equation 2-1. Evaporation of standard solutions is a source of error that is prevented if the mass of the reagent bottle is recorded after each use. If the mass changes between uses, the contents are evaporating.

## Calibration standards

| Element | Source ${ }^{a}$ | Purity | Comments ${ }^{\text {b }}$ |
| :---: | :---: | :---: | :---: |
| Li | SRM $924\left(\mathrm{Li}_{2} \mathrm{CO}_{3}\right)$ | $100.05 \pm 0.02 \%$ | E; dry at $200^{\circ} \mathrm{C}$ for 4 h . |

| Mg | SRM 929 | $100.1 \pm 0.4 \%$ | E; magnesium gluconate clinical standard. |
|  |  | $5.403 \pm 0.022 \% \mathrm{Mg}$ | Dry for 24 h over $\mathrm{Mg}\left(\mathrm{ClO}_{4}\right)_{2}$. |
|  | metal | five 9s | E; purity based on metallic impurities. |
| Ca | SRM $915\left(\mathrm{CaCO}_{3}\right)$ | three 9s | E ; use without drying. |
|  | $\mathrm{CaCO}_{3}$ | five 9 s | $\mathrm{E}, \mathrm{M}$; dry at $200^{\circ} \mathrm{C}$ for 4 h in $\mathrm{CO}_{2}$. User must determine stoichiometry. |
| Sr | SRM $987\left(\mathrm{SrCO}_{3}\right)$ | 99.8\% | E; ignite to establish stoichiometry. Dry at $110^{\circ} \mathrm{C}$ for 1 h . |
|  | $\mathrm{SrCO}_{3}$ | five 9s | M ; up to $1 \%$ off stoichiometry. Ignite to establish stoichiometry. Dry at $200^{\circ} \mathrm{C}$ for 4 h . |
| Ba | $\mathrm{BaCO}_{3}$ | four-five 9s | M; dry at $200^{\circ} \mathrm{C}$ for 4 h . |

Transition metals: Use pure metals (usually $\geq$ four 9 s) for elemental and matrix standards. Assays are based on impurities and do not include dissolved gases.
Lanthanides: Use pure metals (usually $\geq$ four 9 s) for elemental standards and oxides as matrix standards. Oxides may be difficult to dry and stoichiometry is not certain.
a. SRM is the National Institute of Standards and Technology designation for a Standard Reference Material.
b. E means elemental assay standard; M means matrix matching standard.

Calibration standards (continued)

| Element | Source ${ }^{a}$ | Purity | Comments ${ }^{\text {b }}$ |
| :---: | :---: | :---: | :---: |
| B | SRM $951\left(\mathrm{H}_{3} \mathrm{BO}_{3}\right)$ | $100.00 \pm 0.01$ | E; expose to room humidity ( $\sim 35 \%$ ) for 30 min before use. |
| A1 | metal | five 9s | E, M; SRM 1257 Al metal available. |
| Ga | metal | five 9s | E, M; SRM 994 Ga metal available. |
| In | metal | five 9s | E, M |
| Tl | metal | five 9s | E, M; SRM 997 Tl metal available. |
| C |  |  | No recommendation. |
| Si | metal | six 9s | E, M; SRM $990 \mathrm{SiO}_{2}$ available. |
| Ge | metal | five 9s | E, M |
| Sn | metal | six 9s | E, M; SRM 741 Sn metal available. |
| Pb | metal | five 9s | E, M; several SRMs available. |
| N | $\mathrm{NH}_{4} \mathrm{Cl}$ | six 9s | E; can be prepared from $\mathrm{HCl}+\mathrm{NH}_{3}$. |
|  | $\mathrm{N}_{2}$ | $>$ three 9s | E |
|  | $\mathrm{HNO}_{3}$ | six 9s | M ; contaminated with $\mathrm{NO}_{x}$. Purity based on impurities. |
| P | SRM $194\left(\mathrm{NH}_{4} \mathrm{H}_{2} \mathrm{PO}_{4}\right)$ | three 9s | E |
|  | $\mathrm{P}_{2} \mathrm{O}_{5}$ | five 9s | E, M; difficult to keep dry. |
|  | $\mathrm{H}_{3} \mathrm{PO}_{4}$ | four 9s | E ; must titrate 2 hydrogens to be certain of stoichiometry. |
| As | metal | five 9s | E, M |
|  | SRM 83d ( $\mathrm{As}_{2} \mathrm{O}_{3}$ ) | $99.9926 \pm 0.0030 \%$ | Redox standard. As assay not ensured. |
| Sb | metal | four 9s | E, M |
| Bi | metal | five 9s | E, M |
| O | $\mathrm{H}_{2} \mathrm{O}$ | eight 9s | E, M; contains dissolved gases. |
|  | $\mathrm{O}_{2}$ | $>$ four 9s | E |
| S | element | six 9 s | E, M; difficult to dry. Other sources are $\mathrm{H}_{2} \mathrm{SO}_{4}, \mathrm{Na}_{2} \mathrm{SO}_{4}$, and $\mathrm{K}_{2} \mathrm{SO}_{4}$. Stoichiometry must be proved (e.g., no $\mathrm{SO}_{3}^{2-}$ present). |
| Se | metal | five 9s | E, M; SRM 726 Se metal available. |
| Te | metal | five 9s | E, M |
| F | NaF | four 9s | $\mathrm{E}, \mathrm{M}$; no good directions for drying. |
| Cl | NaCl | four 9s | E, M; dry for 24 h over $\mathrm{Mg}\left(\mathrm{ClO}_{4}\right)_{2}$. Several SRMs $(\mathrm{NaCl}$ and KCl ) available. |
| Br | KBr | four 9s | E, M; need to dry and demonstrate stoichiometry. |
|  | $\mathrm{Br}_{2}$ | four 9s | E |
| I | sublimed $\mathrm{I}_{2}$ | six 9s | E |
|  | KI | three 9s | E, M |
|  | $\mathrm{KIO}_{3}$ | three 9s | Stoichiometry not ensured. |

## Chapter 1

1-A. (a) $\frac{(25.00 \mathrm{mG})(0.7914 \mathrm{~g} / \mathrm{mG}) /(32.042 \mathrm{~g} / \mathrm{mol})}{0.500 \mathrm{~L}}=1.235 \mathrm{M}$
(b) 500.0 mL of solution weighs $(1.454 \mathrm{~g} / \mathrm{mL}) \times(500.0 \mathrm{~mL})=727.0 \mathrm{~g}$ and contains $25.00 \mathrm{~mL}(=19.78 \mathrm{~g})$ of methanol. The mass of chloroform in 500.0 mL must be $727.0-19.78=707.2 \mathrm{~g}$. The molality of methanol is

$$
\begin{aligned}
\text { Molality } & =\frac{\text { mol methanol }}{\text { kg chloroform }} \\
& =\frac{(19.78 \mathrm{~g}) /(32.042 \mathrm{~g} / \mathrm{mol})}{0.7072 \mathrm{~kg}}=0.8729 \mathrm{~m}
\end{aligned}
$$

If you keep all the numbers in your calculator, the answer is 0.8731 m . You will find small discrepancies due to intermediate round-offs in many answers in this book.
1-B. (a)
$\left(\frac{48.0 \mathrm{~g} \mathrm{HBr}}{100.0 \text { g solution }}\right)\left(1.50 \frac{\text { g solution }}{\mathrm{mL} \text { solution }}\right)=\left(\frac{0.720 \mathrm{~g} \mathrm{HBr}}{\mathrm{mL} \text { solution }}\right)=\left(\frac{720 \mathrm{~g} \mathrm{HBr}}{\mathrm{L} \text { solution }}\right)$
Formal concentration $=\frac{720 \mathrm{~g} \mathrm{HBr} / \mathrm{L}}{80.912 \mathrm{~g} / \mathrm{mol}}=8.90 \mathrm{M}$
(b) $\frac{36.0 \mathrm{~g} \mathrm{HBr}}{0.480 \mathrm{~g} \mathrm{HBr} / \mathrm{g} \text { solution }}=75.0 \mathrm{~g}$ solution
(c) $233 \mathrm{mmol}=0.233 \mathrm{~mol}$
$\frac{0.233 \mathrm{mot}}{8.90 \mathrm{mot} / \mathrm{L}}=0.0262 \mathrm{~L}=26.2 \mathrm{~mL}$
(d) $\mathrm{M}_{\text {conc }} \cdot V_{\text {conc }}=\mathrm{M}_{\text {dil }} \cdot V_{\text {dil }}$
$(8.90 \mathrm{M}) \cdot(x \mathrm{~mL})=(0.160 \mathrm{M}) \cdot(250 \mathrm{~mL}) \Rightarrow x=4.49 \mathrm{~mL}$
1-C. Each mol of $\mathrm{Ca}\left(\mathrm{NO}_{3}\right)_{2}$ (FM 164.088) contains $2 \mathrm{~mol} \mathrm{NO}_{3}^{-}$
(FM 62.005), so the fraction of mass that is nitrate is
$\left(\frac{2 \mathrm{molNO}_{3}^{-}}{\left.\operatorname{mol~Ca(~} \mathrm{NO}_{3}^{-}\right)_{2}}\right)\left(\frac{62.005 \mathrm{~g} \mathrm{NO}_{3}^{-} / \mathrm{mol} \mathrm{NO}_{3}^{-}}{164.088 \mathrm{~g} \mathrm{Ca}^{-}\left(\mathrm{NO}_{3}^{-}\right)_{2} / \mathrm{mol} \mathrm{Ca}\left(\mathrm{NO}_{3}^{-}\right)_{2}}\right)$
$=0.7557 \frac{\mathrm{~g} \mathrm{NO}_{3}^{-}}{\mathrm{g} \mathrm{Ca}\left(\mathrm{NO}_{3}\right)_{2}}$
If the dissolved $\mathrm{Ca}\left(\mathrm{NO}_{3}\right)_{2}$ has a concentration of 12.6 ppm , the concentration of dissolved $\mathrm{NO}_{3}^{-}$is $(0.7557)(12.6 \mathrm{ppm})=9.52 \mathrm{ppm}$.
1-D. (a) Formula mass of ascorbic acid
$=6($ atomic mass of C$)+8($ atomic mass of H$)+6($ atomic mass of O$)$
$=6(12.0107)+8(1.00794)+6(15.9994)=176.124 \mathrm{~g} / \mathrm{mol}$
(b) $\frac{0.1970 \mathrm{~g} \text { of ascorbic acid }}{176.124 \mathrm{~g} / \mathrm{mol}}=1.1185 \mathrm{mmol}$

Molarity of $\mathrm{I}_{3}^{-}=1.1185 \mathrm{mmol} / 29.41 \mathrm{~mL}$

$$
=0.03803 \mathrm{M}
$$

(c) $31.63 \mathrm{~mL}^{\text {of } \mathrm{I}_{3}^{-}}=1.203 \mathrm{mmol}$ of $\mathrm{I}_{3}^{-}$

$$
\begin{aligned}
& =1.203 \mathrm{mmol} \text { of ascorbic acid } \\
& =0.2119 \mathrm{~g}=49.94 \% \text { of the tablet }
\end{aligned}
$$

1-E. (a) $\frac{0.824 \mathrm{~g} \text { acid }}{204.221 \mathrm{~g} \not \mathrm{~mol}}=4.03_{48} \mathrm{mmol}$. This many mmol of NaOH is contained in 0.038314 kg of NaOH solution

$$
\begin{aligned}
\Rightarrow \text { concentration } & =\frac{4.03_{48} \times 10^{-3} \mathrm{~mol} \mathrm{NaOH}}{0.038314 \mathrm{~kg} \text { solution }} \\
& =0.105_{31} \mathrm{~mol} / \mathrm{kg} \text { solution }
\end{aligned}
$$

(b) $\mathrm{mol} \mathrm{NaOH}=(0.057911 \mathrm{~kg})\left(0.105_{31} \mathrm{~mol} / \mathrm{kg}\right)=6.09_{86} \mathrm{mmol}$ Because 2 mol NaOH react with $1 \mathrm{~mol} \mathrm{H}_{2} \mathrm{SO}_{4}$,

$$
\left[\mathrm{H}_{2} \mathrm{SO}_{4}\right]=\frac{\frac{1}{2}\left(6.09_{86} \mathrm{mmol}\right)}{10.00 \mathrm{~mL}}=0.305 \frac{\mathrm{mmol}}{\mathrm{~mL}}=0.305 \mathrm{M}
$$

## Chapter 2

2-A. (a) At $15^{\circ} \mathrm{C}$, water density $=0.9991026 \mathrm{~g} / \mathrm{mL}$.

$$
m=\frac{(5.3974 \mathrm{~g})\left(1-\frac{0.0012 \mathrm{~g} / \mathrm{mL}}{8.0 \mathrm{~g} / \mathrm{mL}}\right)}{\left(1-\frac{0.0012 \mathrm{~g} / \mathrm{mL}}{0.9991026 \mathrm{~g} / \mathrm{mL}}\right)}=5.4031 \mathrm{~g}
$$

(b) At $25^{\circ} \mathrm{C}$, water density $=0.9970479 \mathrm{~g} / \mathrm{mL}$ and $m=5.4031 \mathrm{~g}$.
$2-B$. Use Equation $2-1$ with $m^{\prime}=0.2961 \mathrm{~g}, d_{\mathrm{a}}=0.0012 \mathrm{~g} / \mathrm{mL}$,
$d_{\mathrm{w}}=8.0 \mathrm{~g} / \mathrm{mL}$, and $d=5.24 \mathrm{~g} / \mathrm{mL} \Rightarrow m=0.2963 \mathrm{~g}$.
2-C. $\frac{c^{\prime}}{d^{\prime}}=\frac{c}{d}$
Let the primes stand for $16^{\circ} \mathrm{C}$ :
$\Rightarrow \frac{c^{\prime} \text { at } 16^{\circ} \mathrm{C}}{0.9989460 \mathrm{~g} / \mathrm{mL}}=\frac{0.05138 \mathrm{M}}{0.9972995 \mathrm{~g} / \mathrm{mL}}$ $\Rightarrow c^{\prime}$ at $16^{\circ} \mathrm{C}=0.05146 \mathrm{M}$
2-D. Column 3 of Table 2-7 tells us that water occupies $1.0033 \mathrm{~mL} / \mathrm{g}$ at $22^{\circ} \mathrm{C}$. Therefore, $(15.569 \mathrm{~g}) \times(1.0033 \mathrm{~mL} / \mathrm{g})=15.620 \mathrm{~mL}$.

## Chapter 3

3-A. (a) $[12.41( \pm 0.09) \div 4.16( \pm 0.01)] \times 7.0682( \pm 0.0004)$
$=\frac{12.41( \pm 0.725 \%) \times 7.0682( \pm 0.0057 \%)}{4.16( \pm 0.240 \%)}$
$=21.086( \pm 0.764 \%)$ (because $\left.\sqrt{0.725^{2}+0.0057^{2}+0.240^{2}}=0.764\right)$
$=21.0_{9}\left( \pm 0.1_{6}\right)$ or $21.1( \pm 0.2)$
Relative uncertainty $=\frac{0.1_{6}}{21.0_{9}} \times 100=0.8 \%$
(b) $[3.26( \pm 0.10) \times 8.47( \pm 0.05)]-0.18( \pm 0.06)$
$=[3.26( \pm 3.07 \%) \times 8.47( \pm 0.59 \%)]-0.18( \pm 0.06)$
$=[27.612( \pm 3.13 \%)]-0.18( \pm 0.06)$
$=[27.612( \pm 0.864)]-0.18( \pm 0.06)$
$=\left[27.4_{3}\left( \pm 0.8_{7}\right)\right]$ or $27.4( \pm 0.9) ;$ relative uncertainty $=3.2 \%$
(c) $6.843( \pm 0.008) \times 10^{4} \div[\underbrace{2.09( \pm 0.04)-1.63( \pm 0.01)}_{\text {Combine absolute uncertainties }}]$
$=\underbrace{6.843( \pm 0.008) \times 10^{4} \div[0.46( \pm 0.0412)]}$
Combine relative uncertainties
$=6.843( \pm 0.117 \%) \times 10^{4} \div[0.46( \pm 8.96 \%)]=1.49( \pm 8.96 \%) \times 10^{5}$
$=1.49\left( \pm 0.1_{3}\right) \times 10^{5}$; relative uncertainty $=9.0 \%$
(d) $\% e_{y}=\frac{1}{2} \% e_{x}=\frac{1}{2}\left(\frac{0.08}{3.24} \times 100\right)=1.235 \%$
$(3.24 \pm 0.08)^{1 / 2}=1.80 \pm 1.235 \%$

$$
=1.80 \pm 0.02_{2}( \pm 1.2 \%)
$$

(e) $\% e_{y}=4 \% e_{x}=4\left(\frac{0.08}{3.24} \times 100\right)=9.877 \%$
$(3.24 \pm 0.08)^{4}=110.20 \pm 9.877 \%$

$$
=1.1_{0}\left( \pm 0.1_{1}\right) \times 10^{2}( \pm 9.9 \%)
$$

(f) $e_{y}=0.43429 \frac{e_{x}}{x}=0.43429\left(\frac{0.08}{3.24}\right)=0.0107$
$\log (3.24 \pm 0.08)=0.5105 \pm 0.0107$

$$
=0.51 \pm 0.01\left( \pm 2 .{ }^{1} \%\right)
$$

(g) $\frac{e_{y}}{y}=2.3026 e_{x}=2.3026(0.08)=0.184$
$10^{3.24 \pm 0.08}=1.74 \times 10^{3} \pm 18.4 \%$

$$
=1.7_{4}\left( \pm 0.3_{2}\right) \times 10^{3}( \pm 18 \%)
$$

$3-B$. (a) 2.000 L of $0.169 \mathrm{M} \mathrm{NaOH}(\mathrm{FM}=39.997)$ requires
$0.338 \mathrm{~mol}=13.52 \mathrm{~g} \mathrm{NaOH}$.
$\frac{13.52 \mathrm{~g} \mathrm{NaOH}}{0.534 \mathrm{~g} \mathrm{NaOH} / \mathrm{g} \text { solution }}=25.32 \mathrm{~g}$ solution
$\frac{25.32 \mathrm{~g} \text { solution }}{1.52 \mathrm{~g} \text { solution } / \mathrm{mL} \text { solution }}=16.66 \mathrm{~mL}$
(b) Molarity $=$
$[16.66( \pm 0.10) \mathrm{mL}]\left[1.52( \pm 0.01) \frac{\mathrm{g} \text { solution }}{\mathrm{mL}}\right]\left[0.534( \pm 0.004) \frac{\mathrm{g} \mathrm{NaOH}}{\mathrm{g} \text { solution }}\right]$

$$
\left(39.9971 \frac{\mathrm{~g} \mathrm{NaOH}}{\mathrm{~mol}}\right)(2.000 \mathrm{~L})
$$

Because the relative errors in formula mass and final volume are negligible ( $\approx 0$ ), we can write
Relative error in molarity $=\sqrt{\left(\frac{0.10}{16.66}\right)^{2}+\left(\frac{0.01}{1.52}\right)^{2}+\left(\frac{0.004}{0.534}\right)^{2}}=1.16 \%$
Molarity $=0.169( \pm 0.002)$
3-C. $0.0500( \pm 2 \%) \mathrm{mol}=$
$[4.18( \pm x) \mathrm{mL}]\left[1.18( \pm 0.01) \frac{\mathrm{g} \text { solution }}{\mathrm{mL}}\right]\left[0.370( \pm 0.005) \frac{\mathrm{g} \mathrm{NaCl}}{\mathrm{g} \text { solution }}\right]$

$$
\left(36.461 \frac{\mathrm{~g} \mathrm{HCl}}{\mathrm{~mol}}\right)
$$

Error analysis:

$$
\begin{aligned}
(0.02)^{2} & =\left(\frac{x}{4.18}\right)^{2}+\left(\frac{0.01}{1.18}\right)^{2}+\left(\frac{0.005}{0.370}\right)^{2} \\
x & =0.05 \mathrm{~mL}
\end{aligned}
$$

3-D. Atomic masses from periodic table:
N : $14.0067 \pm 0.0002$
H: $1.00794 \pm 0.00007$
Standard uncertainties from rectangular distribution:
$\mathrm{N}: 0.0002 / \sqrt{3}=0.00012$
H: $0.00007 / \sqrt{3}=0.000040$
$n \times$ (atomic mass $\pm$ standard uncertainty):
$\mathrm{N}: 14.0067 \pm 0.00012=14.0067 \pm 0.00012$
$\underline{3 H: 3(1.00794 \pm 0.000040)=3.02382 \pm 0.00012}$
$\mathrm{NH}_{3}: 17.03052 \pm \sqrt{0.00012^{2}+0.00012^{2}}$
$=17.03052 \pm 0.00017=17.0305 \pm 0.0002$
Percent relative uncertainty $=100 \times \frac{0.00017}{17.0305}=0.0010 \%$

## Chapter 4

4-A. $\quad$ Mean $=\frac{1}{5}(116.0+97.9+114.2+106.8+108.3)$

$$
=108.6_{4}
$$

Standard deviation $=\sqrt{\frac{\left(116.0-108.6_{4}\right)^{2}+\cdots+\left(108.3-108.6_{4}\right)^{2}}{5-1}}$

$$
=7.1_{4}
$$

Range $=116.0-97.9=18.1$
$90 \%$ confidence interval $=108.6_{4} \pm \frac{(2.132)\left(7.1_{4}\right)}{\sqrt{5}}=108.6_{4} \pm 6.8_{1}$
$G_{\text {calculated }}=\left|97.9-108.6_{4}\right| / 7.1_{4}=1.50$
$G_{\text {table }}=1.672$ for five measurements
Because $G_{\text {calculated }}<G_{\text {table }}$, we retain 97.9.

4-B.

| 21 | sum = | 89.2 |  |  |
| 22 | mean = | 17.84 |  |  |
| 23 | std dev = | 0.3362 |  |  |
| 24 |  |  |  |  |
| 25 | Formulas: | B21 = SUM(B4:B8) |  |  |
| 26 |  | B22 = AVERAGE(B4:B8) |  |  |
| 27 |  | B23 = STDEV(B4:B8) |  |  |

4-C. (a) We need to find the fraction of the area of the Gaussian curve between $x=-\infty$ and $x=40860 \mathrm{~h}$. When $x=40860, z=$ $(40860-62700) / 10400=-2.1000$. The Gaussian curve is symmetric, so the area from $-\infty$ to -2.1000 is the same as the area from 2.1000 to $+\infty$. Table 4-1 tells us that the area between $z=0$ and $z=2.1$ is 0.4821 . Because the area from $z=0$ to $z=\infty$ is 0.5000 , the area from $z=2.1000$ to $z=\infty$ is $0.5000-0.4821=0.0179$. The fraction of brakes expected to be $80 \%$ worn in less than 40860 miles is 0.0179 , or $1.79 \%$.
(b) At 57500 miles, $z=(57500-62700) / 10400=-0.5000$. At 71020 miles, $z=(71020-62700) / 10400=+0.8000$. The area under the Gaussian curve from $z=-0.5000$ to $z=0$ is the same as the area from $z=0$ to $z=+0.5000$, which is 0.1915 in Table 4-1. The area from $z=0$ to $z=+0.8000$ is 0.2881 . The total area from $z=-0.5000$ to $z=+0.8000$ is $0.1915+0.2881=0.4796$. The fraction of brakes expected to be $80 \%$ worn between 57500 and 71020 miles is 0.4796 , or $47.96 \%$.
4-D. The answers in cells C4 and C9 of the following spreadsheet are (a) 0.052 and (b) 0.361 .

|  | A | B | C |
| :---: | :---: | :---: | :---: |
| 1 | Mean = | Std dev = |  |
| 2 | 62700 | 10400 |  |
| 3 |  |  |  |
| 4 | Area from $-\infty$ to $45800=$ |  | 0.052081 |
| 5 | Area from $-\infty$ to $60000=$ |  | 0.397580 |
| 6 | Area from $-\infty$ to $70000=$ |  | 0.758637 |
| 7 |  |  |  |
| 8 | Area from 60000 to 70000 |  |  |
| 9 |  | = C6-C5 = | 0.361056 |
| 10 |  |  |  |
| 11 | Formula: |  |  |
| 12 | C4 = NORMDIST(45800,A2,B2,TRUE) |  |  |

4-E. For $117,119,111,115,120 \mu \mathrm{~mol} / 100 \mathrm{~mL}, \bar{x}=116.4$ and $s=3.58$. The $95 \%$ confidence interval for 4 degrees of freedom is

$$
\begin{aligned}
\bar{x} \pm \frac{t s}{\sqrt{n}} & =116.4 \pm \frac{(2.776)(3.58)}{\sqrt{5}}=116.4 \pm 4.4 \\
& =112.0 \text { to } 120.8 \mu \mathrm{~mol} / 100 \mathrm{~mL}
\end{aligned}
$$

The $95 \%$ confidence interval does not include the accepted value of $111 \mu \mathrm{~mol} / 100 \mathrm{~mL}$, so the difference is significant.
4-F. (a) $\mathrm{pg} / \mathrm{g}$ corresponds to $10^{-12} \mathrm{~g} / \mathrm{g}$, which is parts per trillion.
(b) $F_{\text {calculated }}=4.6^{2} / 3.6^{2}=1.6_{3}<F_{\text {table }}=5.05$ (for 5 degrees of freedom in both numerator and denominator). Standard deviations are not significantly different at $95 \%$ confidence level.
(c) Because $F_{\text {calculated }}<F_{\text {table }}$, we use Equations 4-8 and 4-9.

$$
\begin{aligned}
s_{\text {pooled }} & =\sqrt{\frac{s_{1}^{2}\left(n_{1}-1\right)+s_{2}^{2}\left(n_{2}-1\right)}{n_{1}+n_{2}-2}} \\
& =\sqrt{\frac{4.6^{2}(6-1)+3.6^{2}(6-1)}{6+6-2}}=4.1_{3} \\
t_{\text {calculated }} & =\frac{\left|\bar{x}_{1}-\bar{x}_{2}\right|}{s_{\text {pooled }}} \sqrt{\frac{n_{1} n_{2}}{n_{1}+n_{2}}}=\frac{|51.1-34.4|}{4.1_{3}} \sqrt{\frac{|6 \cdot 6|}{6+6}}=7.0_{0}
\end{aligned}
$$

Because $t_{\text {calculated }}\left(7.0_{0}\right)>t_{\text {table }}(=2.228$ for 10 degrees of freedom), the difference is significant at the $95 \%$ confidence level.
(d) $F_{\text {calculated }}=3.6^{2} / 1.2^{2}=9.0_{0}>F_{\text {table }}=5.05$. The standard deviations are significantly different at the $95 \%$ confidence level. Therefore, we use Equations 4-8a and 4-9a to compare the means:

$$
\begin{aligned}
& \text { Degrees of freedom }=\frac{\left(s_{1}^{2} / n_{1}+s_{2}^{2} / n_{2}\right)^{2}}{\frac{\left(s_{1}^{2} / n_{1}\right)^{2}}{n_{1}-1}+\frac{\left(s_{2}^{2} / n_{2}\right)^{2}}{n_{2}-1}} \\
& \\
& =\frac{\left(3.6^{2} / 6+1.2^{2} / 6\right)^{2}}{\frac{\left(3.6^{2} / 6\right)^{2}}{6-1}+\frac{\left(1.2^{2} / 6\right)^{2}}{6-1}}=6.10 \approx 6 \\
& t_{\text {calculated }}=\frac{\left|\bar{x}_{1}-\bar{x}_{2}\right|}{\sqrt{s_{1}^{2} / n_{1}+s_{2}^{2} / n_{2}}}=\frac{|34.4-42.9|}{\sqrt{3.6^{2} / 6+1.2^{2} / 6}}=5.49
\end{aligned}
$$

Because $t_{\text {calculated }}\left(=5.4_{9}\right)>t_{\text {table }}(=2.447$ for 6 degrees of freedom $)$, the difference is significant at the $95 \%$ confidence level.

\end{aligned}
$$

Spreadsheet for Exercise 4-G.

Equation of the best line

$$
y=[0.0218( \pm 0.0002)] x+[0.471( \pm 0.004)]
$$

(c) $x=\frac{y-b}{m}=\frac{0.973-0.471}{0.0218}=23.0 \mu \mathrm{~g}$.

If you keep more digits for $m$ and $b, x=23.07 \mu \mathrm{~g}$.
Uncertainty in $x\left(s_{x}\right)$
$=\frac{s_{y}}{|m|} \sqrt{\frac{1}{k}+\frac{1}{n}+\frac{(y-\bar{y})^{2}}{m^{2} \sum\left(x_{i}-\bar{x}\right)^{2}}}$
$=\frac{0.00567}{|0.02177|} \sqrt{\frac{1}{1}+\frac{1}{5}+\frac{(0.973-0.8782)^{2}}{(0.02177)^{2}(876.1)}}=0.29 \mu \mathrm{~g}$
Final answer is $23.1 \pm 0.3 \mu \mathrm{~g}$.

## Chapter 5

5-A. (a) Standard deviation of 9 samples $=s=0.0006_{44}$
Mean blank $=y_{\text {blank }}=0.0011_{89}$
$y_{\mathrm{dl}}=y_{\text {blank }}+3 s=0.0011_{8}+(3)\left(0.0006_{44}\right)=0.0031_{12}$
(b) Minimum detectable concentration $=\frac{3 s}{m}=\frac{(3)\left(0.0006_{44}\right)}{2.24 \times 10^{4} \mathrm{M}^{-1}}$
$=8.6 \times 10^{-8} \mathrm{M}$
(c) Lower limit of quantitation $=\frac{10 s}{m}=\frac{(10)\left(0.0006_{44}\right)}{2.24 \times 10^{4} \mathrm{M}^{-1}}=2.9 \times 10^{-7} \mathrm{M}$

5-B. (a) $\left[\mathrm{Ni}^{2+}\right]_{\mathrm{f}}=\left[\mathrm{Ni}^{2+}\right]_{\mathrm{i}} \frac{V_{\mathrm{i}}}{V_{\mathrm{f}}}=\left[\mathrm{Ni}^{2+}\right]_{\mathrm{i}}\left(\frac{25.0}{25.5}\right)=0.980_{4}\left[\mathrm{Ni}^{2+}\right]_{\mathrm{i}}$
(b) $[\mathrm{S}]_{\mathrm{f}}=(0.0287 \mathrm{M})\left(\frac{0.500}{25.5}\right)=0.000562{ }_{7} \mathrm{M}$
(c) $\frac{\left[\mathrm{Ni}^{2+}\right]_{\mathrm{i}}}{0.0005627+0.9804\left[\mathrm{Ni}^{2+}\right]_{\mathrm{i}}}=\frac{2.36 \mu \mathrm{~A}}{3.79 \mu \mathrm{~A}}$
$\Rightarrow\left[\mathrm{Ni}^{2+}\right]_{\mathrm{i}}=9.00 \times 10^{-4} \mathrm{M}$
5-C. Use the standard mixture to find the response factor. We know that, when $[\mathrm{X}]=[\mathrm{S}]$, the ratio of signals $A_{\mathrm{X}} / A_{\mathrm{S}}$ is 1.31 .

$$
\frac{A_{\mathrm{X}}}{[\mathrm{X}]}=F\left(\frac{A_{\mathrm{S}}}{[\mathrm{~S}]}\right) \Rightarrow F=\frac{A_{\mathrm{X}} / A_{\mathrm{S}}}{[\mathrm{X}] /[\mathrm{S}]}=\frac{1.31}{1}=1.31
$$

In the mixture of unknown plus standard, the concentration of S is

$$
[\mathrm{S}]=(\underbrace{(4.13 \mu \mathrm{~g} / \mathrm{mL})}_{\begin{array}{c}
\text { Initial } \\
\text { concentration }
\end{array}} \underbrace{\left(\frac{2.00}{10.0}\right)}_{\begin{array}{c}
\text { Dilution } \\
\text { factor }
\end{array}}=0.826 \mu \mathrm{~g} / \mathrm{mL}
$$

For the unknown mixture: $F=\frac{A_{\mathrm{X}} / A_{\mathrm{S}}}{[\mathrm{X}] /[\mathrm{S}]}$
$1.31=\frac{0.808}{[\mathrm{X}] /[0.826 \mu \mathrm{~g} / \mathrm{mL}]} \Rightarrow[\mathrm{X}]=0.509 \mu \mathrm{~g} / \mathrm{mL}$
Because X was diluted from 5.00 to 10.0 mL in the mixture with S , the original concentration of $X$ was $(10.0 / 5.0)(0.509 \mu \mathrm{~g} / \mathrm{mL})=1.02 \mu \mathrm{~g} / \mathrm{mL}$.
5-D. There are 9 points, so there are $9-2=7$ degrees of freedom. For $90 \%$ confidence, $t=1.895$, so the $90 \%$ confidence interval is $\pm(1.895)(0.098 \mathrm{mM})= \pm 0.19 \mathrm{mM}$. For $99 \%$ confidence, $t=3.500$, and the $99 \%$ confidence interval is $\pm(3.500)(0.098 \mathrm{mM})= \pm 0.34 \mathrm{mM}$.
5-E. For the data in this problem, mean $=0.84_{11}$ and standard deviation $=0.18_{88}$. Stability criteria are

- There should be no observations outside the action lines-One observation (day 101) lies above the upper action line.
- There are not 2 out of 3 consecutive measurements between warning and action lines-OK.
- There are not 7 consecutive measurements all above or all below the center line-OK.
- There are not 6 consecutive measurements all steadily increasing or all steadily decreasing, wherever they are located-OK.
- There are not 14 consecutive points alternating up and down, regardless of where they are located-OK.
- There is no obvious nonrandom pattern-OK.

Chapter 6
6-A. (a) $\mathrm{Ag}^{+}+\mathrm{Cl}^{-} \rightleftharpoons \mathrm{AgCl}(a q)$

$$
\frac{\mathrm{AgCl}(s) \rightleftharpoons \mathrm{Ag}^{+}+\mathrm{Cl}}{\mathrm{AgCl}(s) \rightleftharpoons \mathrm{AgCl}(a q)}
$$

$K_{1}=2.0 \times 10^{3}$
$\frac{K_{2}=1.8 \times 10^{-10}}{K_{3}=K_{1} K_{2}=3.6 \times 10^{-7}}$
(b) The answer to (a) tells us $[\mathrm{AgCl}(a q)]=3.6 \times 10^{-7}$
(c) $\mathrm{AgCl}_{2}^{-} \rightleftharpoons \operatorname{AgCt}(a q)+\mathrm{Cl}^{-}$
$\mathrm{Ag}^{+}+\mathrm{Cl}^{-} \rightleftharpoons \mathrm{AgCl}(s)$
$\xrightarrow{\mathrm{AgCl}(a q)} \rightleftharpoons \mathrm{Ag}^{+}+\mathrm{Cl}^{-}$
$\mathrm{AgCl}_{2}^{-} \rightleftharpoons \mathrm{AgCl}(s)+\mathrm{Cl}^{-}$
$K_{1}=1 /\left(9.3 \times 10^{1}\right)$
$K_{2}=1 /\left(1.8 \times 10^{-10}\right)$
$K_{3}=1 /\left(2.0 \times 10^{3}\right)$
$K_{4}=K_{1} K_{2} K_{3}=3.0 \times 10^{4}$
6-B. $\quad$ (a) $\frac{(x)(x)(1.00+8 x)^{8}}{(0.0100-x)(0.0100-2 x)^{2}}=1 \times 10^{11}$
(b) $\left[\mathrm{Br}^{-}\right]$and $\left[\mathrm{Cr}_{2} \mathrm{O}_{7}^{2-}\right]$ will both be 0.00500 M because $\mathrm{Cr}^{3+}$ is the limiting reagent. The reaction requires 2 moles of $\mathrm{Cr}^{3+}$ per mole of $\mathrm{BrO}_{3}^{-}$. The $\mathrm{Cr}^{3+}$ will be used up first, making $1 \mathrm{~mol} \mathrm{Br}{ }^{-}$and $1 \mathrm{~mol} \mathrm{Cr}_{2} \mathrm{O}_{7}^{2-}$ per 2 mol $\mathrm{Cr}^{3+}$ consumed. To solve the preceding equation, we set $x=0.00500 \mathrm{M}$ in all terms except $\left[\mathrm{Cr}^{3+}\right]$. The concentration of $\mathrm{Cr}^{3+}$ will be a small, unknown quantity.

$$
\frac{(0.00500)(0.00500)[1.00+8(0.00500)]^{8}}{(0.0100-0.00500)\left[\mathrm{Cr}^{3+}\right]^{2}}=1 \times 10^{11}
$$

$\left[\mathrm{Cr}^{3+}\right]=2.6 \times 10^{-7} \mathrm{M}$
$\left[\mathrm{BrO}_{3}^{-}\right]=0.0100-0.00500=0.00500 \mathrm{M}$
6-C. $\quad K_{\text {sp }}$ for $\mathrm{La}\left(\mathrm{IO}_{3}\right)_{3}$ is small $\left(1.0 \times 10^{-11}\right)$, so we presume that the concentration of iodate will not be altered by the small amount of $\mathrm{La}\left(\mathrm{IO}_{3}\right)_{3}$ that dissolves.

$$
\left[\mathrm{La}^{3+}\right]=\frac{K_{\mathrm{sp}}}{\left[\mathrm{IO}_{3}^{-}\right]^{3}}=\frac{1.0 \times 10^{-11}}{(0.050)^{3}}=8.0 \times 10^{-8} \mathrm{M}
$$

The answer agrees with the assumption that iodate from $\mathrm{La}\left(\mathrm{IO}_{3}\right)_{3}$ $\ll 0.050 \mathrm{M}$.
6-D. We expect $\mathrm{Ca}\left(\mathrm{IO}_{3}\right)_{2}$ to be more soluble because its $K_{\text {sp }}$ is larger and the two salts have the same stoichiometry. If the stoichiometry were not the same, we could not directly compare values of $K_{\text {sp }}$. Our prediction could be wrong if, for example, the barium salt formed a great deal of the ion pairs $\mathrm{Ba}\left(\mathrm{IO}_{3}\right)^{+}$or $\mathrm{Ba}\left(\mathrm{IO}_{3}\right)_{2}(\mathrm{aq})$ and the calcium salt did not form ion pairs.
6-E. $\left[\mathrm{Fe}^{3+}\right]\left[\mathrm{OH}^{-}\right]^{3}=\left(10^{-10}\right)\left[\mathrm{OH}^{-}\right]^{3}=1.6 \times 10^{-39}$
$\Rightarrow\left[\mathrm{OH}^{-}\right]=2.5 \times 10^{-10} \mathrm{M}$
$\left[\mathrm{Fe}^{2+}\right]\left[\mathrm{OH}^{-}\right]^{2}=\left(10^{-10}\right)\left[\mathrm{OH}^{-}\right]^{2}=7.9 \times 10^{-16}$
$\Rightarrow\left[\mathrm{OH}^{-}\right]=2.8 \times 10^{-3} \mathrm{M}$

6-F. We want to reduce $\left[\mathrm{Ce}^{3+}\right]$ to $1.0 \%$ of $0.010 \mathrm{M}=0.00010 \mathrm{M}$. The concentration of oxalate in equilibrium with $0.00010 \mathrm{M} \mathrm{Ce}^{3+}$ is computed as follows:
$\left[\mathrm{Ce}^{3+}\right]^{2}\left[\mathrm{C}_{2} \mathrm{O}_{4}^{2-}\right]^{3}=K_{\text {sp }}=5.9 \times 10^{-30}$
$(0.00010)^{2}\left[\mathrm{C}_{2} \mathrm{O}_{4}^{2-}\right]^{3}=5.9 \times 10^{-30}$

$$
\left[\mathrm{C}_{2} \mathrm{O}_{4}^{2-}\right]=\left(\frac{5.9 \times 10^{-30}}{(0.00010)^{2}}\right)^{1 / 3}=8.4 \times 10^{-8} \mathrm{M}
$$

To see if $8.4 \times 10^{-8} \mathrm{M} \mathrm{C}_{2} \mathrm{O}_{4}^{2-}$ will precipitate $0.010 \mathrm{M} \mathrm{Ca}^{2+}$, evaluate $Q$ for $\mathrm{CaC}_{2} \mathrm{O}_{4}$ :

$$
Q=\left[\mathrm{Ca}^{2+}\right]\left[\mathrm{C}_{2} \mathrm{O}_{4}^{2-}\right]=(0.010)\left(8.4 \times 10^{-8}\right)=8.4 \times 10^{-10}
$$

Because $Q<K_{\text {sp }}$ for $\mathrm{CaC}_{2} \mathrm{O}_{4}\left(=1.3 \times 10^{-8}\right), \mathrm{Ca}^{2+}$ will not precipitate. 6-G. Assuming that all nickel is in the form $\mathrm{Ni}(\mathrm{en}) 3_{3}^{2+},\left[\mathrm{Ni}(\mathrm{en}) 3^{2+}\right]=$ $1.00 \times 10^{-5} \mathrm{M}$. This uses up just $3 \times 10^{-5} \mathrm{~mol}$ of en, which leaves the en concentration at 0.100 M . Adding the three equations gives

$$
\begin{gathered}
\mathrm{Ni}^{2+}+3 \mathrm{en} \rightleftharpoons \mathrm{Ni}(\mathrm{en})_{3}^{2+} \\
K=K_{1} K_{2} K_{3}=2.1_{4} \times 10^{18} \\
{\left[\mathrm{Ni}^{2+}\right]=\frac{\left[\mathrm{Ni}(\mathrm{en})_{3}^{2+}\right]}{K[\mathrm{en}]^{3}}} \\
=\frac{\left(1.00 \times 10^{-5}\right)}{\left(2.1_{4} \times 10^{18}\right)(0.100)^{3}}=4.7 \times 10^{-21} \mathrm{M}
\end{gathered}
$$

Now we verify that $\left[\mathrm{Ni}(\mathrm{en})^{2+}\right]$ and $\left[\mathrm{Ni}(\mathrm{en})_{2}^{2+}\right] \ll 10^{-5} \mathrm{M}$ :

$$
\begin{aligned}
{\left[\mathrm{Ni}(\mathrm{en})^{2+}\right] } & =K_{1}\left[\mathrm{Ni}^{2+}\right][\mathrm{en}]=1.5 \times 10^{-14} \mathrm{M} \\
{\left[\mathrm{Ni}(\mathrm{en})_{2}^{2+}\right] } & =K_{2}\left[\mathrm{Ni}(\mathrm{en})^{2+}\right][\mathrm{en}]=3.2 \times 10^{-9} \mathrm{M}
\end{aligned}
$$

6-H. (a) Neutral-Neither $\mathrm{Na}^{+}$nor $\mathrm{Br}^{-}$has any acidic or basic properties. (b) Basic- $\mathrm{CH}_{3} \mathrm{CO}_{2}^{-}$is the conjugate base of acetic acid, and $\mathrm{Na}^{+}$is neither acidic nor basic.
(c) Acidic- $\mathrm{NH}_{4}^{+}$is the conjugate acid of $\mathrm{NH}_{3}$, and $\mathrm{Cl}^{-}$is neither acidic nor basic.
(d) Basic- $\mathrm{PO}_{4}^{3-}$ is a base, and $\mathrm{K}^{+}$is neither acidic nor basic.
(e) Neutral-Neither ion is acidic nor basic.
(f) Basic-The quaternary ammonium ion is neither acidic nor basic, and the $\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{CO}_{2}^{-}$anion is the conjugate base of benzoic acid.
(g) Acidic- $\mathrm{Fe}^{3+}$ is acidic, and nitrate is neither acidic nor basic.

6-I. $\quad K_{\mathrm{b} 1}=K_{\mathrm{w}} / K_{\mathrm{a} 2}=4.3 \times 10^{-9}$
$K_{\mathrm{b} 2}=K_{\mathrm{w}} / K_{\mathrm{a} 1}=1.6 \times 10^{-10}$
6-J. $\quad K \equiv K_{\mathrm{b} 2}=K_{\mathrm{w}} / K_{\mathrm{a} 2}=1.2 \times 10^{-8}$
6-K. (a) $\left[\mathrm{H}^{+}\right]\left[\mathrm{OH}^{-}\right]=x^{2}=K_{\mathrm{w}} \Rightarrow x=\sqrt{K_{\mathrm{w}}} \Rightarrow \mathrm{pH}=-\log \sqrt{K_{\mathrm{w}}}=7.469$ at $0^{\circ} \mathrm{C}, 7.082$ at $20^{\circ} \mathrm{C}$, and 6.770 at $40^{\circ} \mathrm{C}$.
(b) Because $\left[\mathrm{D}^{+}\right]=\left[\mathrm{OD}^{-}\right]$in pure $\mathrm{D}_{2} \mathrm{O}, K=1.35 \times 10^{-15}=$
$\left[\mathrm{D}^{+}\right]\left[\mathrm{OD}^{-}\right]=\left[\mathrm{D}^{+}\right]^{2} \Rightarrow\left[\mathrm{D}^{+}\right]=3.67 \times 10^{-8} \mathrm{M} \Rightarrow \mathrm{pD}=7.435$.

## Chapter 7

7-A. (a) $\mu=\frac{1}{2}\left(\left[\mathrm{~K}^{+}\right] \cdot 1^{2}+\left[\mathrm{NO}_{3}^{-}\right] \cdot(-1)^{2}\right)=0.2 \mathrm{mM}$
(b) $\mu=\frac{1}{2}\left(\left[\mathrm{Cs}^{+}\right] \cdot 1^{2}+\left[\mathrm{CrO}_{4}^{2-}\right] \cdot(-2)^{2}\right)$
$=\frac{1}{2}([0.4] \cdot 1+[0.2] \cdot 4)=0.6 \mathrm{mM}$
(c) $\mu=\frac{1}{2}\left(\left[\mathrm{Mg}^{2+}\right] \cdot 2^{2}+\left[\mathrm{Cl}^{-}\right] \cdot(-1)^{2}+\left[\mathrm{Al}^{3+}\right] \cdot 3^{2}\right)$

7-B. For $0.0050 \mathrm{M}\left(\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}_{2}\right)_{4} \mathrm{~N}^{+} \mathrm{Br}^{-}$plus $0.0050 \mathrm{M}\left(\mathrm{CH}_{3}\right)_{4} \mathrm{~N}^{+} \mathrm{Cl}^{-}$, $\mu=0.010 \mathrm{M}$. The size of the ion $\left(\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}_{2}\right)_{4} \mathrm{~N}^{+}$is 800 pm . At
$\mu=0.01 \mathrm{M}, \gamma=0.912$ for an ion of charge $\pm 1$ with $\alpha=800 \mathrm{pm}$.
$\mathcal{A}=(0.0050)(0.912)=0.0046$.
7-C. $\mu=0.060 \mathrm{M}$ from KSCN, assuming negligible solubility of AgSCN .

The activity coefficients at $\mu=0.060 \mathrm{M}$ are $\gamma_{\mathrm{Ag}^{+}}=0.79$ and
$\gamma_{\mathrm{SCN}^{-}}=0.80$.
$K_{\text {sp }}=\left[\mathrm{Ag}^{+}\right](0.79)[0.060](0.80)=1.1 \times 10^{-12}$
$\Rightarrow\left[\mathrm{Ag}^{+}\right]=2.9 \times 10^{-11} \mathrm{M}$.

7-D. At an ionic strength of $0.050 \mathrm{M}, \gamma_{\mathrm{H}^{+}}=0.86$ and $\gamma_{\mathrm{OH}^{-}}=0.81$.
$\left[\mathrm{H}^{+}\right] \gamma_{\mathrm{H}^{+}}\left[\mathrm{OH}^{-}\right]_{\mathrm{OH}^{-}}=(x)(0.86)(x)(0.81)=1.0 \times 10^{-14}$
$\Rightarrow x=\left[\mathrm{H}^{+}\right]=1.2 \times 10^{-7} \mathrm{M} . \mathrm{pH}=-\log \left[\left(1.2 \times 10^{-7}\right)(0.86)\right]=6.99$.
7-E. (a) Moles of $\mathrm{I}^{-}=2\left(\right.$ moles of $\left.\mathrm{Hg}_{2}^{2+}\right)$
$\left(V_{\mathrm{e}}\right)(0.100 \mathrm{M})=2(40.0 \mathrm{~mL})(0.0400 \mathrm{M}) \Rightarrow \mathrm{V}_{\mathrm{e}}=32.0 \mathrm{~mL}$
(b) Virtually all the $\mathrm{Hg}_{2}^{2+}$ has precipitated, along with 3.20 mmol of $\mathrm{I}^{-}$.

The ions remaining in solution are
$\left[\mathrm{NO}_{3}^{-}\right]=\frac{3.20 \mathrm{mmol}}{100.0 \mathrm{~mL}}=0.0320 \mathrm{M}$
$\left[\mathrm{I}^{-}\right]=\frac{2.80 \mathrm{mmol}}{100.0 \mathrm{~mL}}=0.0280 \mathrm{M}$
$\left[\mathrm{K}^{+}\right]=\frac{6.00 \mathrm{mmol}}{100.0 \mathrm{~mL}}=0.0600 \mathrm{M}$
$\mu=\frac{1}{2} \sum c_{i} z_{i}^{2}=0.0600 \mathrm{M}$
(c) $\mathcal{A}_{\mathrm{Hg}_{2}^{2+}}=K_{\mathrm{sp}} / \mathcal{A}_{\mathrm{I}^{-}}^{2}=K_{\mathrm{sp}} /\left[\mathrm{I}^{-}\right]^{2} \gamma_{\mathrm{I}^{-}}^{2}$
$=4.6 \times 10^{-29} /(0.0280)^{2}(0.795)^{2}=9.3 \times 10^{-26}$
$\Rightarrow \mathrm{pHg}_{2}^{2+}=-\log \mathcal{A}_{\mathrm{Hg}_{2}^{2+}}=25.03$
7-F. (a) $\left[\mathrm{Cl}^{-}\right]=2\left[\mathrm{Ca}^{2+}\right]$
(b) $\underbrace{}_{\text {Species containing Cl }}{\left[\mathrm{Cl}^{-}\right]+\left[\mathrm{CaCl}^{+}\right]}^{\mathrm{Cl}^{-}}=2\{\underbrace{\left[\mathrm{Ca}^{2+}\right]+\left[\mathrm{CaCl}^{+}\right]+\left[\mathrm{CaOH}^{+}\right]}_{\text {Species contaiining } \mathrm{Ca}^{2+}}\}$
(c) $\left[\mathrm{Cl}^{-}\right]+\left[\mathrm{OH}^{-}\right]=2\left[\mathrm{Ca}^{2+}\right]+\left[\mathrm{CaCl}^{+}\right]+\left[\mathrm{CaOH}^{+}\right]+\left[\mathrm{H}^{+}\right]$

7-G. Charge balance:
$\left[\mathrm{F}^{-}\right]+\left[\mathrm{HF}_{2}^{-}\right]+\left[\mathrm{OH}^{-}\right]=2\left[\mathrm{Ca}^{2+}\right]+\left[\mathrm{CaOH}^{+}\right]+\left[\mathrm{CaF}^{+}\right]+\left[\mathrm{H}^{+}\right]$
Mass balance: $\mathrm{CaF}_{2}$ gives 2 mol F for each mol Ca .
$\left[\mathrm{F}^{-}\right]+\left[\mathrm{CaF}^{+}\right]+2\left[\mathrm{CaF}_{2}(a q)\right]+[\mathrm{HF}]+2\left[\mathrm{HF}_{2}^{-}\right]$
$=2\left\{\left[\mathrm{Ca}^{2+}\right]+\left[\mathrm{CaOH}^{+}\right]+\left[\mathrm{CaF}^{+}\right]+\left[\mathrm{CaF}_{2}(a q)\right]\right\}$
Species containing $\mathrm{Ca}^{2+}$
7-H. Charge balance:
$2\left[\mathrm{Ca}^{2+}\right]+\left[\mathrm{CaOH}^{+}\right]+\left[\mathrm{H}^{+}\right]$

$$
=\left[\mathrm{CaPO}_{4}^{-}\right]+3\left[\mathrm{PO}_{4}^{3-}\right]+2\left[\mathrm{HPO}_{4}^{2-}\right]+\left[\mathrm{H}_{2} \mathrm{PO}_{4}^{-}\right]+\left[\mathrm{OH}^{-}\right]
$$

Mass balance: Equate 2(calcium species) $=3$ (phosphate species).
$2\left\{\left[\mathrm{Ca}^{2+}\right]+\left[\mathrm{CaOH}^{+}\right]+\left[\mathrm{CaPO}_{4}^{-}\right]\right\}$
Species containing calcium
$=3\left\{\left[\mathrm{CaPO}_{4}^{-}\right]+\left[\mathrm{PO}_{4}^{3-}\right]+\left[\mathrm{HPO}_{4}^{2-}\right]+\left[\mathrm{H}_{2} \mathrm{PO}_{4}^{-}\right]+\left[\mathrm{H}_{3} \mathrm{PO}_{4}\right]\right\}$
Species containing phosphate
7-I. Pertinent reactions:
$\mathrm{Mn}(\mathrm{OH})_{2}(s) \stackrel{K_{\text {sp }}}{\rightleftharpoons} \mathrm{Mn}^{2+}+2 \mathrm{OH}^{-} \quad K_{\text {sp }}=1.6 \times 10^{-13}$
$\mathrm{Mn}^{2+}+2 \mathrm{OH}^{-} \stackrel{K_{1}}{\rightleftharpoons} \mathrm{MnOH}^{+} \quad K_{1}=2.5 \times 10^{3}$
$\mathrm{H}_{2} \mathrm{O} \stackrel{K_{\mathrm{w}}}{\rightleftharpoons} \mathrm{H}^{+}+\mathrm{OH}^{-} \quad K_{\mathrm{w}}=1.0 \times 10^{-14}$
Charge balance: $2\left[\mathrm{Mn}^{2+}\right]+\left[\mathrm{MnOH}^{+}\right]+\left[\mathrm{H}^{+}\right]=\left[\mathrm{OH}^{-}\right]$
Mass balance: $\underbrace{\left[\mathrm{OH}^{-}\right]+\left[\mathrm{MnOH}^{+}\right]}_{\text {Species containing } \mathrm{OH}^{-}}=2\{\underbrace{\left[\mathrm{Mn}^{2+}\right]+\left[\mathrm{MnOH}^{+}\right]}_{\text {Species containing } \mathrm{Mn}^{2+}}\}+\left[\mathrm{H}^{+}\right]$
(Mass balance gives the same result as charge balance.)
Equilibrium constant expressions:
$K_{\mathrm{sp}}=\left[\mathrm{Mn}^{2+}\right] \gamma_{\mathrm{Mn}^{2+}}\left[\mathrm{OH}^{-}\right]^{2} \gamma_{\mathrm{OH}}^{2}$
$K_{1}=\frac{\left[\mathrm{MnOH}^{+}\right] \gamma_{\mathrm{MnOH}^{+}}}{\left[\mathrm{Mn}^{2+}\right] \gamma_{\mathrm{Mn}^{2+}}\left[\mathrm{OH}^{-}\right] \gamma_{\mathrm{OH}^{-}}}$
$K_{\mathrm{w}}=\left[\mathrm{H}^{+}\right] \gamma_{\mathrm{H}^{+}}\left[\mathrm{OH}^{-}\right] \gamma_{\mathrm{OH}^{-}}$
From $\mathrm{K}_{1}$, we write $\left[\mathrm{MnOH}^{+}\right]=\left(K_{1} / \gamma_{\mathrm{MnOH}^{+}}\right)\left[\mathrm{Mn}^{2+}\right] \gamma_{\mathrm{Mn}^{2+}}\left[\mathrm{OH}^{-}\right] \gamma_{\mathrm{OH}^{-}}$. Substitute for $\left[\mathrm{MnOH}^{+}\right]$in the charge balance:
$2\left[\mathrm{Mn}^{2+}\right]+\left(K_{1} / \gamma_{\mathrm{MnOH}^{+}}\right)\left[\mathrm{Mn}^{2+}\right] \gamma_{\mathrm{Mn}^{2+}}\left[\mathrm{OH}^{-}\right] \gamma_{\mathrm{OH}^{-}}+\left[\mathrm{H}^{+}\right]=\left[\mathrm{OH}^{-}\right]$

Spreadsheet for Exercise 7-I.

In a basic solution, neglect $\left[\mathrm{H}^{+}\right]$in comparison with $\left[\mathrm{OH}^{-}\right]$and solve (A) for $\left[\mathrm{Mn}^{2+}\right]$ :

$$
\begin{equation*}
\left[\mathrm{Mn}^{2+}\right]=\frac{\left[\mathrm{OH}^{-}\right]}{2+\left(K_{1} \gamma_{\mathrm{Mn}^{2}+} / \gamma_{\mathrm{MnOH}^{+}}\right)\left[\mathrm{OH}^{-}\right] \gamma_{\mathrm{OH}^{-}}} \tag{B}
\end{equation*}
$$

Substitute (B) into $K_{\text {sp }}$ :

$$
\begin{align*}
K_{\mathrm{sp}} & =\left[\mathrm{Mn}^{2+}\right] \gamma_{\mathrm{Mn}^{2+}}\left[\mathrm{OH}^{-}\right]^{2} \gamma_{\mathrm{OH}^{-}}^{2} \\
K_{\mathrm{sp}} & =\left(\frac{\gamma_{\mathrm{Mn}^{2+}}\left[\mathrm{OH}^{-}\right]^{3} \gamma_{\mathrm{OH}^{-}}^{2}}{2+\left(K_{1} \gamma_{\mathrm{Mn}^{2+}} / \gamma_{\mathrm{MnOH}^{+}}\right)\left[\mathrm{OH}^{-}\right] \gamma_{\mathrm{OH}^{-}}}\right) \tag{C}
\end{align*}
$$

We take the ion size of $\mathrm{MnOH}^{+}$to be the same as $\mathrm{Mn}^{2+}$, which is 600 pm . (But the charge of $\mathrm{MnOH}^{+}$is +1 , not +2 .) For $\mu=0.10 \mathrm{M}$, the activity coefficients are $\gamma_{\mathrm{Mn}^{2+}}=0.405, \gamma_{\mathrm{MnOH}^{+}}=0.80$, and $\gamma_{\mathrm{OH}^{-}}=0.76$. In the spreadsheet, we use Goal Seek to find the value $\left[\mathrm{OH}^{-}\right]=1.13 \times 10^{-4} \mathrm{M}$ in cell C 4 that makes the right side of Equation (C) equal to $1.6 \times 10^{-13}$ ( $=K_{\mathrm{sp}}$ ) in cell D4. With $\left[\mathrm{OH}^{-}\right]$known, we use $K_{\mathrm{sp}}$ and $K_{1}$ to find:
$\left[\mathrm{Mn}^{2+}\right]=K_{\mathrm{sp}} /\left(\gamma_{\mathrm{Mn}^{2+}}\left[\mathrm{OH}^{-}\right]^{2} \gamma_{\mathrm{OH}^{-}}^{2}\right)=5.36 \times 10^{-5} \mathrm{M}$
$\left[\mathrm{MnOH}^{+}\right]=\left(K_{1} / \gamma_{\mathrm{MnOH}^{+}}\right)\left[\mathrm{Mn}^{2+}\right] \gamma_{\mathrm{Mn}^{2+}}\left[\mathrm{OH}^{-}\right] \gamma_{\mathrm{OH}^{-}}=5.82 \times 10^{-6} \mathrm{M}$
You can check that the charge balance $2\left[\mathrm{Mn}^{2+}\right]+\left[\mathrm{MnOH}^{+}\right] \approx\left[\mathrm{OH}^{-}\right]$ is satisfied.

## Chapter 8

8-A. $\quad \mathrm{pH}=-\log \mathcal{A}_{\mathrm{H}^{+}}$. But $\mathcal{A}_{\mathrm{H}^{+}} \mathcal{A}_{\mathrm{OH}^{-}}=K_{\mathrm{w}} \Rightarrow \mathcal{A}_{\mathrm{H}^{+}}=K_{\mathrm{w}} / \mathcal{A}_{\mathrm{OH}}{ }^{-}$. For $1.0 \times 10^{-2} \mathrm{M} \mathrm{NaOH},\left[\mathrm{OH}^{-}\right]=1.0 \times 10^{-2} \mathrm{M}$ and $\gamma_{\mathrm{OH}^{-}}=0.900$ (Table 7-1, with $\mu=0.010 \mathrm{M}$ ).
$\mathcal{A}_{\mathrm{H}^{+}}=\frac{K_{\mathrm{w}}}{\left[\mathrm{OH}^{-}\right] \gamma_{\mathrm{OH}^{-}}}=\frac{1.0 \times 10^{-14}}{\left(1.0 \times 10^{-2}\right)(0.900)}$
$=1.11 \times 10^{-12} \Rightarrow \mathrm{pH}=-\log \mathcal{A}_{\mathrm{H}^{+}}=11.95$
8-B. (a) Charge balance: $\left[\mathrm{H}^{+}\right]=\left[\mathrm{OH}^{-}\right]+\left[\mathrm{Br}^{-}\right]$
Mass balance: $\left[\mathrm{Br}^{-}\right]=1.0 \times 10^{-8} \mathrm{M}$
Equilibrium: $\left[\mathrm{H}^{+}\right]\left[\mathrm{OH}^{-}\right]=K_{\mathrm{w}}$
Setting $\left[\mathrm{H}^{+}\right]=x$ and $\left[\mathrm{Br}^{-}\right]=1.0 \times 10^{-8} \mathrm{M}$, the charge balance tells us that $\left[\mathrm{OH}^{-}\right]=x-1.0 \times 10^{-8}$. Putting this into the $K_{\mathrm{w}}$ equilibrium gives $(x)\left(x-1.0 \times 10^{-8}\right)=1.0 \times 10^{-14} \Rightarrow x=1.0_{5} \times 10^{-7} \mathrm{M} \Rightarrow \mathrm{pH}=6.98$.
(b) Charge balance: $\left[\mathrm{H}^{+}\right]=\left[\mathrm{OH}^{-}\right]+2\left[\mathrm{SO}_{4}^{2-}\right]$

Mass balance: $\quad\left[\mathrm{SO}_{4}^{2-}\right]=1.0 \times 10^{-8} \mathrm{M}$
Equilibrium: $\quad\left[\mathrm{H}^{+}\right]\left[\mathrm{OH}^{-}\right]=K_{\mathrm{w}}$
As before, writing $\left[\mathrm{H}^{+}\right]=x$ and $\left[\mathrm{SO}_{4}^{2-}\right]=1.0 \times 10^{-8} \mathrm{M}$ gives $\left[\mathrm{OH}^{-}\right]=$ $x-2.0 \times 10^{-8} \mathrm{M}$ and $\left[\mathrm{H}^{+}\right]\left[\mathrm{OH}^{-}\right]=(x)\left[x-\left(2.0 \times 10^{-8}\right)\right]=1.0 \times 10^{-14}$ $\Rightarrow x=1.10 \times 10^{-7} \mathrm{M} \Rightarrow \mathrm{pH}=6.96$.
8-C.

$$
\begin{gathered}
\text { 2-Nitrophenol } \\
\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{NO}_{3}
\end{gathered}
$$

$\mathrm{F}_{\mathrm{HA}}($ formal concentration $)=\frac{1.23 \mathrm{~g} /(139.11 \mathrm{~g} / \mathrm{mol})}{0.250 \mathrm{~L}}$

$$
=0.0354 \mathrm{M}
$$

$$
\underset{\mathrm{F}-x}{\mathrm{HA}} \rightleftharpoons \underset{x}{\mathrm{H}^{+}}+\underset{x}{\mathrm{~A}^{-}}
$$

$$
\frac{x^{2}}{0.0354-x}=5.89 \times 10^{-8} \mathrm{M}
$$

$$
\Rightarrow x=4.56 \times 10^{-5} \mathrm{M} \Rightarrow \mathrm{pH}=-\log x=4.34
$$

8-D.

But $\left[\mathrm{H}^{+}\right]=10^{-\mathrm{pH}}=6.9 \times 10^{-7} \mathrm{M} \Rightarrow\left[\mathrm{A}^{-}\right]=6.9 \times 10^{-7} \mathrm{M}$
and $[\mathrm{HA}]=0.010-\left[\mathrm{H}^{+}\right]=0.010$.
$K_{\mathrm{a}}=\frac{\left[\mathrm{H}^{+}\right]\left[\mathrm{A}^{-}\right]}{[\mathrm{HA}]}=\frac{\left(6.9 \times 10^{-7}\right)^{2}}{0.010}=4.8 \times 10^{-11} \Rightarrow \mathrm{p} K_{\mathrm{a}}=10.32$
8-E. As $[\mathrm{HA}] \rightarrow 0, \mathrm{pH} \rightarrow 7$. If $\mathrm{pH}=7$,
$\frac{\left[\mathrm{H}^{+}\right]\left[\mathrm{A}^{-}\right]}{[\mathrm{HA}]}=K_{\mathrm{a}} \Rightarrow\left[\mathrm{A}^{-}\right]=\frac{K_{\mathrm{a}}}{\left[\mathrm{H}^{+}\right]}[\mathrm{HA}]$
$=\frac{10^{-5.00}}{10^{-7.00}}[\mathrm{HA}]=100[\mathrm{HA}]$
$\alpha=\frac{\left[\mathrm{A}^{-}\right]}{[\mathrm{HA}]+\left[\mathrm{A}^{-}\right]}=\frac{100[\mathrm{HA}]}{[\mathrm{HA}]+100[\mathrm{HA}]}=\frac{100}{101}=99 \%$
If $\mathrm{p} K_{\mathrm{a}}=9.00$, we find $\alpha=0.99 \%$.
8-F. $\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CO}_{2}^{-}+\mathrm{H}_{2} \mathrm{O} \rightleftharpoons \mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CO}_{2} \mathrm{H}+\mathrm{OH}^{-}$

$$
\mathrm{F}-x
$$

$K_{\mathrm{b}}=\frac{K_{\mathrm{w}}}{K_{\mathrm{a}}}=6.58 \times 10^{-10}$
$\frac{x^{2}}{\mathrm{~F}-x}=K_{\mathrm{b}} \Rightarrow x=5.7_{4} \times 10^{-6} \mathrm{M}$
$\mathrm{pH}=-\log \left(\frac{K_{\mathrm{w}}}{x}\right)=8.76$
8-G. (a) $\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{NH}_{2}+\mathrm{H}_{2} \mathrm{O} \rightleftharpoons \mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{NH}_{3}^{+}+\mathrm{OH}^{-}$

$$
\mathrm{F}-x \quad x
$$

Because $\mathrm{pH}=11.82,\left[\mathrm{OH}^{-}\right]=K_{\mathrm{w}} / 10^{-\mathrm{pH}}=6.6 \times 10^{-3} \mathrm{M}=\left[\mathrm{BH}^{+}\right]$.
$[\mathrm{B}]=\mathrm{F}-x=0.093 \mathrm{M}$.
$K_{\mathrm{b}}=\frac{\left[\mathrm{BH}^{+}\right]\left[\mathrm{OH}^{-}\right]}{[\mathrm{B}]}=\frac{\left(6.6 \times 10^{-3}\right)^{2}}{0.093}=4.7 \times 10^{-4}$
(b) $\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{NH}_{3}^{+} \rightleftharpoons \mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{NH}_{2}+\mathrm{H}^{+}$
$K_{\mathrm{a}}=\frac{K_{\mathrm{w}}}{K_{\mathrm{b}}}=2.1 \times 10^{-11}$
$\frac{x^{2}}{\mathrm{~F}-x}=K_{\mathrm{a}} \Rightarrow x=1.4_{5} \times 10^{-6} \mathrm{M} \Rightarrow \mathrm{pH}=5.84$
8-H.
\(\left.\begin{array}{lll}Compound \& \mathrm{p} K_{\mathrm{a}} (for conjugate acid) <br>
\hline Ammonia \& 9.24 \& \leftarrow Most suitable, because \mathrm{pK} <br>

$$
\mathrm{pH}=8.04+\left(\frac{0.012999}{0.009546}\right)=8.17
$$

(d)

|  | $\mathrm{BH}^{+}$ | + | $\mathrm{OH}^{-}$ | $\rightarrow$ |
| :--- | :---: | :---: | :---: | :---: | B

$$
\mathrm{pH}=8.04+\log \left(\frac{0.013999}{0.008546}\right)=8.25
$$

(e) The solution in (a) contains 9.046 mmol glycine amide hydrochloride and 13.499 mmol glycine amide. Now we are adding 9.046 mmol of $\mathrm{OH}^{-}$, which will convert all of the glycine amide hydrochloride into glycine amide. The new solution contains $9.046+13.499=22.545 \mathrm{mmol}$ of glycine amide in 190.46 mL . The concentration of glycine amide is $(22.545 \mathrm{mmol}) /(190.46 \mathrm{~mL})=0.118_{4} \mathrm{M}$. The pH is determined by hydrolysis of glycine amide:

$\frac{x^{2}}{0.118_{4}-x}=K_{\mathrm{b}}=\frac{K_{\mathrm{w}}}{K_{\mathrm{a}}}=\frac{10^{-14.00}}{10^{-8.04}}=1.10 \times 10^{-6} \mathrm{M}$
$\Rightarrow x=3.60 \times 10^{-4} \mathrm{M}$
$\mathrm{pH}=-\log \left(K_{\mathrm{w}} / x\right)=10.56$
$8-\mathrm{K}$. The reaction of phenylhydrazine with water is
$\mathrm{B}+\mathrm{H}_{2} \mathrm{O} \rightleftharpoons \mathrm{BH}^{+}+\mathrm{OH}^{-} \quad K_{\mathrm{b}}$
We know that $\mathrm{pH}=8.13$, so we can find $\left[\mathrm{OH}^{-}\right]$.
$\left[\mathrm{OH}^{-}\right]=\frac{\mathcal{A}_{\mathrm{OH}^{-}}}{\gamma_{\mathrm{OH}^{-}}}=\frac{K_{\mathrm{w}} / 10^{-\mathrm{pH}}}{\gamma_{\mathrm{OH}^{-}}}=1.78 \times 10^{-6} \mathrm{M}$
(using $\gamma_{\mathrm{OH}^{-}}=0.76$ for $\mu=0.10 \mathrm{M}$ )
$K_{\mathrm{b}}=\frac{\left[\mathrm{BH}^{+}\right] \gamma_{\mathrm{BH}^{+}}\left[\mathrm{OH}^{-}\right] \gamma_{\mathrm{OH}^{-}}}{[\mathrm{B}] \gamma_{\mathrm{B}}}$
$=\frac{\left(1.78 \times 10^{-6}\right)(0.80)\left(1.78 \times 10^{-6}\right)(0.76)}{\left[0.010-\left(1.78 \times 10^{-6}\right)\right](1.00)}$
$=1.93 \times 10^{-10}$
$K_{\mathrm{a}}=\frac{K_{\mathrm{w}}}{K_{\mathrm{b}}}=5.19 \times 10^{-5} \Rightarrow \mathrm{p} K_{\mathrm{a}}=4.28$
To find $K_{\mathrm{b}}$, we made use of the equality $\left[\mathrm{BH}^{+}\right]=\left[\mathrm{OH}^{-}\right]$.
8-L. We use Goal Seek to vary cell B5 until cell D4 is equal to $K_{\mathrm{a}}$. The spreadsheet shows that $\left[\mathrm{H}^{+}\right]=4.236 \times 10^{-3}$ (cell B5) and $\mathrm{pH}=2.37$ in cell B 7 .

|  | A | B | C | D |
| :---: | :---: | :---: | :---: | :---: |
| 1 | $\mathrm{Ka}=10^{\wedge}-\mathrm{pKa}=$ | 0.00316228 |  | Reaction quotient |

If we were doing this problem by hand with the approximation that what we mix is what we get, $\left[\mathrm{H}^{+}\right]=K_{\mathrm{a}}[\mathrm{HA}] /\left[\mathrm{A}^{-}\right]=10^{-2.50}[0.030] /[0.015]=$ $0.00632 \mathrm{M} \Rightarrow \mathrm{pH}=2.20$.

## Chapter 9

9-A. (a) $\mathrm{H}_{2} \mathrm{SO}_{3} \rightleftharpoons \mathrm{HSO}_{3}^{-}+\mathrm{H}^{+}$
$\frac{x^{2}}{0.050-x}=K_{1}=1.39 \times 10^{-2} \Rightarrow x=2.03 \times 10^{-2}$
$\left[\mathrm{HSO}_{3}^{-}\right]=\left[\mathrm{H}^{+}\right]=2.03 \times 10^{-2} \mathrm{M} \Rightarrow \mathrm{pH}=1.69$
$\left[\mathrm{H}_{2} \mathrm{SO}_{3}\right]=0.050-x=0.030 \mathrm{M}$
$\left[\mathrm{SO}_{3}^{2-}\right]=\frac{K_{2}\left[\mathrm{HSO}_{3}^{-}\right]}{\left[\mathrm{H}^{+}\right]}=K_{2}=6.7 \times 10^{-8} \mathrm{M}$
(b) $\left[\mathrm{H}^{+}\right]=\sqrt{\frac{K_{1} K_{2}(0.050)+K_{1} K_{\mathrm{w}}}{K_{1}+(0.050)}}$
$=2.70 \times 10^{-5} \mathrm{M} \Rightarrow \mathrm{pH}=4.57$
$\left[\mathrm{H}_{2} \mathrm{SO}_{3}\right]=\frac{\left[\mathrm{H}^{+}\right]\left[\mathrm{HSO}_{3}^{-}\right]}{K_{1}}=\frac{\left(2.70 \times 10^{-5}\right)(0.050)}{1.39 \times 10^{-2}}$
$=9.7 \times 10^{-5} \mathrm{M}$
$\left[\mathrm{SO}_{3}^{2-}\right]=\frac{K_{2}\left[\mathrm{HSO}_{3}^{-}\right]}{\left[\mathrm{H}^{+}\right]}=1.2 \times 10^{-4} \mathrm{M}$
$\left[\mathrm{HSO}_{3}^{-}\right]=0.050 \mathrm{M}$
(c) $\mathrm{SO}_{3}^{2-}+\mathrm{H}_{2} \mathrm{O} \rightleftharpoons \mathrm{HSO}_{3}^{-}+\mathrm{OH}^{-}$
$\frac{x^{2}}{0.050-x}=K_{\mathrm{b} 1}=\frac{K_{\mathrm{w}}}{K_{\mathrm{a} 2}}=1.49 \times 10^{-7}$
$\left[\mathrm{HSO}_{3}^{-}\right]=x=8.6 \times 10^{-5} \mathrm{M}$
$\left[\mathrm{H}^{+}\right]=\frac{K_{\mathrm{w}}}{x}=1.16 \times 10^{-10} \mathrm{M} \Rightarrow \mathrm{pH}=9.94$
$\left[\mathrm{SO}_{3}^{2-}\right]=0.050-x=0.050 \mathrm{M}$
$\left[\mathrm{H}_{2} \mathrm{SO}_{3}\right]=\frac{\left[\mathrm{H}^{+}\right]\left[\mathrm{HSO}_{3}^{-}\right]}{K_{1}}=7.2 \times 10^{-13} \mathrm{M}$
9-B. (a) $\mathrm{pH}=\mathrm{p} K_{2}\left(\right.$ for $\left.\mathrm{H}_{2} \mathrm{CO}_{3}\right)+\log \frac{\left[\mathrm{CO}_{3}^{2-}\right]}{\left[\mathrm{HCO}_{3}^{-}\right]}$
$10.80=10.329+\log \frac{(4.00 \mathrm{~g}) /(138.206 \mathrm{~g} / \mathrm{mol})}{x /(84.007 \mathrm{~g} / \mathrm{mol})}$
$\Rightarrow x=0.822 \mathrm{~g}$
(b)

|  | $\mathrm{CO}_{3}^{2-}$ | + | $\mathrm{H}^{+}$ | $\rightarrow$ |
| :--- | :--- | :---: | :---: | :---: |
| Initial moles: | $0.0289_{4}^{-}$ |  |  |  |
| Final moles: | $0.0189_{4}$ | 0.0100 | 0.00978 |  |

$$
\mathrm{pH}=10.329+\log \frac{0.0189_{4}}{0.0197_{8}}=10.31
$$

(c)

|  | $\mathrm{CO}_{3}^{2-}$ | + | $\mathrm{H}^{+}$ | $\rightarrow$ |
| :--- | :--- | :---: | :--- | :---: |
| HCO |  |  |  |  |

$10.00=10.329+\log \frac{0.0289_{4}-x}{x} \Rightarrow x=0.0197 \mathrm{~mol}$
$\Rightarrow$ volume $=\frac{0.0197 \mathrm{~mol}}{0.320 \mathrm{M}}=61.6 \mathrm{~mL}$

pH 4.40 is above $\mathrm{p} K_{1}$. At $\mathrm{pH}=\mathrm{p} K_{1}$, there would be a $1: 1$ mixture of $\mathrm{H}_{2} \mathrm{~A}$ and $\mathrm{HA}^{-}$. We must add enough KOH to convert some $\mathrm{H}_{2} \mathrm{~A}$ to $\mathrm{HA}^{-}$ to create a mixture with $\mathrm{pH}=4.40 .5 .02 \mathrm{~g} \mathrm{H}_{2} \mathrm{~A} /(132.11 \mathrm{~g} / \mathrm{mol})=$ $0.0380 \mathrm{~mol} \mathrm{H}_{2} \mathrm{~A}$.

|  | $\mathrm{H}_{2} \mathrm{~A}$ | + | $\mathrm{OH}^{-}$ | $\rightarrow$ |
| :--- | :---: | :---: | :---: | :---: |
| Initial moles: | 0.0380 | $x$ |  | - |
| Final moles: | $0.0380-x$ | - |  | $x$ |

$$
\mathrm{pH}=\mathrm{p} K_{1}+\log \frac{\left[\mathrm{HA}^{-}\right]}{\left[\mathrm{H}_{2} \mathrm{~A}\right]}
$$

$4.40=4.345+\log \frac{x}{0.0380-x} \Rightarrow x=0.0202 \mathrm{~mol}$
Volume of $\mathrm{KOH}=(0.0202 \mathrm{~mol}) /(0.800 \mathrm{M})=25.2 \mathrm{~mL}$.
9-D. (a) Call the three forms of glutamine $\mathrm{H}_{2} \mathrm{G}^{+}, \mathrm{HG}$, and $\mathrm{G}^{-}$. The form shown is HG.
$\left[\mathrm{H}^{+}\right]=\sqrt{\frac{K_{1} K_{2}(0.010)+K_{1} K_{\mathrm{w}}}{K_{1}+0.010}}=1.9_{8} \times 10^{-6} \mathrm{M} \Rightarrow \mathrm{pH}=5.70$
(b) Call the four forms of cysteine $\mathrm{H}_{3} \mathrm{C}^{+}, \mathrm{H}_{2} \mathrm{C}, \mathrm{HC}^{-}$, and $\mathrm{C}^{2-}$. The form shown is $\mathrm{HC}^{-}$.
$\left[\mathrm{H}^{+}\right]=\sqrt{\frac{K_{2} K_{3}(0.010)+K_{2} K_{\mathrm{w}}}{K_{2}+0.010}}=2.8_{9} \times 10^{-10} \mathrm{M} \Rightarrow \mathrm{pH}=9.54$
(c) Call the four forms of arginine $\mathrm{H}_{3} \mathrm{~A}^{2+}, \mathrm{H}_{2} \mathrm{~A}^{+}, \mathrm{HA}$, and $\mathrm{A}^{-}$. The form shown is HA.
$\left[\mathrm{H}^{+}\right]=\sqrt{\frac{K_{2} K_{3}(0.010)+K_{2} K_{\mathrm{w}}}{K_{2}+0.010}}=4.2_{8} \times 10^{-11} \mathrm{M} \Rightarrow \mathrm{pH}=10.37$
9-E.
Principal species:

The percentage in the major form was calculated with the formulas for $\alpha_{\mathrm{H}_{2} \mathrm{~A}}$ (Equation 9-19 at pH 9.00 ) and $\alpha_{\mathrm{HA}^{-}}$(Equation 9-20 at pH 11.00).
9-F.
pH 9.0
pH 10.0

9-G. The isoionic pH is the pH of a solution of pure neutral lysine, which is

$\left[\mathrm{H}^{+}\right]=\sqrt{\frac{K_{2} K_{3} \mathrm{~F}+K_{2} K_{\mathrm{w}}}{K_{2}+\mathrm{F}}} \Rightarrow \mathrm{pH}=9.93$
$9-\mathrm{H}$. We know that the isoelectric point will be near $\frac{1}{2}\left(\mathrm{p} K_{2}+\mathrm{p} K_{3}\right) \approx 9.95$. At this pH , the fraction of lysine in the form $\mathrm{H}_{3} \mathrm{~L}^{2+}$ is negligible.
Therefore, the electroneutrality condition reduces to $\left[\mathrm{H}_{2} \mathrm{~L}^{+}\right]=\left[\mathrm{L}^{-}\right]$, for which the expression isoelectric $\mathrm{pH}=\frac{1}{2}\left(\mathrm{p} K_{2}+\mathrm{p} K_{3}\right)=9.95$ applies.

## Chapter 10

10-A. The titration reaction is $\mathrm{H}^{+}+\mathrm{OH}^{-} \rightarrow \mathrm{H}_{2} \mathrm{O}$ and $V_{\mathrm{e}}=5.00 \mathrm{~mL}$. Three representative calculations are given:
At $1.00 \mathrm{~mL}: \quad\left[\mathrm{OH}^{-}\right]=\left(\frac{4.00}{5.00}\right)(0.0100 \mathrm{M})\left(\frac{50.00}{51.00}\right)=0.00784 \mathrm{M}$ $\mathrm{pH}=-\log \left(\frac{K_{\mathrm{w}}}{\left[\mathrm{OH}^{-}\right]}\right)=11.89$
At $5.00 \mathrm{~mL}: \mathrm{H}_{2} \mathrm{O} \rightleftharpoons \mathrm{H}^{+}+\mathrm{OH}^{-}$
$x^{2}=K_{\mathrm{w}} \Rightarrow x=1.0 \times 10^{-7} \mathrm{M}$
$\mathrm{pH}=-\log x=7.00$
At $5.01 \mathrm{~mL}: \quad\left[\mathrm{H}^{+}\right]=\left(\frac{0.01}{55.01}\right)(0.100 \mathrm{M})=1.82 \times 10^{-5} \mathrm{M} \Rightarrow \mathrm{pH}=4.74$

| $V_{\mathrm{e}}(\mathrm{mL})$ | pH | $V_{\mathrm{e}}$ | pH | $V_{\mathrm{e}}$ | pH |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 0.00 | 12.00 | 4.50 | 10.96 | 5.10 | 3.74 |
| 1.00 | 11.89 | 4.90 | 10.26 | 5.50 | 3.05 |
| 2.00 | 11.76 | 4.99 | 9.26 | 6.00 | 2.75 |
| 3.00 | 11.58 | 5.00 | 7.00 | 8.00 | 2.29 |
| 4.00 | 11.27 | 5.01 | 4.74 | 10.00 | 2.08 |

10-B. The titration reaction is $\mathrm{HCO}_{2} \mathrm{H}+\mathrm{OH}^{-} \rightarrow \mathrm{HCO}_{2}^{-}+\mathrm{H}_{2} \mathrm{O}$ and $V_{\mathrm{e}}$ $=50.0 \mathrm{~mL}$. For formic acid, $K_{\mathrm{a}}=1.80 \times 10^{-4}$. Four representative calculations are given:
At $0.0 \mathrm{~mL}: \quad \mathrm{HA} \rightleftharpoons \mathrm{H}^{+}+\mathrm{A}^{-}$
$\frac{x^{2}}{0.0500-x}=K_{\mathrm{a}} \Rightarrow x=2.91 \times 10^{-3} \mathrm{M} \Rightarrow \mathrm{pH}=2.54$
At 48.0 mL :

|  | HA | + | $\mathrm{OH}^{-}$ | $\rightarrow$ | $\mathrm{A}^{-}$ | + | $\mathrm{H}_{2} \mathrm{O}$ |
| :--- | ---: | :--- | :--- | :--- | :--- | :--- | :--- |
| Initial: | 50 |  | 48 |  | - | - |  |
| Final: | 2 |  | - |  | 48 |  | 48 |

$\mathrm{pH}=\mathrm{p} K_{\mathrm{a}}+\log \frac{\left[\mathrm{A}^{-}\right]}{[\mathrm{HA}]}=3.744+\log \frac{48.0}{2.0}=5.12$
At $50.0 \mathrm{~mL}: \underset{\mathrm{F}-x}{\mathrm{~A}^{-}+}+\mathrm{H}_{2} \mathrm{O} \xlongequal[x]{\stackrel{K_{b}}{\rightleftharpoons}} \underset{x}{\mathrm{HA}}+\underset{x}{\mathrm{OH}^{-}}$
$K_{\mathrm{b}}=\frac{K_{\mathrm{w}}}{K_{\mathrm{a}}} \quad$ and $\quad \mathrm{F}=\left(\frac{50}{100}\right)(0.05 \mathrm{M})$
$\frac{x^{2}}{0.0250-x}=5.56 \times 10^{-11} \Rightarrow x=1.18 \times 10^{-6} \mathrm{M}$
$\mathrm{pH}=-\log \left(\frac{K_{\mathrm{w}}}{x}\right)=8.07$
At $60.0 \mathrm{~mL}: \quad\left[\mathrm{OH}^{-}\right]=\left(\frac{10.0}{110.0}\right)(0.0500 \mathrm{M})$

$$
=4.55 \times 10^{-3} \mathrm{M} \Rightarrow \mathrm{pH}=11.66
$$

| $V_{\mathrm{b}}(\mathrm{mL})$ | pH | $V_{\mathrm{b}}$ | pH | $V_{\mathrm{b}}$ | pH |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 0.0 | 2.54 | 45.0 | 4.70 | 50.5 | 10.40 |
| 10.0 | 3.14 | 48.0 | 5.12 | 51.0 | 10.69 |
| 20.0 | 3.57 | 49.0 | 5.43 | 52.0 | 10.99 |
| 25.0 | 3.74 | 49.5 | 5.74 | 55.0 | 11.38 |
| 30.0 | 3.92 | 50.0 | 8.07 | 60.0 | 11.66 |
| 40.0 | 4.35 |  |  |  |  |

$10-\mathrm{C}$. The titration reaction is $\mathrm{B}+\mathrm{H}^{+} \rightarrow \mathrm{BH}^{+}$and $V_{\mathrm{e}}=50.0 \mathrm{~mL}$. Representative calculations:
At $V_{\mathrm{a}}=0.0 \mathrm{~mL}: \underset{0.100-x}{\mathrm{~B}+\mathrm{H}_{2} \mathrm{O}} \rightleftharpoons \underset{x}{\mathrm{BH}^{+}}+\underset{x}{\mathrm{OH}^{-}}$
$\frac{x^{2}}{0.100-x}=2.6 \times 10^{-6} \Rightarrow x=5.09 \times 10^{-4} \mathrm{M}$
$\mathrm{pH}=-\log \left(\frac{K_{\mathrm{w}}}{x}\right)=10.71$
At $V_{\mathrm{a}}=20.0 \mathrm{~mL}$ :

|  | B | + | $\mathrm{H}^{+}$ | $\rightarrow$ | $\mathrm{BH}^{+}$ |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Initial: | 50.0 |  | 20.0 |  | - |
| Final: | 30.0 |  | - |  | 20.0 |

$\mathrm{pH}=\mathrm{p} K_{\mathrm{a}}\left(\right.$ for $\left.\mathrm{BH}^{+}\right)+\log \frac{[\mathrm{B}]}{\left[\mathrm{BH}^{+}\right]}=8.41+\log \frac{30.0}{20.0}=8.59$
At $V_{\mathrm{a}}=V_{\mathrm{e}}=50.0 \mathrm{~mL}: ~ A l l ~ B ~ h a s ~ b e e n ~ c o n v e r t e d ~ i n t o ~ t h e ~ c o n j u g a t e ~ a c i d, ~$ $\mathrm{BH}^{+}$. The formal concentration of $\mathrm{BH}^{+}$is $\left(\frac{100}{150}\right)(0.100 \mathrm{M})=0.0667 \mathrm{M}$.
The pH is determined by the reaction
$\underset{0.067-x}{\mathrm{BH}^{+}} \rightleftharpoons \underset{x}{\mathrm{~B}}+\underset{x}{\mathrm{H}^{+}}$
$\frac{x^{2}}{0.0667-x}=K_{\mathrm{a}}=\frac{K_{\mathrm{w}}}{K_{\mathrm{b}}} \Rightarrow x=1.60 \times 10^{-5} \mathrm{M} \Rightarrow \mathrm{pH}=4.80$
At $V_{\mathrm{a}}=51.0 \mathrm{~mL}$ : There is excess $\mathrm{H}^{+}$:
$\left[\mathrm{H}^{+}\right]=\left(\frac{1.0}{151.0}\right)(0.200 \mathrm{M})=1.32 \times 10^{-3} \mathrm{M} \Rightarrow \mathrm{pH}=2.88$

| $V_{\mathrm{a}}(\mathrm{mL})$ | pH | $V_{\mathrm{a}}$ | pH | $V_{\mathrm{a}}$ | pH |
| ---: | ---: | :---: | :---: | :---: | :---: |
| 0.0 | 10.71 | 30.0 | 8.23 | 50.0 | 4.80 |
| 10.0 | 9.01 | 40.0 | 7.81 | 50.1 | 3.88 |
| 20.0 | 8.59 | 49.0 | 6.72 | 51.0 | 2.88 |
| 25.0 | 8.41 | 49.9 | 5.71 | 60.0 | 1.90 |

10-D. The titration reactions are
$\mathrm{HO}_{2} \mathrm{CCH}_{2} \mathrm{CO}_{2} \mathrm{H}+\mathrm{OH}^{-} \rightarrow{ }^{-} \mathrm{O}_{2} \mathrm{CCH}_{2} \mathrm{CO}_{2} \mathrm{H}+\mathrm{H}_{2} \mathrm{O}$
${ }^{-} \mathrm{O}_{2} \mathrm{CCH}_{2} \mathrm{CO}_{2} \mathrm{H}+\mathrm{OH}^{-} \rightarrow{ }^{-} \mathrm{O}_{2} \mathrm{CCH}_{2} \mathrm{CO}_{2}^{-}+\mathrm{H}_{2} \mathrm{O}$
and the equivalence points are 25.0 and 50.0 mL . Let's designate malonic acid as $\mathrm{H}_{2} \mathrm{M}$. Also, $K_{\mathrm{a} 1}=1.42 \times 10^{-3}$ and $K_{\mathrm{a} 2}=2.01 \times 10^{-6}$.
At $0.0 \mathrm{~mL}: \quad \underset{0.050-x}{ } \mathrm{H}_{2} \mathrm{M} \rightleftharpoons \mathrm{H}^{+}+\underset{x}{\mathrm{HM}^{-}}$
$\frac{x^{2}}{0.0500-x}=K_{1} \Rightarrow x=7.75 \times 10^{-3} \mathrm{M} \Rightarrow \mathrm{pH}=2.11$
At 8.0 mL :

|  | $\mathrm{H}_{2} \mathrm{M}$ | + | $\mathrm{OH}^{-}$ | $\rightarrow$ | $\mathrm{HM}^{-}$ | + |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| $\mathrm{H}_{2} \mathrm{O}$ |  |  |  |  |  |  |
| Initial: | 25 | 8 |  | - |  | - |
| Final: | 17 | - |  | 8 |  | - |

$\mathrm{pH}=\mathrm{p} K_{1}+\log \frac{\left[\mathrm{HM}^{-}\right]}{\left[\mathrm{H}_{2} \mathrm{M}\right]}=2.847+\log \frac{8}{17}=2.52$
At $12.5 \mathrm{~mL}: \quad V_{\mathrm{b}}=\frac{1}{2} V_{\mathrm{e}} \Rightarrow \mathrm{pH}=\mathrm{p} K_{1}=2.85$
At 19.3 mL :

|  | $\mathrm{H}_{2} \mathrm{M}$ | $+\mathrm{OH}^{-}$ | $\rightarrow$ | $\mathrm{HM}^{-}$ | + | $\mathrm{H}_{2} \mathrm{O}$ |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| Initial: | 25 | 19.3 |  | - | - |  |
| Final: | 5.7 | - |  | 19.3 | - |  |

$\mathrm{pH}=\mathrm{p} K_{1}+\log \frac{19.3}{5.7}=3.38$
At $25.0 \mathrm{~mL}: \quad$ At $V_{\mathrm{e}}, \mathrm{H}_{2} \mathrm{M}$ has been converted into $\mathrm{HM}^{-}$.
$\left[\mathrm{H}^{+}\right]=\sqrt{\frac{K_{1} K_{2} \mathrm{~F}+K_{1} K_{\mathrm{w}}}{K_{1}+\mathrm{F}}}$
where $\mathrm{F}=\left(\frac{50}{75}\right)(0.0500 \mathrm{M})=0.0333 \mathrm{M}$.
$\left[\mathrm{H}^{+}\right]=5.23 \times 10^{-5} \mathrm{M} \Rightarrow \mathrm{pH}=4.28$
At $37.5 \mathrm{~mL}: \quad V_{\mathrm{b}}=\frac{3}{2} V_{\mathrm{e}} \Rightarrow \mathrm{pH}=\mathrm{p} K_{2}=5.70$
At $50.0 \mathrm{~mL}: \quad$ At $2 V_{\mathrm{e}}, \mathrm{HM}^{-}$has been converted into $\mathrm{M}^{2-}$ :

$$
\mathrm{M}^{2-}+\mathrm{H}_{2} \mathrm{O} \rightleftharpoons \mathrm{HM}^{-}+\mathrm{OH}^{-}
$$

$\left(\frac{50}{100}\right)(0.0500)-x$
$\frac{x^{2}}{0.0250-x}=K_{\mathrm{b} 1}=\frac{K_{\mathrm{w}}}{K_{\mathrm{a} 2}} \Rightarrow x=1.12 \times 10^{-5} \mathrm{M}$
$\Rightarrow \mathrm{pH}=-\log \left(\frac{K_{\mathrm{w}}}{x}\right)=9.05$
At 56.3 mL : There are 6.3 mL of excess NaOH .
$\left[\mathrm{OH}^{-}\right]=\left(\frac{6.3}{106.3}\right)(0.100 \mathrm{M})=5.93 \times 10^{-3} \mathrm{M} \Rightarrow \mathrm{pH}=11.77$

$10-\mathrm{E}$.

The equivalence points occur at 25.0 and 50.0 mL .
At 0 mL : HHis is the second intermediate form derived from the triprotic acid $\mathrm{H}_{3} \mathrm{His}^{2+}$.
$\left[\mathrm{H}^{+}\right]=\sqrt{\frac{K_{2} K_{3}(0.0500)+K_{2} K_{\mathrm{w}}}{K_{2}+(0.0500)}}$

$$
=2.37 \times 10^{-8} \mathrm{M} \Rightarrow \mathrm{pH}=7.62
$$

At 4.0 mL :

|  | HHis | + | $\mathrm{H}^{+}$ | $\rightarrow$ | $\mathrm{H}_{2} \mathrm{His}^{+}$ |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Initial: | 25 |  | 4 |  | - |
| Final: | 21 |  | - |  | 4 |

$\mathrm{pH}=\mathrm{p} K_{2}+\log \frac{21}{4}=6.69$
At $12.5 \mathrm{~mL}: \quad \mathrm{pH}=\mathrm{p} K_{2}=5.97$
At 25.0 mL : The histidine has been converted into $\mathrm{H}_{2} \mathrm{His}^{+}$at the formal concentration $\mathrm{F}=\left(\frac{25}{50}\right)(0.0500 \mathrm{M})=0.0250 \mathrm{M}$.
$\left[\mathrm{H}^{+}\right]=\sqrt{\frac{K_{1} K_{2} \mathrm{~F}+K_{1} K_{\mathrm{w}}}{K_{1}+\mathrm{F}}}=1.16 \times 10^{-4} \mathrm{M} \Rightarrow \mathrm{pH}=3.94$
At 26.0 mL :

|  | $\mathrm{H}_{2} \mathrm{His}^{+}$ | + | $\mathrm{H}^{+}$ | $\rightarrow$ |
| :--- | :---: | :---: | :---: | :---: |
|  | $\mathrm{H}_{3} \mathrm{His}^{2+}$ |  |  |  |
| Initial: | 25 |  | 1 |  |
| Final: | 24 |  | - |  |

$\mathrm{pH}=\mathrm{p} K_{1}+\log \frac{24}{1}=2.98$
The approximation that histidine reacts completely with HCl breaks down between 25 and 50 mL . If you use titration equations in Table 10-5, you would find $\mathrm{pH}=3.28$, instead of 2.98 , at $V_{\mathrm{a}}=26.0 \mathrm{~mL}$.
At 50.0 mL : The histidine has been converted into $\mathrm{H}_{3} \mathrm{His}^{2+}$ at the formal concentration $\mathrm{F}=\left(\frac{25}{75}\right)(0.0500 \mathrm{M})=0.0167 \mathrm{M}$.
$\mathrm{H}_{3} \mathrm{His}^{2+} \rightleftharpoons \mathrm{H}_{2} \mathrm{His}^{+}+\mathrm{H}^{+}$
$\frac{x^{2}}{0.0167-x}=K_{1} \Rightarrow 0.0115 \mathrm{M} \Rightarrow \mathrm{pH}=1.94$
10-F. Figure 10-1: bromothymol blue: blue $\rightarrow$ yellow
Figure 10-2: thymol blue: yellow $\rightarrow$ blue
Figure 10-3: thymolphthalein: colorless $\rightarrow$ blue
10-G. The titration reaction is $\mathrm{HA}+\mathrm{OH}^{-} \rightarrow \mathrm{A}^{-}+\mathrm{H}_{2} \mathrm{O}$. It requires 1 mol NaOH to react with 1 mol HA . Therefore, the formal concentration of $\mathrm{A}^{-}$at the equivalence point is
$\left(\frac{27.63}{127.63}\right) \times(0.09381)=0.02031 \mathrm{M}$
Dilution factor Initial concentration
for $\mathrm{NaOH} \quad$ of NaOH
Because the pH is $10.99,\left[\mathrm{OH}^{-}\right]=9.77 \times 10^{-4} \mathrm{M}$, and we can write $\mathrm{A}^{-}+\mathrm{H}_{2} \mathrm{O} \rightleftharpoons \mathrm{HA}+\mathrm{OH}^{-}$
$K_{\mathrm{b}}=\frac{[\mathrm{HA}]\left[\mathrm{OH}^{-}\right]}{\left[\mathrm{A}^{-}\right]}=\frac{\left(9.77 \times 10^{-4}\right)^{2}}{0.02031-\left(9.77 \times 10^{-4}\right)}=4.94 \times 10^{-5}$
$K_{\mathrm{a}}=\frac{K_{\mathrm{w}}}{K_{\mathrm{b}}}=2.03 \times 10^{-10} \Rightarrow \mathrm{p} K_{\mathrm{a}}=9.69$
For the $19.47-\mathrm{mL}$ point, we have

|  | HA | + | $\mathrm{OH}^{-}$ | $\rightarrow$ | $\mathrm{A}^{-}$ | + |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| Initial: | 27.63 |  | 19.47 |  | - |  |
| Final: | 8.16 |  | - |  | 19.47 |  |

$\mathrm{pH}=\mathrm{p} K_{\mathrm{a}}+\log \frac{\left[\mathrm{A}^{-}\right]}{[\mathrm{HA}]}=9.69+\log \frac{19.47}{8.16}=10.07$
$10-\mathrm{H}$. When $V_{\mathrm{b}}=\frac{1}{2} V_{\mathrm{e}},[\mathrm{HA}]=\left[\mathrm{A}^{-}\right]=0.0333 \mathrm{M}$ (using a correction for dilution by NaOH ). $\left[\mathrm{Na}^{+}\right]=0.0333 \mathrm{M}$ as well. Ionic strength $=0.0333 \mathrm{M}$.

$$
\begin{aligned}
\mathrm{p} K_{\mathrm{a}} & =\mathrm{pH}-\log \frac{\left[\mathrm{A}^{-}\right] \gamma_{\mathrm{A}^{-}}}{[\mathrm{HA}] \gamma_{\mathrm{HA}}} \\
& =4.62-\log \frac{(0.0333)(0.854)}{(0.0333)(1.00)}=4.69
\end{aligned}
$$

The activity coefficient of $\mathrm{A}^{-}$was found by interpolation in Table 7-1.
10-I. (a) The derivatives are shown in the spreadsheet below. In the first derivative graph, the maximum is near 119 mL . In Figure 10-7, the second derivative graph gives an end point of $118.9 \mu \mathrm{~L}$.

(b) Column G in the spreadsheet gives $V_{\mathrm{b}}\left(10^{-\mathrm{pH}}\right)$. In a graph of $V_{\mathrm{b}}\left(10^{-\mathrm{pH}}\right)$ vs. $V_{\mathrm{b}}$, the points from 113 to $117 \mu \mathrm{~L}$ give a straight line whose slope is $-1.178 \times 10^{6}$ and whose intercept (end point) is $118.7 \mu \mathrm{~L}$.
$10-\mathrm{J}$. (a) pH 9.6 is past the equivalence point, so excess volume, $V$, is given by $\left[\mathrm{OH}^{-}\right]=10^{-4.4}=(0.1000 \mathrm{M}) \frac{V}{50.00+10.00+V} \Rightarrow V=0.024 \mathrm{~mL}$.
(b) pH 8.8 is before the equivalence point:

| $8.8=6.27+\log \frac{\left[\mathrm{A}^{-}\right]}{[\mathrm{HA}]} \Rightarrow \frac{\left[\mathrm{A}^{-}\right]}{[\mathrm{HA}]}=339$ |
| :--- |
| Titration reaction: |
| HA |$+\mathrm{OH}^{-} \quad \rightarrow \quad \mathrm{A}^{-} \quad+\quad \mathrm{H}_{2} \mathrm{O}$.

To attain a ratio $\left[\mathrm{A}^{-}\right] /[\mathrm{HA}]=339$, we need $V /(10-V)=339 \Rightarrow$ $V=9.97 \mathrm{~mL}$. The indicator error is $10-9.97=0.03 \mathrm{~mL}$.
$10-\mathrm{K}$. (a) $A=2080[\mathrm{HIn}]+14200\left[\mathrm{In}^{-}\right]$
(b) $[\mathrm{HIn}]=x ;\left[\mathrm{In}^{-}\right]=1.84 \times 10^{-4}-x$
$A=0.868=2080 x+14200\left(1.84 \times 10^{-4}-x\right)$

$$
\begin{aligned}
\Rightarrow x & =1.44 \times 10^{-4} \mathrm{M} \\
\mathrm{p} K_{\mathrm{a}} & =\mathrm{pH}-\log \frac{[\mathrm{In}]}{[\mathrm{HIn}]} \\
& =6.23-\log \frac{\left(1.84 \times 10^{-4}\right)-\left(1.44 \times 10^{-4}\right)}{\left(1.44 \times 10^{-4}\right)}=6.79
\end{aligned}
$$

## Chapter 11

11-A. For every mole of $\mathrm{K}^{+}$entering the first reaction, 4 moles of EDTA are produced in the second reaction.
Moles of EDTA $=$ moles of $\mathrm{Zn}^{2+}$ used in titration
$\left[\mathrm{K}^{+}\right]=\frac{\frac{1}{4}\left(\text { moles of } \mathrm{Zn}^{2+}\right)}{\text { volume of original sample }}$

$$
\begin{aligned}
& =\frac{\frac{1}{4}[28.73( \pm 0.03)][0.0437( \pm 0.0001)]}{250.0( \pm 0.1)} \\
& =\frac{\left[\frac{1}{4}( \pm 0 \%)\right][28.73( \pm 0.104 \%)][0.0437( \pm 0.229 \%)]}{250.0( \pm 0.0400 \%)} \\
& =1.256( \pm 0.255 \%) \times 10^{-3} \mathrm{M}=1.256( \pm 0.003) \mathrm{mM}
\end{aligned}
$$

11-B. Total $\mathrm{Fe}^{3+}+\mathrm{Cu}^{2+}$ in $25.00 \mathrm{~mL}=(16.06 \mathrm{~mL}) \times(0.05083 \mathrm{M})=$ 0.8163 mmol .

Second titration:
millimoles EDTA used: $(25.00 \mathrm{~mL})(0.05083 \mathrm{M})=1.2708$
millimoles $\mathrm{Pb}^{2+}$ needed: $(19.77 \mathrm{~mL})(0.01883 \mathrm{M})=\underline{0.372} \mathbf{3}$
millimoles $\mathrm{Fe}^{3+}$ present: (difference) 0.8985
Because 50.00 mL of unknown were used in the second titration, $\mathrm{Fe}^{3+}$ in $25.00 \mathrm{~mL}=\frac{1}{2}(0.8985 \mathrm{mmol})=0.4492 \mathrm{mmol}$. The millimoles of $\mathrm{Cu}^{2+}$ in 25.00 mL are $0.8163-0.4492=0.3671 \mathrm{mmol} / 25.00 \mathrm{~mL}=0.01468 \mathrm{M}$. 11-C. Designating the total concentration of free EDTA as [EDTA], we can write
$K_{\mathrm{f}}^{\prime}=\frac{\left[\mathrm{CuY}^{2-}\right]}{\left[\mathrm{Cu}^{2+}\right][\text { EDTA }]}=\alpha_{\mathrm{Y}^{4-}} K_{\mathrm{f}}=\left(2.9 \times 10^{-7}\right)\left(10^{18.78}\right)$
$=1.7_{4} \times 10^{12}$
Representative calculations:
At 0.1 mL :

$$
\begin{aligned}
& {[\mathrm{EDTA}]=\left(\frac{25.0-0.1}{25.0}\right)(0.0400 \mathrm{M})\left(\frac{50.0}{50.1}\right)=0.0398 \mathrm{M}} \\
& {\left[\mathrm{CuY}^{2-}\right]}
\end{aligned}=\left(\frac{0.1}{50.1}\right)(0.0800 \mathrm{M})=1.60 \times 10^{-4} \mathrm{M}, ~ \begin{aligned}
{\left[\mathrm{Cu}^{2+}\right] } & =\frac{\left[\mathrm{CuY}{ }^{2-}\right]}{K_{\mathrm{f}}^{\prime}[\mathrm{EDTA}]}=\frac{\left(1.60 \times 10^{-4} \mathrm{M}\right)}{\left(1.7_{4} \times 10^{12}\right)(0.0398 \mathrm{M})} \\
& =2.3 \times 10^{-15} \mathrm{M} \Rightarrow \mathrm{pCu}^{2+}=14.64
\end{aligned}
$$

At 25.0 mL :
Formal concentration of $\mathrm{CuY}^{2-}=\left(\frac{25.0}{75.0}\right)(0.0800 \mathrm{M})=0.0267 \mathrm{M}$

|  | $\mathrm{Cu}^{2+}$ | + | EDTA | $\rightleftharpoons$ |
| :--- | :---: | :---: | :---: | :--- |
| Initial concentration: | - |  | $\mathrm{CuY}^{2-}$ |  |
| Final concentration: | $x$ |  | $x$ |  |

$\frac{0.0267-x}{x^{2}}=1.7_{4} \times 10^{12} \Rightarrow\left[\mathrm{Cu}^{2+}\right]=1.2_{4} \times 10^{-7} \mathrm{M} \Rightarrow \mathrm{pCu}^{2+}=6.91$ At 26.0 mL :
$\left[\mathrm{Cu}^{2+}\right]=\left(\frac{1.0}{76.0}\right)(0.0800 \mathrm{M})=1.05 \times 10^{-3} \mathrm{M} \Rightarrow \mathrm{pCu}^{2+}=2.98$

| Volume (mL) | $\mathrm{pCu}^{2+}$ | Volume | $\mathrm{pCu}^{2+}$ | Volume | $\mathrm{pCu}^{2+}$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 0.1 | 14.64 | 15.0 | 12.07 | 25.0 | 6.91 |
| 5.0 | 12.84 | 20.0 | 11.64 | 26.0 | 2.98 |
| 10.0 | 12.42 | 24.0 | 10.86 | 30.0 | 2.30 |

11-D. We seek a relationship between $\left[\mathrm{H}_{2} \mathrm{Y}^{2-}\right]$ and $\left[\mathrm{Y}^{4-}\right]$, which we can relate to total EDTA:

$$
\begin{aligned}
\mathrm{HY}^{3-} & \rightleftharpoons \mathrm{H}^{+}+\mathrm{Y}^{4-}
\end{aligned} \quad K_{6} .
$$

Using the values $\left[\mathrm{H}^{+}\right]=10^{-5.00} \mathrm{M}, \alpha_{\mathrm{Y}^{4-}}=2.9 \times 10^{-7}$, and $[$ EDTA $]=$ $1.2_{4} \times 10^{-7} \mathrm{M}$ gives $\left[\mathrm{H}_{2} \mathrm{Y}^{2-}\right]=1.1 \times 10^{-7} \mathrm{M}$.
11-E. (a) One volume of $\mathrm{Mn}^{2+}$ requires two volumes of EDTA to reach the equivalence point. The formal concentration of $\mathrm{MnY}^{2-}$ at the equivalence point is $\left(\frac{1}{3}\right)(0.0100 \mathrm{M})=0.00333 \mathrm{M}$.

$$
\begin{gathered}
\mathrm{Mn}_{x}^{2+}+\underset{x}{\mathrm{EDTA}} \rightleftharpoons \mathrm{MnY}^{2-} \\
\frac{0.00333-x}{x^{2}}=\alpha_{\mathrm{Y}^{4-}} K_{\mathrm{f}}=\left(3.8 \times 10^{-4}\right) 10^{13.89}=2.9 \times 10^{10} \\
\Rightarrow x=\left[\mathrm{Mn}^{2+}\right]=3.4 \times 10^{-7} \mathrm{M}
\end{gathered}
$$

(b) pH is constant, so the quotient $\left[\mathrm{H}_{3} \mathrm{Y}^{-}\right] /\left[\mathrm{H}_{2} \mathrm{Y}^{2-}\right]$ is constant throughout the entire titration.
$\frac{\left[\mathrm{H}_{2} \mathrm{Y}^{2-}\right]\left[\mathrm{H}^{+}\right]}{\left[\mathrm{H}_{3} \mathrm{Y}^{-}\right]}=K_{4} \Rightarrow \frac{\left[\mathrm{H}_{3} \mathrm{Y}^{-}\right]}{\left[\mathrm{H}_{2} \mathrm{Y}^{2-}\right]}=\frac{\left[\mathrm{H}^{+}\right]}{K_{4}}=\frac{10^{-7.00}}{10^{-2.69}}=4.9 \times 10^{-5}$
11-F. $K_{\mathrm{f}}$ for $\mathrm{CoY}^{2-}=10^{16.45}=2.8 \times 10^{16}$
$\alpha_{\mathrm{Y}^{4-}}=0.041$ at pH 9.00
$\alpha_{\mathrm{Co}^{2+}}=\frac{1}{1+\beta_{1}\left[\mathrm{C}_{2} \mathrm{O}_{4}^{2-}\right]+\beta_{2}\left[\mathrm{C}_{2} \mathrm{O}_{4}^{2-}\right]^{2}}=6.8 \times 10^{-6}$
(using $\beta_{1}=K_{1}=10^{4.69}$ and $\beta_{2}=K_{1} K_{2}=10^{7.15}$ )
$K_{\mathrm{f}}^{\prime}=\alpha_{\mathrm{Y}^{4-}} K_{\mathrm{f}}=1.1_{6} \times 10^{15}$
$K_{\mathrm{f}}^{\prime \prime}=\alpha_{\mathrm{Co}^{2+}} \alpha_{\mathrm{Y}^{4-}} K_{\mathrm{f}}=7.9 \times 10^{9}$
At 0 mL :

$$
\left[\mathrm{Co}^{2+}\right]=\alpha_{\mathrm{Co}^{2+}}\left(1.00 \times 10^{-3} \mathrm{M}\right)=6.8 \times 10^{-9} \mathrm{M} \Rightarrow \mathrm{pCo}^{2+}=8.17
$$

At 1.00 mL :

$$
\left.\begin{array}{rlr}
\mathrm{C}_{\mathrm{Co}^{2+}} & =\underset{\substack{\text { Fraction } \\
\text { remaining }}}{\left(\frac{1.00}{2.00}\right)} & \left(1.00 \times 10^{-3} \mathrm{M}\right)
\end{array} \quad \begin{array}{c}
\text { Initial } \\
\text { concentration }
\end{array}\right)
$$

$\left[\mathrm{Co}^{2+}\right]=\alpha_{\mathrm{Co}^{2+}} \mathrm{C}_{\mathrm{Co}^{2+}}=3.2 \times 10^{-9} \mathrm{M} \Rightarrow \mathrm{pCo}^{2+}=8.49$
At 2.00 mL : This is the equivalence point.

$$
\begin{array}{ccc}
\mathrm{C}_{\mathrm{Co}^{2+}}+ & \text { EDTA } & \stackrel{K_{\mathrm{f}}^{\prime \prime}}{\rightleftharpoons} \mathrm{CoY}^{2-} \\
x & x & \left(\frac{20.00}{22.00}\right)\left(1.00 \times 10^{-3} \mathrm{M}\right)-x
\end{array}
$$

$K_{\mathrm{f}}^{\prime \prime}=\frac{9.09 \times 10^{-4}-x}{x^{2}} \Rightarrow x=3.4 \times 10^{-7} \mathrm{M}=\mathrm{C}_{\mathrm{Co}^{2+}}$
$\left[\mathrm{Co}^{2+}\right]=\alpha_{\mathrm{Co}^{2+}} \mathrm{C}_{\mathrm{Co}^{2+}}=2.3 \times 10^{-12} \mathrm{M} \Rightarrow \mathrm{pCo}^{2+}=11.64$
At 3.00 mL :
$\left[\right.$ excess EDTA] $=\frac{1.00}{23.00}\left(1.00 \times 10^{-2} \mathrm{M}\right)=4.35 \times 10^{-4} \mathrm{M}$
$\left[\mathrm{CoY}^{2-}\right]=\frac{20.00}{23.00}\left(1.00 \times 10^{-3} \mathrm{M}\right)=8.70 \times 10^{-4} \mathrm{M}$
Knowing [EDTA] and $\left[\mathrm{CoY}^{2-}\right]$, we use $K_{\mathrm{f}}^{\prime}$ to find $\left[\mathrm{Co}^{2+}\right]$ :
$K_{\mathrm{f}}^{\prime}=\frac{\left[\mathrm{CoY}^{2-}\right]}{\left[\mathrm{Co}^{2+}\right][\text { EDTA }]}=\frac{\left[8.70 \times 10^{-4} \mathrm{M}\right]}{\left[\mathrm{Co}^{2+}\right]\left[4.35 \times 10^{-4} \mathrm{M}\right]}$
$\Rightarrow\left[\mathrm{Co}^{2+}\right]=1.7 \times 10^{-15} \mathrm{M} \Rightarrow \mathrm{pCo}^{2+}=14.76$

11-G. 25.0 mL of 0.120 M iminodiacetic acid $=3.00 \mathrm{mmol}$ 25.0 mL of $0.0500 \mathrm{M} \mathrm{Cu}^{2+}=1.25 \mathrm{mmol}$

|  | $\mathrm{Cu}^{2+}$ | + | 2 iminodiacetic <br> acid | $\rightleftharpoons$ | $\mathrm{CuX}_{2}^{2-}$ |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Initial mmol: |  | 1.25 | 3.00 |  | - |
| Final mmol: |  | - | 0.50 |  | 1.25 |

$\frac{\left[\mathrm{CuX}_{2}^{2-}\right]}{\left[\mathrm{Cu}^{2+}\right]\left[\mathrm{X}^{2-}\right]^{2}}=K_{\mathrm{f}}$
$\frac{[1.25 / 50.0]}{\left[\mathrm{Cu}^{2+}\right]\left[(0.50 / 50.0)\left(4.6 \times 10^{-3}\right)\right]^{2}}=3.5 \times 10^{16}$
$\Rightarrow\left[\mathrm{Cu}^{2+}\right]=3.4 \times 10^{-10} \mathrm{M}$

## Chapter 12

12-A. Hydroxybenzene $=$ HA with $\mathrm{p} K_{\mathrm{HA}}=9.997$
Dimethylamine $=\mathrm{B}$ from monoprotic $\mathrm{BH}^{+}$with $\mathrm{p}_{\mathrm{BH}^{+}}=10.774$
Mixture contains $0.010 \mathrm{~mol} \mathrm{HA}, 0.030 \mathrm{~mol} \mathrm{~B}$, and 0.015 mol HCl in 1.00 L
Chemical reactions:

$$
\begin{array}{lll}
\text { Chemical reactions: } & \mathrm{HA} \rightleftharpoons \mathrm{~A}^{-}+\mathrm{H}^{+} & K_{\mathrm{HA}}=10^{-9.997} \\
& \mathrm{BH}^{+} \rightleftharpoons \mathrm{B}+\mathrm{H}^{+} & K_{\mathrm{BH}^{+}}=10^{-10.774} \\
& \mathrm{H}_{2} \mathrm{O} \rightleftharpoons \mathrm{H}^{+}+\mathrm{OH}^{-} & K_{\mathrm{w}}=10^{-14.00} \\
\text { Charge balance: } & {\left[\mathrm{H}^{+}\right]+\left[\mathrm{BH}^{+}\right]=\left[\mathrm{OH}^{-}\right]+\left[\mathrm{A}^{-}\right]+\left[\mathrm{Cl}^{-}\right]} \\
\text {Mass balances: } & {\left[\mathrm{Cl}^{-}\right]=0.015 \mathrm{M}} \\
& {\left[\mathrm{BH}^{+}\right]+[\mathrm{B}]=0.030 \mathrm{M} \equiv \mathrm{~F}_{\mathrm{B}}} \\
& {[\mathrm{HA}]+\left[\mathrm{A}^{-}\right]=0.010 \mathrm{M} \equiv \mathrm{~F}_{\mathrm{A}}}
\end{array}
$$

Mass balances: $\quad\left[\mathrm{Cl}^{-}\right]=0.015 \mathrm{M}$

We have seven equations and seven chemical species.
Fractional composition equations:
$\left[\mathrm{BH}^{+}\right]=\alpha_{\mathrm{BH}^{+}} \mathrm{F}_{\mathrm{B}}=\frac{\left[\mathrm{H}^{+}\right] \mathrm{F}_{\mathrm{B}}}{\left[\mathrm{H}^{+}\right]+K_{\mathrm{BH}^{+}}}$
$[\mathrm{B}]=\alpha_{\mathrm{B}} \mathrm{F}_{\mathrm{B}}=\frac{K_{\mathrm{BH}^{+}} \mathrm{F}_{\mathrm{B}}}{\left[\mathrm{H}^{+}\right]+K_{\mathrm{BH}^{+}}}$
$[\mathrm{HA}]=\alpha_{\mathrm{HA}} \mathrm{F}_{\mathrm{A}}=\frac{\left[\mathrm{H}^{+}\right] \mathrm{F}_{\mathrm{A}}}{\left[\mathrm{H}^{+}\right]+K_{\mathrm{HA}}}$
$\left[\mathrm{A}^{-}\right]=\alpha_{\mathrm{A}}-\mathrm{F}_{\mathrm{A}}=\frac{K_{\mathrm{HA}} \mathrm{F}_{\mathrm{A}}}{\left[\mathrm{H}^{+}\right]+K_{\mathrm{HA}}}$
Substitute into charge balance:
$\left[\mathrm{H}^{+}\right]+\alpha_{\mathrm{BH}^{+}} \mathrm{F}_{\mathrm{B}}=K_{\mathrm{w}} /\left[\mathrm{H}^{+}\right]+\alpha_{\mathrm{A}^{-}} \mathrm{F}_{\mathrm{A}}+[0.015 \mathrm{M}]$
We solve Equation A for $\left[\mathrm{H}^{+}\right]$by using Solver in the spreadsheet, with an initial guess of $\mathrm{pH}=10$ in cell H10. In the Data ribbon, select Solver and choose Options. Set Precision to 1e-16 and click OK. In the Solver

window, Set Target Cell E12 Equal To Value of $\underline{0}$ By Changing Cells H10 . Click Solve and Solver finds $\mathrm{pH}=10.33$ in cell H10, giving a net charge near 0 in cell E12.
12-B. We use effective equilibrium constants, $K^{\prime}$, as follows:
$K_{\mathrm{HA}}=\frac{\left[\mathrm{A}^{-}\right] \gamma_{\mathrm{A}^{-}}\left[\mathrm{H}^{+}\right] \gamma_{\mathrm{H}^{+}}}{[\mathrm{HA}] \gamma_{\mathrm{HA}}}=10^{-9.997}$
$K_{\mathrm{HA}}^{\prime}=K_{\mathrm{HA}}\left(\frac{\gamma_{\mathrm{HA}}}{\gamma_{\mathrm{A}^{-}} \gamma_{\mathrm{H}^{+}}}\right)=\frac{\left[\mathrm{A}^{-}\right]\left[\mathrm{H}^{+}\right]}{[\mathrm{HA}]}$
$[\mathrm{HA}]=\alpha_{\mathrm{HA}} \mathrm{F}_{\mathrm{A}}=\frac{\left[\mathrm{H}^{+}\right] \mathrm{F}_{\mathrm{A}}}{\left[\mathrm{H}^{+}\right]+K_{\mathrm{HA}}^{\prime}}$
$\left[\mathrm{A}^{-}\right]=\alpha_{\mathrm{A}^{-}} \mathrm{F}_{\mathrm{A}}=\frac{K_{\mathrm{HA}}^{\prime} \mathrm{F}_{\mathrm{A}}}{\left[\mathrm{H}^{+}\right]+K_{\mathrm{HA}}^{\prime}}$
$K_{\mathrm{BH}^{+}}=\frac{[\mathrm{B}] \gamma_{\mathrm{B}}\left[\mathrm{H}^{+}\right] \gamma_{\mathrm{H}^{+}}}{\left[\mathrm{BH}^{+}\right] \gamma_{\mathrm{BH}^{+}}}=10^{-10.774}$
$K_{\mathrm{BH}^{+}}^{\prime}=K_{\mathrm{BH}^{+}}\left(\frac{\gamma_{\mathrm{BH}^{+}}}{\gamma_{\mathrm{B}} \gamma_{\mathrm{H}^{+}}}\right)=\frac{[\mathrm{B}]\left[\mathrm{H}^{+}\right]}{\left[\mathrm{BH}^{+}\right]}$
$\left[\mathrm{BH}^{+}\right]=\alpha_{\mathrm{BH}^{+}} \mathrm{F}_{\mathrm{B}}=\frac{\left[\mathrm{H}^{+}\right] \mathrm{F}_{\mathrm{B}}}{\left[\mathrm{H}^{+}\right]+K_{\mathrm{BH}^{+}}^{\prime}}$
$[\mathrm{B}]=\alpha_{\mathrm{B}} \mathrm{F}_{\mathrm{B}}=\frac{K_{\mathrm{BH}^{+}}^{\prime} \mathrm{F}_{\mathrm{B}}}{\left[\mathrm{H}^{+}\right]+K_{\mathrm{BH}^{+}}^{\prime}}$
$K_{\mathrm{w}}=\left[\mathrm{H}^{+}\right] \gamma_{\mathrm{H}^{+}}\left[\mathrm{OH}^{-}\right] \gamma_{\mathrm{OH}^{-}}=10^{-13.995}$
$K_{\mathrm{w}}^{\prime}=\frac{K_{\mathrm{w}}}{\gamma_{\mathrm{H}^{+}} \gamma_{\mathrm{OH}^{-}}}=\left[\mathrm{H}^{+}\right]\left[\mathrm{OH}^{-}\right]$
$\left[\mathrm{OH}^{-}\right]=K_{\mathrm{w}}^{\prime} /\left[\mathrm{H}^{+}\right]$
$\mathrm{pH}=-\log \left(\left[\mathrm{H}^{+}\right] \gamma_{\mathrm{H}^{+}}\right)$
$\left[\mathrm{H}^{+}\right]=\left(10^{-\mathrm{pH}}\right) / \gamma_{\mathrm{H}^{+}}$

The spreadsheet in Exercise 12-A is modified to add activity coefficients in cells A8:H9. Effective equilibrium constants are computed in row 5. Because we are going to the trouble of using activity coefficients, we use $\mathrm{p} K_{\mathrm{w}}=$ 13.995 in cell H 4 instead of the less accurate value of 14.00 . With an initial ionic strength of 0 in cell C 17 and a guess of $\mathrm{pH}=10$ in cell H 14 , the net charge in cell E16 is 0.00556 m . Execute Solver to find the pH that reduces the net charge to near 0 . Results are shown in the spreadsheet. The calculated ionic strength in cell C 18 is 0.0220 m . We write this number in cell C 17 and use Solver again to find pH . Here are the results:

| Iteration | Ionic strength | pH |
| :---: | :---: | :---: |
| 1 | 0 | 10.331 |
| 2 | 0.0220 | 10.357 |
| 3 | 0.0225 | 10.358 |
| 4 | 0.0225 | 10.358 |

12-C. (a) 2-Aminobenzoic acid $=\mathrm{HA}$ from diprotic $\mathrm{H}_{2} \mathrm{~A}^{+}, \mathrm{p} K_{1}=2.08$, $\mathrm{p} K_{2}=4.96$
Dimethylamine $=\mathrm{B}$ from monoprotic $\mathrm{BH}^{+}, \mathrm{p} K_{\mathrm{a}}=10.774$
Mixture contains $0.040 \mathrm{~mol} \mathrm{HA}, 0.020 \mathrm{~mol} \mathrm{~B}$, and 0.015 mol HCl in 1.00 L .
Chemical reactions: $\quad \mathrm{H}_{2} \mathrm{~A}^{+} \rightleftharpoons \mathrm{HA}+\mathrm{H}^{+} \quad K_{1}=10^{-2.08}$

$$
\begin{array}{ll}
\mathrm{HA} \rightleftharpoons \mathrm{~A}^{-}+\mathrm{H}^{+} & K_{2}=10^{-4.96} \\
\mathrm{BH}^{+} \rightleftharpoons \mathrm{B}+\mathrm{H}^{+} & K_{\mathrm{a}}=10^{-10.774} \\
\mathrm{H}_{2} \mathrm{O} \rightleftharpoons \mathrm{H}^{+}+\mathrm{OH}^{-} & K_{\mathrm{w}}=10^{-14.00}
\end{array}
$$

Charge balance:
$\left[\mathrm{H}^{+}\right]+\left[\mathrm{H}_{2} \mathrm{~A}^{+}\right]+\left[\mathrm{BH}^{+}\right]=\left[\mathrm{OH}^{-}\right]+\left[\mathrm{A}^{-}\right]+\left[\mathrm{Cl}^{-}\right]$
Mass balances:
$\left[\mathrm{Cl}^{-}\right]=0.015 \mathrm{M}$
$\left[\mathrm{BH}^{+}\right]+[\mathrm{B}]=0.020 \mathrm{M} \equiv \mathrm{F}_{\mathrm{B}}$
$\left[\mathrm{H}_{2} \mathrm{~A}^{+}\right]+[\mathrm{HA}]+\left[\mathrm{A}^{-}\right]=0.040 \mathrm{M} \equiv \mathrm{F}_{\mathrm{A}}$

We have eight equations and eight chemical species.

Spreadsheet for Exercise 12-C.

Fractional composition equations:

$$
\begin{aligned}
& {\left[\mathrm{BH}^{+}\right]=\alpha_{\mathrm{BH}^{+}} \mathrm{F}_{\mathrm{B}}=\frac{\left[\mathrm{H}^{+}\right] \mathrm{F}_{\mathrm{B}}}{\left[\mathrm{H}^{+}\right]+K_{\mathrm{a}}}} \\
& {[\mathrm{~B}]=\alpha_{\mathrm{B}} \mathrm{~F}_{\mathrm{B}}=\frac{K_{\mathrm{a}} \mathrm{~F}_{\mathrm{B}}}{\left[\mathrm{H}^{+}\right]+K_{\mathrm{a}}}} \\
& {\left[\mathrm{H}_{2} \mathrm{~A}^{+}\right]=\alpha_{\mathrm{H}_{2} \mathrm{~A}^{+}} \mathrm{F}_{\mathrm{A}}=\frac{\left[\mathrm{H}^{+}\right]^{2} \mathrm{~F}_{\mathrm{A}}}{\left[\mathrm{H}^{+}\right]^{2}+\left[\mathrm{H}^{+}\right] K_{1}+K_{1} K_{2}}} \\
& {[\mathrm{HA}]=\alpha_{\mathrm{HA}} \mathrm{~F}_{\mathrm{A}}=\frac{K_{1}\left[\mathrm{H}^{+}\right] \mathrm{F}_{\mathrm{A}}}{\left[\mathrm{H}^{+}\right]^{2}+\left[\mathrm{H}^{+}\right] K_{1}+K_{1} K_{2}}} \\
& {\left[\mathrm{~A}^{-}\right]=\alpha_{\mathrm{A}^{-}} \mathrm{F}_{\mathrm{A}}=\frac{K_{1} K_{2} \mathrm{~F}_{\mathrm{A}}}{\left[\mathrm{H}^{+}\right]^{2}+\left[\mathrm{H}^{+}\right] K_{1}+K_{1} K_{2}}}
\end{aligned}
$$

Substitute into charge balance:

$$
\begin{equation*}
\left[\mathrm{H}^{+}\right]+\alpha_{\mathrm{H}_{2} \mathrm{~A}^{+}} \mathrm{F}_{\mathrm{A}}+\alpha_{\mathrm{BH}^{+}} \mathrm{F}_{\mathrm{B}}=K_{\mathrm{w}} /\left[\mathrm{H}^{+}\right]+\alpha_{\mathrm{A}}-\mathrm{F}_{\mathrm{A}}+[0.015 \mathrm{M}] \tag{A}
\end{equation*}
$$

Solve Equation A for $\left[\mathrm{H}^{+}\right]$by using Solver in the spreadsheet, with an initial guess of $\mathrm{pH}=7$ in cell H12. In the Data ribbon, select Solver and choose Options. Set Precision to 1e-16 and click OK. In the Solver window, Set Target Cell E14 Equal To Value of $\underline{0}$ By Changing Cells H12. Click Solve and Solver finds $\mathrm{pH}=4.15$ in cell H 12 , giving a net charge near 0 in cell E14.
(b) From the concentrations in the spreadsheet, we find the following fractions of 2-aminobenzoic acid: $\mathrm{H}_{2} \mathrm{~A}^{+}=0.7 \%$, $\mathrm{HA}=85.9 \%$, and $\mathrm{A}^{-}=$ $13.4 \%$. The fractions of dimethylamine are $\mathrm{BH}^{+}=100.0 \%$ and $\mathrm{B}=$ $0.0 \%$. The simple prediction is that HCl would consume B , giving $100 \%$ $\mathrm{BH}^{+}$. The remaining 5 mmol B consumes 5 mmol HA , making 5 mmol $\mathrm{A}^{-}$and leaving 35 mmol HA .
Predicted fractions: $\mathrm{A}^{-}=5 / 40=12.5 \%, \mathrm{HA}=35 / 40=87.5 \%$
Estimated $\mathrm{pH}=\mathrm{p} K_{2}+\log \left(\left[\mathrm{A}^{-}\right] /[\mathrm{HA}]\right)=4.96+\log (5 / 35)=4.11$

12-D. Effective equilibrium constants:
$\mathrm{H}_{2} \mathrm{~T} \stackrel{\mathrm{p} K_{1}=3.036}{\rightleftharpoons} \mathrm{HT}^{-}+\mathrm{H}^{+}$

$$
K_{1}^{\prime}=K_{1}\left(\frac{\gamma_{\mathrm{H}_{2} \mathrm{~T}}}{\gamma_{\mathrm{HT}^{-}} \gamma_{\mathrm{H}^{+}}}\right)=\frac{\left[\mathrm{HT}^{-}\right]\left[\mathrm{H}^{+}\right]}{\left[\mathrm{H}_{2} \mathrm{~T}\right]}
$$

$\mathrm{HT}^{-} \stackrel{\mathrm{p} K_{2}=4.366}{\rightleftharpoons} \mathrm{~T}^{2-}+\mathrm{H}^{+}$
$K_{2}^{\prime}=K_{2}\left(\frac{\gamma_{\mathrm{HT}^{-}}}{\gamma_{\mathrm{T}^{2-}} \gamma_{\mathrm{H}^{+}}}\right)=\frac{\left[\mathrm{T}^{2-}\right]\left[\mathrm{H}^{+}\right]}{\left[\mathrm{HT}^{-}\right]}$
$\mathrm{PyH}^{+} \stackrel{\mathrm{p} K_{\mathrm{a}}=5.20}{\rightleftharpoons} \mathrm{Py}+\mathrm{H}^{+}$

$$
K_{\mathrm{a}}^{\prime}=K_{\mathrm{a}}\left(\frac{\gamma_{\mathrm{PyH}^{+}}}{\gamma_{\mathrm{Py} \gamma_{\mathrm{H}^{+}}}}\right)=\frac{[\mathrm{Py}]\left[\mathrm{H}^{+}\right]}{\left[\mathrm{PyH}^{+}\right]}
$$

$\mathrm{H}_{2} \mathrm{O} \stackrel{\mathrm{p} K_{\mathrm{w}}=13.995}{\rightleftharpoons} \mathrm{H}^{+}+\mathrm{OH}^{-}$

$$
K_{\mathrm{w}}^{\prime}=\frac{K_{\mathrm{w}}}{\gamma_{\mathrm{H}^{+}} \gamma_{\mathrm{OH}^{-}}}=\left[\mathrm{H}^{+}\right]\left[\mathrm{OH}^{-}\right]
$$

$\left[\mathrm{OH}^{-}\right]=K_{\mathrm{w}}^{\prime} /\left[\mathrm{H}^{+}\right]$

The spreadsheet is modified from the one in the text by addition of activity coefficients in cells $\mathrm{A} 10: \mathrm{H} 11$. The ionic strength for computing activity coefficients with the Davies equation is in cell C20. The initial ionic strength is set to 0 . The first guess for pH in cell H17 is 5 . Then use Solver to find the pH in cell H17 that makes the net charge in cell E19 nearly 0. From this pH , all concentrations are computed and the new ionic strength is found in cell C21. This new ionic strength is typed into cell C20 for the next iteration. From the new ionic strength, new activity coefficients are computed and new values of $K^{\prime}$ are computed in cells B6, B7, E5, and H5. The pH satisfying the charge balance in cell E19 is then found again with Solver and the process is repeated until ionic strength reaches a constant value.

Spreadsheet for Exercise 12-D.

12-E. $\mathrm{Mg}^{2+}+\mathrm{SO}_{4}^{2-} \rightleftharpoons \mathrm{MgSO}_{4}(a q)$ $K_{\text {ip }}=10^{2.23}(=169.8)$
If hydrolysis is neglected, $\left[\mathrm{Mg}^{2+}\right]=\left[\mathrm{SO}_{4}^{2-}\right]$ and $\left[\mathrm{MgSO}_{4}\right]=\mathrm{F}-\left[\mathrm{Mg}^{2+}\right]$, where F is the formal concentration $(0.025 \mathrm{M})$. We will solve the equation
$K_{\mathrm{ip}}^{\prime}=K_{\mathrm{ip}}\left(\frac{\gamma_{\mathrm{Mg}^{2+}} \gamma_{\mathrm{SO}_{4}^{2-}}}{\gamma_{\mathrm{MgSO}_{4}}}\right)=\frac{\left[\mathrm{MgSO}_{4}(a q)\right]}{\left[\mathrm{Mg}^{2+}\right]\left[\mathrm{SO}_{4}^{2-}\right]}=\frac{\mathrm{F}-\left[\mathrm{Mg}^{2+}\right]}{\left[\mathrm{Mg}^{2+}\right]^{2}}$
with $\gamma_{\mathrm{MgSO}_{4}}=1$ because it is neutral.
(a) First, set $\gamma_{\mathrm{Mg}^{2+}}=\gamma_{\mathrm{SO}_{4}^{2-}}=1.00$ and use Solver (or the quadratic equation) to find $\left[\mathrm{Mg}^{2+}\right]$ to satisfy Equation A. In the spreadsheet, guess an initial value of $\left[\mathrm{Mg}^{2+}\right]=0.0125 \mathrm{M}$ in cell B11. Open Solver from the Data ribbon. Select Solver Options and set Precision $=1 \mathrm{e}-6$. Click OK. In the Solver window, Set Target Cell F14 Equal To Value of 169.8 By Changing Cells B11. Solver finds $\left[\mathrm{Mg}^{2+}\right]=0.00954 \mathrm{M}$ and $\mu=0.0382 \mathrm{M}$.
(b) Write the value $\mu=0.0382 \mathrm{M}$ in cell F3. This ionic strength changes $K_{\text {ip }}^{\prime}$ from 169.8 to 40.7. Execute Solver again. This time Set Target Cell $\underline{\text { F14 }}$ Equal To Value of 40.7 By Changing Cells B11. Solver finds $\left[\mathrm{Mg}^{2+}\right]$ $=0.0154 \mathrm{M}$ and $\mu=0.0615 \mathrm{M}$. Write 0.0615 in cell F 3 and repeat the process again. The succession of results is shown in the table. The fraction of ion pairing is $\left[\mathrm{MgSO}_{4}(a q)\right] / \mathrm{F}=33 \%$.

| Iteration | Ionic strength $(\mathrm{mM})$ | $\left[\mathrm{Mg}^{2+}\right](\mathrm{mM})$ |
| :---: | :---: | :---: |
| 1 | 0 | 9.54 |
| 2 | 38.2 | 15.4 |
| 3 | 61.5 | 16.5 |
| 4 | 66.0 | 16.7 |
| 5 | 66.7 | 16.7 |
| 6 | 66.8 | 16.7 |

(c) The ionic strength is 0.067 M , not 0.10 M .

12-F. (a) In addition to Reactions 12-32 through 12-36, we add the reaction
$\mathrm{HF}(a q)+\mathrm{F}^{-} \rightleftharpoons \mathrm{HF}_{2}^{-} \quad K_{\mathrm{HF}_{2}^{-}}=10^{0.58}$
$\Rightarrow\left[\mathrm{HF}_{2}^{-}\right]=K_{\mathrm{HF}_{2}^{-}}\left[\mathrm{F}^{-}\right][\mathrm{HF}]=K_{\mathrm{HF}_{2}^{-}}\left[\mathrm{F}^{-}\right]\left(\left[\mathrm{H}^{+}\right]\left[\mathrm{F}^{-}\right] / K_{\mathrm{HF}}\right)$
$=K_{\mathrm{HF}_{2}^{-}}\left[\mathrm{F}^{-}\right]^{2}\left[\mathrm{H}^{+}\right] / K_{\mathrm{HF}}$
The charge balance becomes
$\left[\mathrm{H}^{+}\right]+2\left[\mathrm{Ca}^{2+}\right]+\left[\mathrm{CaOH}^{+}\right]+\left[\mathrm{CaF}^{+}\right]-\left[\mathrm{OH}^{-}\right]-\left[\mathrm{F}^{-}\right]-\left[\mathrm{HF}_{2}^{-}\right]=0$
and the mass balance is
$2\left\{\left[\mathrm{Ca}^{2+}\right]+\left[\mathrm{CaOH}^{+}\right]+\left[\mathrm{CaF}^{+}\right]\right\}=\left[\mathrm{F}^{-}\right]+[\mathrm{HF}]+\left[\mathrm{CaF}^{+}\right]+2\left[\mathrm{HF}_{2}^{-}\right]$
$2\left[\mathrm{Ca}^{2+}\right]+2\left[\mathrm{CaOH}^{+}\right]+\left[\mathrm{CaF}^{+}\right]-\left[\mathrm{F}^{-}\right]-[\mathrm{HF}]-2\left[\mathrm{HF}_{2}^{-}\right]=0$

Spreadsheet for Exercise 12-E.

Substitute equilibrium expressions for the various species into the mass balance:
$\frac{2 K_{\mathrm{sp}}}{\left[\mathrm{F}^{-}\right]^{2}}+\frac{2 K_{\mathrm{a}} K_{\mathrm{sp}}}{\left[\mathrm{H}^{+}\right]\left[\mathrm{F}^{-}\right]^{2}}+\frac{K_{\mathrm{ip}} K_{\mathrm{sp}}}{\left[\mathrm{F}^{-}\right]}-\left[\mathrm{F}^{-}\right]-\frac{\left[\mathrm{H}^{+}\right]\left[\mathrm{F}^{-}\right]}{K_{\mathrm{HF}}}-\frac{2 K_{\mathrm{HF}_{2}}\left[\mathrm{~F}^{-}\right]^{2}\left[\mathrm{H}^{+}\right]}{K_{\mathrm{HF}}}=0$
For a given value of $\left[\mathrm{H}^{+}\right]$, use Solver to find the value of $\left[\mathrm{F}^{-}\right]$that makes the left side of Equation $B$ equal to 0 . From $\left[\mathrm{H}^{+}\right]$and $\left[\mathrm{F}^{-}\right]$, compute the remaining concentrations with the equilibrium expressions. Results are shown in the graph.

Graph for Exercise 12-F.
(b) To find the pH of unbuffered solution, find $\left[\mathrm{H}^{+}\right]$at which the charge balance (A) is also satisfied. Because $\left[\mathrm{HF}_{2}^{-}\right]$is negligible near neutral pH , the pH is unchanged from the case worked in the text. The pH of unbuffered solution is 7.10 and concentrations are

$$
\begin{array}{cl}
{\left[\mathrm{F}^{-}\right]=4.00 \times 10^{-4} \mathrm{M}} & {\left[\mathrm{Ca}^{2+}\right]=2.00 \times 10^{-4} \mathrm{M}} \\
{[\mathrm{HF}]=4.67 \times 10^{-8} \mathrm{M}} & {\left[\mathrm{CaOH}^{+}\right]=5.03 \times 10^{-10} \mathrm{M}} \\
{\left[\mathrm{HF}_{2}^{-}\right]=7.11 \times 10^{-11} \mathrm{M}} & {\left[\mathrm{CaF}^{+}\right]=3.44 \times 10^{-7} \mathrm{M}} \\
\text { 12-G. } \mathrm{AgCN}(s) \rightleftharpoons \mathrm{Ag}^{+}+\mathrm{CN}^{-} & \mathrm{p} K_{\mathrm{sp}}=15.66 \\
\mathrm{HCN}(a q) \rightleftharpoons \mathrm{CN}^{-}+\mathrm{H}^{+} & \mathrm{p} K_{\mathrm{HCN}}=9.21 \\
\mathrm{Ag}^{+}+\mathrm{H}_{2} \mathrm{O} \rightleftharpoons \mathrm{AgOH}(a q)+\mathrm{H}^{+} & \mathrm{p} K_{\mathrm{Ag}}=12.0
\end{array}
$$

Express all concentrations in terms of $\left[\mathrm{Ag}^{+}\right]$and $\left[\mathrm{H}^{+}\right]$:
$\left[\mathrm{CN}^{-}\right]=K_{\mathrm{sp}} /\left[\mathrm{Ag}^{+}\right]$
$[\mathrm{HCN}(a q)]=\frac{\left[\mathrm{H}^{+}\right]\left[\mathrm{CN}^{-}\right]}{K_{\mathrm{HCN}}}=\frac{\left[\mathrm{H}^{+}\right] K_{\mathrm{sp}}}{K_{\mathrm{HCN}}\left[\mathrm{Ag}^{+}\right]}$
$[\mathrm{AgOH}(a q)]=\frac{K_{\mathrm{Ag}}\left[\mathrm{Ag}^{+}\right]}{\left[\mathrm{H}^{+}\right]}$
Mass balance: total silver $=$ total cyanide
$\left[\mathrm{Ag}^{+}\right]+[\mathrm{AgOH}(a q)]=\left[\mathrm{CN}^{-}\right]+[\mathrm{HCN}(a q)]$
Substitute expressions for concentrations into the mass balance:
$\left[\mathrm{Ag}^{+}\right]+\frac{K_{\mathrm{Ag}}\left[\mathrm{Ag}^{+}\right]}{\left[\mathrm{H}^{+}\right]}=\frac{K_{\mathrm{sp}}}{\left[\mathrm{Ag}^{+}\right]}+\frac{\left[\mathrm{H}^{+}\right] K_{\mathrm{sp}}}{K_{\mathrm{HCN}}\left[\mathrm{Ag}^{+}\right]}$
Rearrange Equation A to solve for $\left[\mathrm{Ag}^{+}\right]$as a function of $\left[\mathrm{H}^{+}\right]$or use Solver to find $\left[\mathrm{Ag}^{+}\right]$as a function of $\left[\mathrm{H}^{+}\right]$. We will use the algebraic

Spreadsheet for Exercise 12-G.

Graph for Exercise 12-G.
solution, which is easy for this exercise. Multiply both sides by $\left[\mathrm{Ag}^{+}\right]$and solve:
$\left[\mathrm{Ag}^{+}\right]^{2}+\frac{K_{\mathrm{Ag}}\left[\mathrm{Ag}^{+}\right]^{2}}{\left[\mathrm{H}^{+}\right]}=K_{\mathrm{sp}}+\frac{\left[\mathrm{H}^{+}\right] K_{\mathrm{sp}}}{K_{\mathrm{HCN}}}$
$\left[\mathrm{Ag}^{+}\right]^{2}\left(\frac{\left[\mathrm{H}^{+}\right]+K_{\mathrm{Ag}}}{\left[\mathrm{H}^{+}\right]}\right)=K_{\mathrm{sp}}\left(\frac{K_{\mathrm{HCN}}+\left[\mathrm{H}^{+}\right]}{K_{\mathrm{HCN}}}\right)$
$\left[\mathrm{Ag}^{+}\right]=\sqrt{\frac{K_{\mathrm{sp}}\left(K_{\mathrm{HCN}}+\left[\mathrm{H}^{+}\right]\right)\left[\mathrm{H}^{+}\right]}{K_{\mathrm{HCN}}\left(\left[\mathrm{H}^{+}\right]+K_{\mathrm{Ag}}\right)}}$

The spreadsheet uses Equation B to find $\left[\mathrm{Ag}^{+}\right]$in column C. pH is input in column A. To find the pH of unbuffered solution, we find the pH at which the net charge in column H is zero. We used Solver to find that $\mathrm{pH}=7.28$ in cell A12 makes the net charge in cell H 12 equal to 0 .

12-H. (a) $\bar{n}_{\mathrm{H}}=\frac{\text { moles of bound } \mathrm{H}^{+}}{\text {total moles of weak acid }}=\frac{[\mathrm{HA}]}{[\mathrm{HA}]+\left[\mathrm{A}^{-}\right]}$
$=\frac{[\mathrm{HA}]}{\mathrm{F}_{\mathrm{HA}}}=\frac{\mathrm{F}_{\mathrm{HA}}-\left[\mathrm{A}^{-}\right]}{\mathrm{F}_{\mathrm{HA}}}$
Charge balance: $\left[\mathrm{H}^{+}\right]+\left[\mathrm{Na}^{+}\right]=\left[\mathrm{OH}^{-}\right]+\left[\mathrm{Cl}^{-}\right]_{\mathrm{HCl}}+\left[\mathrm{A}^{-}\right]$
or $-\left[\mathrm{A}^{-}\right]=\left[\mathrm{OH}^{-}\right]+\left[\mathrm{Cl}^{-}\right]_{\mathrm{HCl}}-\left[\mathrm{H}^{+}\right]-\left[\mathrm{Na}^{+}\right]$
Put this expression for $-\left[\mathrm{A}^{-}\right]$into numerator of $(\mathrm{A})$ :
$\bar{n}_{\mathrm{H}}($ measured $)=\frac{\mathrm{F}_{\mathrm{HA}}+\left[\mathrm{OH}^{-}\right]+\left[\mathrm{Cl}^{-}\right]_{\mathrm{HCl}}-\left[\mathrm{H}^{+}\right]-\left[\mathrm{Na}^{+}\right]}{\mathrm{F}_{\mathrm{HA}}}$

$$
=1+\frac{\left[\mathrm{OH}^{-}\right]+\left[\mathrm{Cl}^{-}\right]_{\mathrm{HCl}}-\left[\mathrm{H}^{+}\right]-\left[\mathrm{Na}^{+}\right]}{\mathrm{F}_{\mathrm{HA}}}
$$

Making the same substitutions used in Section 12-4 produces Equation 12-59 with $n=1$. The theoretical expression is $\bar{n}_{\mathrm{H}}($ theoretical $)=\alpha_{\mathrm{HA}}=$ $\left[\mathrm{H}^{+}\right] /\left(\left[\mathrm{H}^{+}\right]+K_{\mathrm{a}}\right)$.
(b) Optimized values of $\mathrm{p} K_{\mathrm{w}}^{\prime}$ and $\mathrm{p} K_{\mathrm{a}}$ in cells B 9 and B 10 in the spreadsheet are 13.869 and 4.726. These were obtained from initial guesses of $\mathrm{p} K_{\mathrm{w}}^{\prime}=14$ and $\mathrm{p} K_{\mathrm{a}}=5$ after executing Solver to minimize the sum of squared residuals in cell B11. The NIST database lists $\mathrm{p} K_{\mathrm{a}}=4.757$ at $\mu=0$ and $\mathrm{p} K_{\mathrm{a}}=4.56$ at $\mu=0.1 \mathrm{M}$. Our value of 4.726 at $\mu=0.1 \mathrm{M}$ suggests that the titration experiment was not very accurate.

\end{aligned}
$$

Electrons flow from the more negative Hg electrode $(0.340 \mathrm{~V})$ to the more positive Pt electrode $(1.434 \mathrm{~V})$.
13-D. (a) $\mathrm{H}^{+}+\mathrm{e}^{-} \rightleftharpoons \frac{1}{2} \mathrm{H}_{2}(g) \quad E_{+}^{\circ}=0 \mathrm{~V}$
$\mathrm{Ag}^{+}+\mathrm{e}^{-} \rightleftharpoons \mathrm{Ag}(s) \quad E_{-}^{\circ}=0.799 \mathrm{~V}$
$E^{\circ}=E_{+}^{\circ}-E_{-}^{\circ}=-0.799 \mathrm{~V}$
$E=\left\{0-0.05916 \log \frac{P_{\mathrm{H}_{2}}^{1 / 2}}{\left[\mathrm{H}^{+}\right]}\right\}-\left\{0.799-0.05916 \log \frac{1}{\left[\mathrm{Ag}^{+}\right]}\right\}$
(b) $\left[\mathrm{Ag}^{+}\right]=\frac{K_{\text {sp }}}{\left[\mathrm{I}^{-}\right]}=\frac{8.3 \times 10^{-17}}{0.10}=8.3 \times 10^{-16} \mathrm{M}$

$$
\begin{aligned}
E & =\left\{0-0.059 \log \frac{\sqrt{0.20}}{0.10}\right\}-\left\{0.799-0.05916 \log \frac{1}{8.3 \times 10^{-16}}\right\} \\
& =-0.038-(-0.093)=0.055 \mathrm{~V}
\end{aligned}
$$

Electrons flow from the more negative Ag electrode ( -0.093 V ) to the more positive Pt electrode $(-0.038 \mathrm{~V})$.
(c) $\mathrm{H}^{+}+\mathrm{e}^{-} \rightleftharpoons \frac{1}{2} \mathrm{H}_{2}(g) \quad E_{+}^{\circ}=0 \mathrm{~V}$
$\operatorname{AgI}(s)+\mathrm{e}^{-} \rightleftharpoons \operatorname{Ag}(s)+\mathrm{I}^{-} \quad E_{-}^{\circ}=$ ?
$0.055=\left\{0-0.05916 \log \frac{\sqrt{0.20}}{0.10}\right\}-\left\{E_{-}^{\circ}-0.05916 \log (0.10)\right\}$
$\Rightarrow E_{-}^{\circ}=-0.153 \mathrm{~V}$
(Appendix H gives $E_{-}^{\circ}=-0.152 \mathrm{~V}$.)

13-E. $\operatorname{Ag}(\mathrm{CN})_{2}^{-}+\mathrm{e}^{-} \rightleftharpoons \mathrm{Ag}(s)+2 \mathrm{CN}^{-} \quad E_{+}^{\circ}=-0.310 \mathrm{~V}$
$\mathrm{Cu}^{2+}+2 \mathrm{e}^{-} \rightleftharpoons \mathrm{Cu}(s) \quad E_{-}^{\circ}=0.339 \mathrm{~V}$
$E=\left\{-0.310-0.05916 \log \frac{\left[\mathrm{CN}^{-}\right]^{2}}{\left[\mathrm{Ag}(\mathrm{CN})_{2}^{-}\right]}\right\}-\left\{0.339-\frac{0.05916}{2} \log \frac{1}{\left[\mathrm{Cu}^{2+}\right]}\right\}$
We know that $\left[\mathrm{Ag}(\mathrm{CN})_{2}^{-}\right]=0.010 \mathrm{M}$ and $\left[\mathrm{Cu}^{2+}\right]=0.030 \mathrm{M}$. To find $\left[\mathrm{CN}^{-}\right.$] at pH 8.21 , we write
$\frac{\left[\mathrm{CN}^{-}\right]}{[\mathrm{HCN}]}=\frac{K_{\mathrm{a}}}{\left[\mathrm{H}^{+}\right]} \Rightarrow\left[\mathrm{CN}^{-}\right]=0.10[\mathrm{HCN}]$
But, because $\left[\mathrm{CN}^{-}\right]+[\mathrm{HCN}]=0.10 \mathrm{M},\left[\mathrm{CN}^{-}\right]=0.0091 \mathrm{M}$. Putting this concentration into the Nernst equation gives $E=-0.187-(0.294)=$
-0.481 V . Electrons flow from the more negative Ag electrode ( -0.187 V ) to the more positive Cu electrode $(0.294 \mathrm{~V})$.
13-F. (a) $\mathrm{PuO}_{2}^{+}+\mathrm{e}^{-}+4 \mathrm{H}^{+} \rightleftharpoons \mathrm{Pu}^{4+}+2 \mathrm{H}_{2} \mathrm{O}$
$\mathrm{PuO}_{2}^{2+} \rightarrow \mathrm{PuO}_{2}^{+} \quad \Delta G=-1 F(0.966)$

$-3 F(1.021)=-1 F(0.966)-1 F E^{\circ}-1 F(1.006) \Rightarrow E^{\circ}=1.091 \mathrm{~V}$
(b) $\begin{aligned} & 2 \mathrm{PuO}_{2}^{2+}+2 \mathrm{e}^{-} \rightleftharpoons 2 \mathrm{PuO}_{2}^{+} \quad E_{+}^{\circ}=0.966 \mathrm{~V} \\ & -\frac{1}{2} \mathrm{O}_{2}(g)+2 \mathrm{H}^{+}+2 \mathrm{e}^{-} \rightleftharpoons \mathrm{H}_{2} \mathrm{O} \quad E_{-}^{\circ}=1.229 \mathrm{~V}\end{aligned}$
$2 \mathrm{PuO}_{2}^{2+}+\mathrm{H}_{2} \mathrm{O} \rightleftharpoons 2 \mathrm{PuO}_{2}^{+}+\frac{1}{2} \mathrm{O}_{2}(g)+2 \mathrm{H}^{+}$$\quad \begin{aligned} & E=\left\{0.966-\frac{0.05916}{2} \log \frac{\left[\mathrm{PuO}_{2}^{+}\right]^{2}}{\left[\mathrm{PuO}_{2}^{2+}\right]^{2}}\right\}-\left\{1.229-\frac{0.05916}{2} \log \frac{1}{\left.P_{\mathrm{O}_{2}}^{1 / 2}\left[\mathrm{H}^{+}\right]^{2}\right\}}\right.\end{aligned}$
$\left[\mathrm{PuO}_{2}^{+}\right]$cancels $\left[\mathrm{PuO}_{2}^{2+}\right]$ because they are equal. At pH 2.00 , we insert $\left[\mathrm{H}^{+}\right]=10^{-2.00}$ and $P_{\mathrm{O}_{2}}=0.20$ to find $E=-0.134 \mathrm{~V}$. Because E $<0$, the reaction is not spontaneous and water is not oxidized. At pH 7.00 , we find $E=+0.161 \mathrm{~V}$, so water will be oxidized.
13-G. $2 \mathrm{H}^{+}+2 \mathrm{e}^{-} \rightleftharpoons \mathrm{H}_{2}(g) \quad E_{+}^{\circ}=0 \mathrm{~V}$
$\mathrm{Hg}_{2} \mathrm{Cl}_{2}(s)+2 \mathrm{e}^{-} \rightleftharpoons 2 \mathrm{Hg}(l)+2 \mathrm{Cl}^{-} \quad E_{-}^{\circ}=0.268 \mathrm{~V}$
$E=\left\{-\frac{0.05916}{2} \log \frac{P_{\mathrm{H}_{2}}}{\left[\mathrm{H}^{+}\right]^{2}}\right\}-\left\{0.268-\frac{0.05916}{2} \log \left[\mathrm{Cl}^{-}\right]^{2}\right\}$
We find $\left[\mathrm{H}^{+}\right]$in the right half-cell by considering the acid-base chemistry of KHP, the intermediate form of a diprotic acid:
$\left[\mathrm{H}^{+}\right]=\sqrt{\frac{K_{1} K_{2}(0.050)+K_{1} K_{\mathrm{w}}}{K_{1}+0.050}}=6.5 \times 10^{-5} \mathrm{M}$
$E=\left\{\frac{-0.05916}{2} \log \frac{1}{\left(6.5 \times 10^{-5}\right)^{2}}\right\}-\left\{0.268-\frac{0.05916}{2} \log (0.10)^{2}\right\}$ $=-0.247_{7}-0.327_{2}=-0.575 \mathrm{~V}$
Electrons flow from the more negative Pt electrode $\left(-0.247_{7} \mathrm{~V}\right)$ to the more positive Hg electrode $\left(0.327_{2} \mathrm{~V}\right)$.
13-H. $2 \mathrm{H}^{+}+2 \mathrm{e}^{-} \rightleftharpoons \mathrm{H}_{2}(g) \quad E_{+}^{\circ}=0 \mathrm{~V}$
$\mathrm{Hg}^{2+}+2 \mathrm{e}^{-} \rightleftharpoons \mathrm{Hg}(l) \quad E_{-}^{\circ}=0.852 \mathrm{~V}$
$E=\left\{\frac{-0.05916}{2} \log \frac{P_{\mathrm{H}_{2}}}{\left[\mathrm{H}^{+}\right]^{2}}\right\}-\left\{0.852-\frac{0.05916}{2} \log \frac{1}{\left[\mathrm{Hg}^{2+}\right]}\right\}$
$0.083=\left\{\frac{-0.05916}{2} \log \frac{1}{1^{2}}\right\}-\left\{0.852-\frac{0.05916}{2} \log \frac{1}{\left[\mathrm{Hg}^{2+}\right]}\right\}$
$\Rightarrow\left[\mathrm{Hg}^{2+}\right]=2.5 \times 10^{-32} \mathrm{M}$
$\left[\mathrm{HgI}_{4}^{2-}\right]=0.0010 \mathrm{M}$. To make this much $\mathrm{HgI}_{4}^{2-}$, the concentration of $\mathrm{I}^{-}$ must have been reduced from 0.500 M to 0.496 M , because one $\mathrm{Hg}^{2+}$ ion reacts with four $\mathrm{I}^{-}$ions.
$K=\frac{\left[\mathrm{HgI}_{4}^{2-}\right]}{\left[\mathrm{Hg}^{2+}\right]\left[\mathrm{I}^{-}\right]^{4}}=\frac{(0.0010)}{\left(2.5 \times 10^{-32}\right)(0.496)^{4}}=7 \times 10^{29}$
13-I. $\mathrm{CuY}^{2-}+2 \mathrm{e}^{-} \rightleftharpoons \mathrm{Cu}(s)+\mathrm{Y}^{4-} \quad E_{+}^{\circ}=$ ?

$$
\begin{array}{ll}
\mathrm{Cu}^{2+}+2 \mathrm{e}^{-} \rightleftharpoons \mathrm{Cu}(s) & E_{-}^{\circ}=0.339 \mathrm{~V} \\
\mathrm{CuY}^{2-} \stackrel{1 / \mathrm{K}_{\mathrm{f}}}{\rightleftharpoons} \mathrm{Cu}^{2+}+\mathrm{Y}^{4-} & E^{\circ}
\end{array}
$$

$E^{\circ}=\frac{0.05916}{2} \log \frac{1}{K_{\mathrm{f}}}=-0.556 \mathrm{~V}$
$E_{+}^{\circ}=E^{\circ}+E_{-}^{\circ}=-0.556+0.339=-0.217 \mathrm{~V}$

13-J. To compare glucose and $\mathrm{H}_{2}$ at $\mathrm{pH}=0$, we need to know $E^{\circ}$ for each. For $\mathrm{H}_{2}, E^{\circ}=0 \mathrm{~V}$. For glucose, we find $E^{\circ}$ from $E^{\circ \prime}$ :

$$
\underset{\text { Gluconic acid }}{\mathrm{HA}}+2 \mathrm{H}^{+}+2 \mathrm{e}^{-} \rightleftharpoons \underset{\text { Glucose }}{\rightleftharpoons} \mathrm{G}+\mathrm{H}_{2} \mathrm{O}
$$

$E=E^{\circ}-\frac{0.05916}{2} \log \frac{[\mathrm{G}]}{[\mathrm{HA}]\left[\mathrm{H}^{+}\right]^{2}}$
But $\mathrm{F}_{\mathrm{G}}=[\mathrm{G}]$ and $[\mathrm{HA}]=\frac{\left[\mathrm{H}^{+}\right] \mathrm{F}_{\mathrm{HA}}}{\left[\mathrm{H}^{+}\right]+K_{\mathrm{a}}}$. Putting these into the Nernst equation gives
$E=E^{\circ}-\frac{0.05916}{2} \log \frac{\mathrm{~F}_{\mathrm{G}}}{\left(\frac{\left[\mathrm{H}^{+}\right] \mathrm{F}_{\mathrm{HA}}}{\left[\mathrm{H}^{+}\right]+K_{\mathrm{a}}}\right)\left[\mathrm{H}^{+}\right]^{2}}$
$=\underbrace{E^{\circ}-\frac{0.05916}{2} \log \frac{\left[\mathrm{H}^{+}\right]+K_{\mathrm{a}}}{\left[\mathrm{H}^{+}\right]^{3}}}-\frac{0.05916}{2} \log \frac{\mathrm{~F}_{\mathrm{G}}}{\mathrm{F}_{\mathrm{HA}}}$
This is $\mathrm{E}^{00}=-0.45 \mathrm{~V}$ when $\left[\mathrm{H}^{+}\right]=10^{-7}$
$-0.45 \mathrm{~V}=E^{\circ}-\frac{0.05916}{2} \log \frac{10^{-7.00}+10^{-3.56}}{\left(10^{-7.00}\right)^{3}}$
$\Rightarrow E^{\circ}=+0.06_{6} \mathrm{~V}$ for glucose
Because $E^{\circ}$ for $\mathrm{H}_{2}$ is more negative than $E^{\circ}$ for glucose, $\mathrm{H}_{2}$ is the stronger reducing agent at pH 0.00 .
13-K. (a) Each $\mathrm{H}^{+}$must provide $\frac{1}{2}(34.5 \mathrm{~kJ})$ when it passes from outside to inside.
$\Delta G=-\frac{1}{2}\left(34.5 \times 10^{3} \mathrm{~J}\right)=-R T \ln \frac{\mathcal{A}_{\text {high }}}{\mathcal{A}_{\text {low }}}$
$\frac{\mathcal{A}_{\text {high }}}{\mathcal{A}_{\text {low }}}=1.05 \times 10^{3} \Rightarrow \Delta \mathrm{pH}=\log \left(1.05 \times 10^{3}\right)=3.02 \mathrm{pH}$ units
(b) $\Delta \mathrm{G}=-n F E\left(\right.$ where $n=$ charge of $\left.\mathrm{H}^{+}=1\right)$
$-\frac{1}{2}\left(34.5 \times 10^{3} \mathrm{~J}\right)=-1 F E \Rightarrow E=0.179 \mathrm{~V}$
(c) If $\Delta \mathrm{pH}=1.00, \mathcal{A}_{\text {high }} / \mathcal{A}_{\text {low }}=10$.
$\Delta G(\mathrm{pH})=-R T \ln 10=-5.7 \times 10^{3} \mathrm{~J}$
$\Delta G($ electric $)=\left[\frac{1}{2}(34.5)-5.7\right] \mathrm{kJ}=11.5 \mathrm{~kJ}$
$E=\frac{\Delta G(\text { electric })}{F}=0.120 \mathrm{~V}$

## Chapter 14

14-A. The reaction at the silver electrode (written as a reduction) is $\mathrm{Ag}^{+}+\mathrm{e}^{-} \rightleftharpoons \mathrm{Ag}(s)$, and the cell voltage is written as

$$
E=E_{+}-E_{-}=E_{+}-E(\text { S.C.E. })=E_{+}-0.241
$$

$$
=\left(0.799-0.05916 \log \frac{1}{\left[\mathrm{Ag}^{+}\right]}\right)-0.241
$$

$=0.558+0.05916 \log \left[\mathrm{Ag}^{+}\right]$
Titration reaction: $\mathrm{Br}^{-}+\mathrm{Ag}^{+} \rightarrow \mathrm{AgBr}(s) \quad K_{\text {sp }}=5.0 \times 10^{-13}$
The equivalence point is $V_{\mathrm{e}}=25.0$. Between 0 and 25 mL , there is unreacted $\mathrm{Ag}^{+}$in the solution.
$1.0 \mathrm{~mL}: \quad\left[\mathrm{Ag}^{+}\right]=\left(\frac{24.0}{25.0}\right) \underbrace{(0.100 \mathrm{M})}_{\begin{array}{c}\text { Fraction of } \mathrm{Ag}^{+} \\ \text {remaining }\end{array}}\left(\frac{50.0}{51.0}\right)=\underbrace{\left(\begin{array}{c}\text { Dilution } \\ \text { factor }\end{array}\right.}_{\begin{array}{c}\text { Initial concentration } \\ \text { of } \mathrm{Ag}^{+}\end{array}}$
$\Rightarrow E==0.558+0.05916 \log [0.0941]=0.497 \mathrm{~V}$
$12.5 \mathrm{~mL}: \quad\left[\mathrm{Ag}^{+}\right]=\left(\frac{12.5}{25.0}\right)(0.100 \mathrm{M})\left(\frac{50.0}{62.5}\right)=0.0400 \mathrm{M}$
$\Rightarrow E=0.475 \mathrm{~V}$
$24.0 \mathrm{~mL}: \quad\left[\mathrm{Ag}^{+}\right]=\left(\frac{1.0}{25.0}\right)(0.100 \mathrm{M})\left(\frac{50.0}{74.0}\right)=0.00270 \mathrm{M}$

$$
\Rightarrow E=0.406 \mathrm{~V}
$$

$24.9 \mathrm{~mL}: \quad\left[\mathrm{Ag}^{+}\right]=\left(\frac{0.10}{25.0}\right)(0.100 \mathrm{M})\left(\frac{50.0}{74.9}\right)=2.67 \times 10^{-4} \mathrm{M}$

$$
\Rightarrow E=0.347 \mathrm{~V}
$$

Beyond 25 mL , all AgBr has precipitated and there is excess $\mathrm{Br}^{-}$in solution.
$25.1 \mathrm{~mL}: \quad\left[\mathrm{Br}^{-}\right]=\left(\frac{0.1}{75.1}\right)(0.200 \mathrm{M})=2.67 \times 10^{-4} \mathrm{M}$
$\Rightarrow\left[\mathrm{Ag}^{+}\right]=K_{\text {sp }} /\left[\mathrm{Br}^{-}\right]=\left(5.0 \times 10^{-13}\right) /\left(2.67 \times 10^{-4}\right)=1.88 \times 10^{-9} \mathrm{M}$
$\Rightarrow E=+0.042 \mathrm{~V}$
$26.0 \mathrm{~mL}: \quad\left[\mathrm{Br}^{-}\right]=\left(\frac{1.0}{76.0}\right)(0.200 \mathrm{M})=2.6_{6} \times 10^{-4} \mathrm{M}$
$\Rightarrow\left[\mathrm{Ag}^{+}\right]=1.9_{0} \times 10^{-10} \mathrm{M} \Rightarrow E=-0.017 \mathrm{~V}$
At $35.0 \mathrm{~mL}: \quad\left[\mathrm{Br}^{-}\right]=\left(\frac{10.0}{85.0}\right)(0.200 \mathrm{M})=0.0235 \mathrm{M}$
$\Rightarrow\left[\mathrm{Ag}^{+}\right]=2.1_{2} \times 10^{-11} \mathrm{M} \Rightarrow E=-0.073 \mathrm{~V}$

14-B. The cell voltage is given by Equation C, in which $K_{\mathrm{f}}$ is the formation constant for $\mathrm{Hg}(\mathrm{EDTA})^{2-}\left(=10^{21.5}\right)$. To find the voltage, we must calculate $\left[\mathrm{HgY}^{2-}\right]$ and $\left[\mathrm{Y}^{4-}\right]$ at each point. The concentration of $\mathrm{HgY}^{2-}$ is $1.0 \times$ $10^{-4} \mathrm{M}$ when $V=0$ and is thereafter affected only by dilution because $K_{\mathrm{f}}\left(\mathrm{HgY}^{2-}\right) \gg K_{\mathrm{f}}\left(\mathrm{MgY}^{2-}\right)$. The concentration of $\mathrm{Y}^{4-}$ is found from the Mg-EDTA equilibrium at all but the first point. At $V=0 \mathrm{~mL}$, the Hg EDTA equilibrium determines [ $\mathrm{Y}^{4-}$ ].
$0 \mathrm{~mL}: \frac{\mathrm{Hg} \mathrm{Y}^{2-}}{\left[\mathrm{Hg}^{2+}\right][E D T A]}=\alpha_{\mathrm{Y}^{4-}} K_{\mathrm{f}}\left(\right.$ for $\left.\mathrm{HgY}^{4-}\right)=(0.30)\left(10^{21.5}\right)$
$\frac{1.0 \times 10^{-4}-x}{(x)(x)}=9.5 \times 10^{20} \Rightarrow x=[E D T A]=3.2 \times 10^{-13} \mathrm{M}$
$\left[\mathrm{Y}^{4-}\right]=\alpha_{\mathrm{Y}^{4-}}[$ EDTA $]=9.7 \times 10^{-14} \mathrm{M}$
Using Equation C, we write

$$
\begin{aligned}
E= & 0.852-0.241-\frac{0.05916}{2} \log \frac{10^{21.5}}{1.0 \times 10^{-4}} \\
& -\frac{0.05916}{2} \log \left(9.7 \times 10^{-14}\right)=0.242 \mathrm{~V}
\end{aligned}
$$

$10.0 \mathrm{~mL}: \quad V_{\mathrm{e}}=25.0 \mathrm{~mL}$, so $\frac{10}{25}$ of $\mathrm{Mg}^{2+}$ is in the form $\mathrm{MgY}^{2-}$, and $\frac{15}{25}$ is in the form $\mathrm{Mg}^{2+}$.
$\left[\mathrm{Y}^{4-}\right]=\frac{\left[\mathrm{MgY}^{2-}\right]}{\left[\mathrm{Mg}^{2+}\right]} / K_{\mathrm{f}}\left(\right.$ for $\left.\mathrm{MgY}^{2-}\right)=\left(\frac{10}{15}\right) / 6.2 \times 10^{8}=1.08 \times 10^{-9} \mathrm{M}$
$\left[\mathrm{HgY}^{2-}\right]=\underset{\text { Dilution factor }}{\left(\frac{50.0}{60.0}\right)\left(1.0 \times 10^{-4} \mathrm{M}\right)=8.33 \times 10^{-5} \mathrm{M}}$
$E=0.852-0.241-\frac{0.05916}{2} \log \frac{10^{21.5}}{8.33 \times 10^{-5}}$

$$
-\frac{0.05916}{2} \log \left(1.08 \times 10^{-9}\right)=0.120 \mathrm{~V}
$$

$20.0 \mathrm{~mL}: \quad\left[\mathrm{Y}^{4-}\right]=\left(\frac{20}{5}\right) / 6.2 \times 10^{8}=6.45 \times 10^{-9} \mathrm{M}$
$\left[\mathrm{Hg} \mathrm{Y}^{2-}\right]=\left(\frac{50.0}{70.0}\right)\left(1.0 \times 10^{-4} \mathrm{M}\right)=7.14 \times 10^{-5} \mathrm{M}$
$\Rightarrow E=0.095 \mathrm{~V}$
$24.9 \mathrm{~mL}: \quad\left[\mathrm{Y}^{4-}\right]=\left(\frac{24.9}{0.1}\right) / 6.2 \times 10^{8}=4.02 \times 10^{-7} \mathrm{M}$
$\left[\mathrm{HgY}^{2-}\right]=\left(\frac{50.0}{74.9}\right)\left(1.0 \times 10^{-4} \mathrm{M}\right)=6.68 \times 10^{-5} \mathrm{M}$
$\Rightarrow E=0.041 \mathrm{~V}$
25.0 mL : This is the equivalence point, at which $\left[\mathrm{Mg}^{2+}\right]=[$ EDTA $]$.
$\frac{\left[\mathrm{MgY}^{2-}\right]}{\left[\mathrm{Mg}^{2+}\right][\text { EDTA }]}=\alpha_{\mathrm{Y}^{4-}} K_{\mathrm{f}}\left(\right.$ for $\left.\mathrm{MgY}^{2-}\right)$
$\left(\frac{50.0}{75.0}\right)(0.0100)-x$
$\frac{x^{2}}{}=1.85 \times 10^{8} \Rightarrow x=6.0 \times 10^{-6} \mathrm{M}$
$\left[\mathrm{Y}^{4-}\right]=\alpha_{\mathrm{Y}^{4-}}\left(6.0 \times 10^{-6} \mathrm{M}\right)=1.80 \times 10^{-6} \mathrm{M}$
$\left[\mathrm{HgY}^{2-}\right]=\left(\frac{50.0}{75.0}\right)\left(1.0 \times 10^{-4} \mathrm{M}\right)=6.67 \times 10^{-5} \mathrm{M}$
$\Rightarrow E=0.021 \mathrm{~V}$
26.0 mL : Now there is excess EDTA in the solution.
$\left.\left[\mathrm{Y}^{4-}\right]=\alpha_{\mathrm{Y}^{4}-[E D T A}\right]=(0.30)\left[\left(\frac{1.0}{76.0}\right)(0.0200 \mathrm{M})\right]=7.89 \times 10^{-5} \mathrm{M}$
$\left[\mathrm{HgY}^{2-}\right]=\left(\frac{50.0}{76.0}\right)\left(1.0 \times 10^{-4} \mathrm{M}\right)=6.58 \times 10^{-5} \mathrm{M}$
$\Rightarrow E=-0.027 \mathrm{~V}$
14-C. At intermediate pH , the voltage will be constant at 100 mV . When
$\left[\mathrm{OH}^{-}\right] \approx\left[\mathrm{F}^{-}\right] / 10=10^{-6} \mathrm{M}(\mathrm{pH}=8)$, the electrode begins to respond to $\mathrm{OH}^{-}$and the voltage will decrease (i.e., the electrode potential will change in the same direction as if more $\mathrm{F}^{-}$were being added). Near $\mathrm{pH}=3.17$ ( $=\mathrm{p} K_{\mathrm{a}}$ for HF ), $\mathrm{F}^{-}$reacts with $\mathrm{H}^{+}$and the concentration of free $\mathrm{F}^{-}$ decreases. At $\mathrm{pH}=1.17,\left[\mathrm{~F}^{-}\right] \approx 1 \%$ of $10^{-5} \mathrm{M}=10^{-7} \mathrm{M}$, and $E \approx 100+2(59)=218 \mathrm{mV}$. A qualitative sketch of this behavior is shown here.

14-D. (a) For $1.00 \mathrm{mM} \mathrm{Na}^{+}$at pH 8.00 , we can write $E=$ constant $+0.05916 \log \left(\left[\mathrm{Na}^{+}\right]+36\left[\mathrm{H}^{+}\right]\right)-0.038$
$=$ constant $+0.05916 \log \left[\left(1.00 \times 10^{-3}\right)+\left(36 \times 10^{-8}\right)\right]$ $\Rightarrow$ constant $=+0.139 \mathrm{~V}$
For $5.00 \mathrm{mM} \mathrm{Na}^{+}$at pH 8.00 , we have
$E=+0.139+0.05916 \log \left[\left(5.00 \times 10^{-3}\right)+\left(36 \times 10^{-8}\right)\right]$
$=0.003 \mathrm{~V}$
(b) For $1.00 \mathrm{mM} \mathrm{Na}^{+}$at pH 3.87 , we have
$E=+0.139+0.05916 \log \left[\left(1.00 \times 10^{-3}\right)+\left(36 \times 10^{-3.87}\right)\right]$
$=0.007 \mathrm{~V}$
14-E. A graph of $E(\mathrm{mV})$ versus $\log \left[\mathrm{NH}_{3}(\mathrm{M})\right]$ gives a straight line whose equation is $E=563.4+59.05 \times \log \left[\mathrm{NH}_{3}\right]$. For $E=339.3 \mathrm{mV}$, $\left[\mathrm{NH}_{3}\right]=$ $1.60 \times 10^{-4} \mathrm{M}$. The sample analyzed contains $(100 \mathrm{~mL})\left(1.60 \times 10^{-4} \mathrm{M}\right)=$ 0.0160 mmol of nitrogen. But this sample represents just $2.00 \%$ $(20.0 \mathrm{~mL} / 1.00 \mathrm{~L})$ of the food sample. Therefore, the food contains $(0.016 \mathrm{mmol} \mathrm{N}) / 0.0200=0.800 \mathrm{mmol} \mathrm{N}=11.2 \mathrm{mg}$ of $\mathrm{N}=3.59 \mathrm{wt} \% \mathrm{~N}$. 14-F. The function to plot on the $y$-axis is $\left(V_{0}+V_{\mathrm{S}}\right) 10^{E / S}$, where $S=(\beta R T / n F) \ln 10 . \beta$ is 0.985 . Putting in $R=8.3145 \mathrm{~J} / \mathrm{mol} \cdot \mathrm{K})$, $F=96485 \mathrm{C} / \mathrm{mol}, T=298.15 K$, and $n=-2$ gives $S=$ $-0.029136 \mathrm{~J} / \mathrm{C}=-0.029136 \mathrm{~V}$. (Recall that joule/coulomb $=$ volt.)

| $V_{\mathrm{S}}(\mathrm{mL})$ | $E(\mathrm{~V})$ | $y$ |
| :--- | :---: | :---: |
| 0 | 0.0465 | 0.6338 |
| 1.00 | 0.0407 | 1.0425 |
| 2.00 | 0.0344 | 1.7811 |
| 3.00 | 0.0300 | 2.6152 |
| 4.00 | 0.0265 | 3.5717 |

The data are plotted in Figure 14-30, which has a slope of $m=0.74484$ and an intercept of $b=0.43919$, giving an $x$-intercept of $-b / m=$ $-0.589{ }_{65} \mathrm{~mL}$. The concentration of original unknown is

$$
c_{\mathrm{X}}=\frac{(x \text {-intercept }) c_{\mathrm{S}}}{V_{0}}=-\frac{\left(-0.58_{965} \mathrm{~mL}\right)(1.78 \mathrm{mM})}{25.0 \mathrm{~mL}}=4.2 \times 10^{-5} \mathrm{M}
$$

(We decided that the last significant digit in the $x$-intercept was the 0.01 decimal place because the original data were only measured to the 0.01 decimal place.)

## Chapter 15

15-A. Titration: $\mathrm{Sn}^{2+}+2 \mathrm{Ce}^{4+} \rightarrow \mathrm{Sn}^{4+}+2 \mathrm{Ce}^{3+} \quad V_{\mathrm{e}}=10.0 \mathrm{~mL}$ Representative calculations:
0.100 mL :

$$
\begin{aligned}
E_{+} & =0.139-\frac{0.05916}{2} \log \frac{\left[\mathrm{Sn}^{2+}\right]}{\left[\mathrm{Sn}^{4+}\right]} \\
& =0.139-\frac{0.05916}{2} \log \frac{9.90}{0.100}=0.080 \mathrm{~V}
\end{aligned}
$$

$E=E_{+}-E_{-}=0.080-0.241=-0.161 \mathrm{~V}$
10.00 mL :

$$
\begin{aligned}
2 E_{+} & =2(0.139)-0.05916 \log \frac{\left[\mathrm{Sn}^{2+}\right]}{\left[\mathrm{Sn}^{4+}\right]} \\
E_{+} & =1.47-0.05916 \log \frac{\left[\mathrm{Ce}^{3+}\right]}{\left[\mathrm{Ce}^{4+}\right]} \\
3 E_{+} & =1.748-0.05916 \log \frac{\left[\mathrm{Sn}^{2+}\right]\left[\mathrm{Ce}^{3+}\right]}{\left[\mathrm{Sn}^{4+}\right]\left[\mathrm{Ce}^{4+}\right]}
\end{aligned}
$$

At the equivalence point, $\left[\mathrm{Sn}^{4+}\right]=\frac{1}{2}\left[\mathrm{Ce}^{3+}\right]$ and $\left[\mathrm{Sn}^{2+}\right]=\frac{1}{2}\left[\mathrm{Ce}^{4+}\right]$, which makes the log term 0 . Therefore, $3 E_{+}=1.748$ and $E_{+}=0.583 \mathrm{~V}$. $E=E_{+}-E_{-}=0.583-0.241=0.342 \mathrm{~V}$

$$
\begin{aligned}
& 10.10 \mathrm{~mL}: \quad E_{+}=1.47-0.05916 \log \frac{\left[\mathrm{Ce}^{3+}\right]}{\left[\mathrm{Ce}^{4+}\right]} \\
& =1.47-0.05916 \log \frac{10.0}{0.10}=1.35_{2} \mathrm{~V} \\
& E=E_{+}-E_{-}=1.35_{2}-0.241=1.11 \mathrm{~V}
\end{aligned}
$$

15-B. Standard potentials: indigo tetrasulfonate, $0.36 \mathrm{~V} ; \mathrm{Fe}[\mathrm{CN}]_{6}^{3-} \mid$ $\mathrm{Fe}[\mathrm{CN}]_{6}^{4-}, 0.356 \mathrm{~V} ; \mathrm{Tl}^{3+} \mid \mathrm{Tl}^{+}, 0.77 \mathrm{~V}$. The end-point potential will be between 0.356 and 0.77 V . Indigo tetrasulfonate changes color near 0.36 V . Therefore, it will not be a useful indicator for this titration.
15-C. Titration: $\mathrm{MnO}_{4}^{-}+5 \mathrm{Fe}^{2+}+8 \mathrm{H}^{+} \rightarrow \mathrm{Mn}^{2+}+5 \mathrm{Fe}^{3+}+4 \mathrm{H}_{2} \mathrm{O}$
$\mathrm{Fe}^{3+}+\mathrm{e}^{-} \rightleftharpoons \mathrm{Fe}^{2+} \quad E^{\circ}=0.68 \mathrm{~V}$ in $1 \mathrm{M} \mathrm{H}_{2} \mathrm{SO}_{4}$
$\mathrm{MnO}_{4}^{-}+8 \mathrm{H}^{+}+5 \mathrm{e}^{-} \rightarrow \mathrm{Mn}^{2+}+4 \mathrm{H}_{2} \mathrm{O} \quad E^{\circ}=1.507 \mathrm{~V}$
The equivalence point comes at 15.0 mL . Before the equivalence point,
$E=E_{+}-E_{-}=\left(0.68-0.05916 \log \frac{\left[\mathrm{Fe}^{2+}\right]}{\left[\mathrm{Fe}^{3+}\right]}\right)-0.241$
$1.0 \mathrm{~mL}: \quad\left[\mathrm{Fe}^{2+}\right] /\left[\mathrm{Fe}^{3+}\right]=14.0 / 1.0 \Rightarrow E=0.371 \mathrm{~V}$
$7.5 \mathrm{~mL}: \quad\left[\mathrm{Fe}^{2+}\right] /\left[\mathrm{Fe}^{3+}\right]=7.5 / 7.5 \Rightarrow E=0.439 \mathrm{~V}$
$14.0 \mathrm{~mL}: \quad\left[\mathrm{Fe}^{2+}\right] /\left[\mathrm{Fe}^{3+}\right]=1.0 / 14.0 \Rightarrow E=0.507 \mathrm{~V}$

At the equivalence point, use Equation E of Demonstration 15-1:
$6 E_{+}=8.215-0.05916 \log \frac{1}{\left[\mathrm{H}^{+}\right]^{8}} \stackrel{\mathrm{pH}=0}{\Rightarrow} E_{+}=1.369 \mathrm{~V}$
$E=E_{+}-E_{-}=1.369-0.241=1.128 \mathrm{~V}$
After the equivalence point:
$E=E_{+}-E_{-}=\left(1.507-\frac{0.05916}{5} \log \frac{\left[\mathrm{Mn}^{2+}\right]}{\left[\mathrm{MnO}_{4}^{-}\right]\left[\mathrm{H}^{+}\right]^{8}}\right]-0241$
$16.0 \mathrm{~mL}: \quad\left[\mathrm{Mn}^{2+}\right] /\left[\mathrm{MnO}_{4}^{-}\right]=15.0 / 1.0$ and $\left[\mathrm{H}^{+}\right]=1 \mathrm{M}$ $\Rightarrow E=1.252 \mathrm{~V}$
$30.0 \mathrm{~mL}: \quad\left[\mathrm{Mn}^{2+}\right] /\left[\mathrm{MnO}_{4}^{-}\right]=15.0 / 15.0$ and $\left[\mathrm{H}^{+}\right]=1 \mathrm{M}$
$\Rightarrow E=1.266 \mathrm{~V}$

15-D. The Gran plot of $V \cdot 10^{-E / 0.059}{ }^{16}$ versus $V$ is shown in Figure 15-4. The data from 8.5 to 12.5 mL appear to be on a straight line. The leastsquares line through these four points has a slope of $m=-1.5673 \times 10^{-11}$ and an intercept of $b=2.1702 \times 10^{-10}$. The $x$-intercept is
$-b / m=13.85 \mathrm{~mL}$. The amount of $\mathrm{Ce}^{4+}$ required to reach the equivalence point is $(0.100 \mathrm{mmol} / \mathrm{mL})(13.85 \mathrm{~mL})=1.385 \mathrm{mmol}$, and the concentration of unknown $\mathrm{Fe}^{2+}$ is $1.385 \mathrm{mmol} / 50.0 \mathrm{~mL}=0.0277 \mathrm{M}$.

| Titrant volume, $V(\mathrm{~mL})$ | $E$ (volts) | $V \cdot 10^{-E / 0.05916}$ |
| :---: | :---: | :---: |
| 6.50 | 0.635 | $1.2003 \times 10^{-10}$ |
| 8.50 | 0.651 | $8.4210 \times 10^{-11}$ |
| 10.50 | 0.669 | $5.1626 \times 10^{-11}$ |
| 11.50 | 0.680 | $3.6851 \times 10^{-11}$ |
| 12.50 | 0.696 | $2.1488 \times 10^{-11}$ |

15-E. Let $x=\mathrm{mg}$ of $\mathrm{FeSO}_{4} \cdot\left(\mathrm{NH}_{4}\right)_{2} \mathrm{SO}_{4} \cdot 6 \mathrm{H}_{2} \mathrm{O}$ and $(54.85-x)=$ mg of $\mathrm{FeCl}_{2} \cdot 6 \mathrm{H}_{2} \mathrm{O}$.
mmol of $\mathrm{Ce}^{4+}=$ mmol $\mathrm{FeSO}_{4} \cdot\left(\mathrm{NH}_{4}\right)_{2} \mathrm{SO}_{4} \cdot 6 \mathrm{H}_{2} \mathrm{O}+\mathrm{mmol} \mathrm{FeCl} 2 \cdot 6 \mathrm{H}_{2} \mathrm{O}$
$(13.39 \mathrm{~mL})(0.01234 \mathrm{M})=\frac{x \mathrm{mg}}{392.13 \mathrm{mg} / \mathrm{mmol}}+\frac{(54.85-x)}{234.84 \mathrm{mg} / \mathrm{mmol}}$ $\Rightarrow x=40.01 \mathrm{mg} \mathrm{FeSO} 4 \cdot\left(\mathrm{NH}_{4}\right)_{2} \mathrm{SO}_{4} \cdot 6 \mathrm{H}_{2} \mathrm{O}$
Mass of $\mathrm{FeCl}_{2} \cdot 6 \mathrm{H}_{2} \mathrm{O}=14.84 \mathrm{mg}=0.06319 \mathrm{mmol}=4.48 \mathrm{mg} \mathrm{Cl}$ $\mathrm{wt} \% \mathrm{Cl}=\frac{4.48 \mathrm{mg}}{54.85 \mathrm{mg}} \times 100=8.17 \%$

## Chapter 16

16-A. Cathode: $2 \mathrm{H}^{+}+2 \mathrm{e}^{-} \rightleftharpoons \mathrm{H}_{2}(g) \quad E^{\circ}=0 \mathrm{~V}$
Anode (written as a reduction):
$\frac{1}{2} \mathrm{O}_{2}(g)+2 \mathrm{H}^{+}+2 \mathrm{e}^{-} \rightleftharpoons \mathrm{H}_{2} \mathrm{O} \quad E=1.229 \mathrm{~V}$
$E($ cathode $)=0-\frac{0.05916}{2} \log \frac{P_{\mathrm{H}_{2}}}{\left[\mathrm{H}^{+}\right]^{2}}$
$E($ anode $)=1.229-\frac{0.05916}{2} \log \frac{1}{\left[\mathrm{H}^{+}\right]^{2} P_{\mathrm{O}_{2}}^{1 / 2}}$
$E($ cell $)=E($ cathode $)-E($ anode $)$
$=-1.229-\frac{0.05916}{2} \log P_{\mathrm{H}_{2}} P_{\mathrm{O}_{2}}^{1 / 2}=-1.229 \mathrm{~V}$
$E=E($ cell $)-I \cdot R-$ overpotentials
$=-1.229-(0.100 \mathrm{~A})(2.00 \Omega)$

$$
\begin{gathered}
\begin{array}{c}
00 \mathrm{~A})(2.00 \Omega) \\
\begin{array}{c}
-0.85 \mathrm{~V}-2.068 \mathrm{~V} \\
\text { Anode } \\
\text { overpotential }
\end{array} \begin{array}{c}
\text { Cathode } \\
\text { overpotential }
\end{array}
\end{array}
\end{gathered}=-2.35 \mathrm{~V}
$$

For Au electrodes, overpotentials of 0.963 and 0.390 V , give $E=-2.78 \mathrm{~V}$.
16-B. (a) To electrolyze $0.010 \mathrm{M} \mathrm{SbO}^{+}$requires a potential of
$E($ cathode $)=0.208-\frac{0.05916}{3} \log \frac{1}{\left[\mathrm{SbO}^{+}\right]\left[\mathrm{H}^{+}\right]^{2}}$
$=0.208-\frac{0.05916}{3} \log \frac{1}{(0.010)(1.0)^{2}}=0.169 \mathrm{~V}$
$E($ cathode versus $\mathrm{Ag} \mid \mathrm{AgCl})=E($ versus S.H.E. $)-E(\mathrm{Ag} \mid \mathrm{AgCl})$
$=0.169-0.197=-0.028 \mathrm{~V}$
(b) The concentration of $\mathrm{Cu}^{2+}$ in equilibrium with $\mathrm{Cu}(s)$ at 0.169 V is
$\mathrm{Cu}^{2+}+2 \mathrm{e}^{-} \rightleftharpoons \mathrm{Cu}(s) \quad E^{\circ}=0.339$
$E($ cathode $)=0.339-\frac{0.05916}{2} \log \frac{1}{\left[\mathrm{Cu}^{2+}\right]}$
$0.169=0.339-\frac{0.05916}{2} \log \frac{1}{\left[\mathrm{Cu}^{2+}\right]} \Rightarrow\left[\mathrm{Cu}^{2+}\right]=1.8 \times 10^{-6} \mathrm{M}$
Percentage of $\mathrm{Cu}^{2+}$ not reduced $=\frac{1.8 \times 10^{-6}}{0.10} \times 100=1.8 \times 10^{-3} \%$
Percentage of $\mathrm{Cu}^{2+}$ reduced $=99.998 \%$
16-C. (a) $\mathrm{Co}^{2+}+2 \mathrm{e}^{-} \rightleftharpoons \mathrm{Co}(s) \quad E^{\circ}=-0.282 \mathrm{~V}$
$E($ cathode versus S.H.E. $)=-0.282-\frac{0.05916}{2} \log \frac{1}{\left[\mathrm{Co}^{2+}\right]}$
Putting in $\left[\mathrm{Co}^{2+}\right]=1.0 \times 10^{-6} \mathrm{M}$ gives $E=-0.459 \mathrm{~V}$ and
$E($ cathode versus S.C.E. $)=-0.459-\underbrace{0.241}=-0.700 \mathrm{~V}$
(b) $\mathrm{Co}\left(\mathrm{C}_{2} \mathrm{O}_{4}\right)_{2}^{2-}+2 \mathrm{e}^{-} \rightleftharpoons \mathrm{Co}(s)+2 \mathrm{C}_{2} \mathrm{O}_{4}^{2-} \quad E^{\circ}=-0.474 \mathrm{~V}$

E(cathode versus S.C.E.)
$=-0.474-\frac{0.05916}{2} \log \frac{\left[\mathrm{C}_{2} \mathrm{O}_{4}^{2-}\right]^{2}}{\left[\mathrm{Co}\left(\mathrm{C}_{2} \mathrm{O}_{4}\right)_{2}^{2^{-}}\right]}-0.241$
For $\left[\mathrm{C}_{2} \mathrm{O}_{4}^{2-}\right]=0.10 \mathrm{M}$ and $\left[\mathrm{Co}\left(\mathrm{C}_{2} \mathrm{O}_{4}\right)_{2}^{2-}\right]=1.0 \times 10^{-6} \mathrm{M}, E=-0.833 \mathrm{~V}$.
(c) We can think of the reduction as $\mathrm{Co}^{2+}+2 \mathrm{e}^{-} \rightleftharpoons \mathrm{Co}(s)$, for which $E^{\circ}=-0.282 \mathrm{~V}$. But $\left[\mathrm{Co}^{2+}\right]$ is the tiny amount in equilibrium with 0.10 M EDTA plus $1.0 \times 10^{-6} \mathrm{M} \mathrm{Co}(\text { EDTA })^{2-}$. In Table 11-2, we find that the formation constant for $\operatorname{Co}(E D T A)^{2-}$ is $10^{16.45}=2.8 \times 10^{16}$.
$K_{\mathrm{f}}=\frac{\left[\mathrm{Co}(\mathrm{EDTA})^{2-}\right]}{\left[\mathrm{Co}^{2^{+}}\right]\left[\mathrm{EDTA}^{4-}\right]}=\frac{\left[\mathrm{Co}(\mathrm{EDTA})^{2-}\right]}{\left[\mathrm{Co}^{2+}\right] \alpha_{\mathrm{Y}^{4-}} \mathrm{F}}$
where F is the formal concentration of EDTA $(=0.10 \mathrm{M})$ and $\alpha_{\mathrm{Y}^{4-}}=$ $3.8 \times 10^{-4}$ at pH 7.00 (Table 11-1). Putting in $\left[\mathrm{Co}(E D T A)^{2-}\right]=$
$1.0 \times 10^{-6} \mathrm{M}$ and solving for $\left[\mathrm{Co}^{2+}\right]$ gives $\left[\mathrm{Co}^{2+}\right]=9.4 \times 10^{-19} \mathrm{M}$.
$E=-0.282-\frac{0.05916}{2} \log \frac{1}{9.4 \times 10^{-19}}-0.241=-1.056 \mathrm{~V}$
16-D. (a) 75.00 mL of $0.02380 \mathrm{M} \mathrm{KSCN}=1.785 \mathrm{mmol}$ of $\mathrm{SCN}^{-}$, which gives 1.785 mmol of AgSCN , containing 0.1037 g of SCN. Final mass $=12.4638+0.1037=12.5675 \mathrm{~g}$.
(b) Anode: $\operatorname{AgBr}(s)+\mathrm{e}^{-} \rightleftharpoons \operatorname{Ag}(s)+\mathrm{Br}^{-} \quad E^{\circ}=0.071 \mathrm{~V}$
$E($ anode $)=0.071-0.05916 \log \left[\mathrm{Br}^{-}\right]$
$=0.071-0.05916 \log [0.10]=0.130 \mathrm{~V}$
$E($ cathode $)=E($ S.C.E. $)=0.241 \mathrm{~V}$
$E=E($ cathode $)-E($ anode $)=0.111 \mathrm{~V}$
(c) To remove $99.99 \%$ of 0.10 M KI will leave $\left[\mathrm{I}^{-}\right]=1.0 \times 10^{-5} \mathrm{M}$. The concentration of $\mathrm{Ag}^{+}$in equilibrium with this much $\mathrm{I}^{-}$is
$\left[\mathrm{Ag}^{+}\right]=K_{\text {sp }} /\left[\mathrm{I}^{-}\right]=\left(8.3 \times 10^{-17}\right) /\left(1.0 \times 10^{-5}\right)=8.3 \times 10^{-12} \mathrm{M}$. The concentration of $\mathrm{Ag}^{+}$in equilibrium with $0.10 \mathrm{M} \mathrm{Br}^{-}$is $\left[\mathrm{Ag}^{+}\right]=$ $K_{\text {sp }} /\left[\mathrm{Br}^{-}\right]=\left(5.0 \times 10^{-13}\right) /(0.10)=5.0 \times 10^{-12} \mathrm{M}$. Therefore,
$8.3 \times 10^{-12} \mathrm{M} \mathrm{Ag}^{+}$will begin to precipitate $0.10 \mathrm{M} \mathrm{Br}^{-}$. The separation is not possible.
16-E. The corrected coulometric titration time is $387-6=381$ s. $q=$ $I t / F=(4.23 \mathrm{~mA})(381 \mathrm{~s}) /(96485 \mathrm{C} / \mathrm{mol})=16.7 \mu \mathrm{~mol} \mathrm{e}{ }^{-}$. Because $1 \mathrm{e}^{-}$is equivalent to one $\mathrm{X}^{-}$, the concentration of organohalide is $16.7 \mu \mathrm{M}$. If all halogen is Cl , this corresponds to $592 \mu \mathrm{~g} \mathrm{Cl} / \mathrm{L}$.
16-F. (a) Use the internal standard equation with $\mathrm{X}=\mathrm{Pb}^{2+}$ and $\mathrm{S}=\mathrm{Cd}^{2+}$. From the standard mixture, we find the response factor, $F$ :

$$
\begin{gathered}
\frac{\text { Signal }_{\mathrm{X}}}{[\mathrm{X}]}=F\left(\frac{\text { signal }_{\mathrm{S}}}{[\mathrm{~S}]}\right) \\
\frac{1.58 \mu \mathrm{~A}}{[41.8 \mu \mathrm{M}]}=F\left(\frac{1.64 \mu \mathrm{~A}}{[32.3 \mu \mathrm{M}]}\right) \Rightarrow F=0.744_{5}
\end{gathered}
$$

$\left[\mathrm{Cd}^{2+}\right]$ standard added to unknown
$=\left(\frac{10.00}{50.00}\right)\left(3.23 \times 10^{-4} \mathrm{M}\right)=6.46 \times 10^{-5} \mathrm{M}$
For the unknown mixture, we can now say

$$
\begin{gathered}
\frac{\text { Signal }_{\mathrm{X}}}{[\mathrm{X}]}=F\left(\frac{\text { signal }_{\mathrm{S}}}{[\mathrm{~S}]}\right) \\
\frac{3.00 \mu \mathrm{~A}}{\left[\mathrm{~Pb}^{2+}\right]}=0.744_{5}\left(\frac{2.00 \mu \mathrm{~A}}{[64.6 \mu \mathrm{M}]}\right) \Rightarrow\left[\mathrm{Pb}^{2+}\right]=130_{.2} \mu \mathrm{M}
\end{gathered}
$$

The concentration of $\mathrm{Pb}^{2+}$ in diluted unknown is $130.2 \mu \mathrm{M}$. In the undiluted unknown, the concentration is $\left(\frac{50.00}{25.00}\right)\left(130_{.2} \mu \mathrm{M}\right)=2.60 \times 10^{-4} \mathrm{M}$.
(b) First find the relative uncertainty in the response factor:
$F=\frac{(1.58 \pm 0.03)(32.3 \pm 0.1)}{(1.64 \pm 0.03)(41.8 \pm 0.1)} \Rightarrow F=0.7445 \pm 0.0199( \pm 2.67 \%)$
Then find the uncertainty in $\left[\mathrm{Pb}^{2+}\right]$ :
$\left[\mathrm{Pb}^{2+}\right]=\frac{(3.00 \pm 0.03) \frac{(10.00 \pm 0.05)}{(50.00 \pm 0.05)}\left(3.23( \pm 0.01) \times 10^{-4}\right)}{(2.00 \pm 0.03)(0.7445 \pm 0.0199)}$
$\Rightarrow\left[\mathrm{Pb}^{2+}\right]=2.60( \pm 0.09) \times 10^{-4} \mathrm{M}$
16-G. We see two consecutive reductions. From the value of $E_{\mathrm{pa}}-E_{\mathrm{pc}}$, we find that one electron is involved in each reduction (using Equation 16-20). A possible sequence of reaction is
$\mathrm{Co}(\mathrm{III})\left(\mathrm{B}_{9} \mathrm{C}_{2} \mathrm{H}_{11}\right)_{2}^{-} \rightarrow \mathrm{Co}(\mathrm{II})\left(\mathrm{B}_{9} \mathrm{C}_{2} \mathrm{H}_{11}\right)_{2}^{2-} \rightarrow \mathrm{Co}(\mathrm{I})\left(\mathrm{B}_{9} \mathrm{C}_{2} \mathrm{H}_{11}\right)_{2}^{3-}$
The equality of the anodic and cathodic peak heights suggests that the reactions are reversible. The expected sampled current (panel $a$ ) and square wave (panel $b$ ) polarograms are sketched below.

(b)
$16-\mathrm{H}$. Electricity required for $\mathrm{H}_{2} \mathrm{O}$ in 0.847 g of polymer $=$
$(63.16-4.23)=58.93 \mathrm{C}$.
$\frac{58.93 \mathrm{C}}{96485 \mathrm{C} / \mathrm{mol}}=0.6108 \mathrm{mmol}$ of $\mathrm{e}^{-}$which corresponds to
$\frac{1}{2}(0.6108)=0.3054 \mathrm{mmol}^{8} \mathrm{I}_{2}=0.3054 \mathrm{mmol}$ of $\mathrm{H}_{2} \mathrm{O}=5.502 \mathrm{mg} \mathrm{H}_{2} \mathrm{O}$.
Water content $=100 \times \frac{5.502 \mathrm{mg} \mathrm{H}_{2} \mathrm{O}}{847.6 \mathrm{mg} \text { polymer }}=0.6491 \mathrm{wt} \%$

## Chapter 17

17-A. (a) $A=-\log P / P_{0}=-\log T=-\log (0.45)=0.347$
(b) Absorbance is proportional to concentration, so the absorbance will double to 0.694 , giving $T=10^{-A}=10^{-0.694}=0.202 \Rightarrow \% T=20.2 \%$.

17-B. (a) $\varepsilon=\frac{A}{c b}=\frac{0.624-0.029}{\left(3.96 \times 10^{-4} \mathrm{M}\right)(1.000 \mathrm{~cm})}=1.50 \times 10^{3} \mathrm{M}^{-1} \mathrm{~cm}^{-1}$
(b) $c=\frac{A}{\varepsilon b}=\frac{0.375-0.029}{\left(1.50 \times 10^{3} \mathrm{M}^{-1} \mathrm{~cm}^{-1}\right)(1.000 \mathrm{~cm})}=2.31 \times 10^{-4} \mathrm{M}$

17-C. (a) $1.00 \times 10^{-2} \mathrm{~g}$ of $\mathrm{NH}_{4} \mathrm{Cl}$ in $1.00 \mathrm{~L}=1.869 \times 10^{-4} \mathrm{M}$. In the colored solution, the concentration is $\left(\frac{10}{50}\right)\left(1.869 \times 10^{-4} \mathrm{M}\right)=$ $3.739 \times 10^{-5} \mathrm{M} . \varepsilon=A / b c=(0.308-0.140) /\left[(1.00)\left(3.739 \times 10^{-5}\right)\right]=$ $4.49_{3} \times 10^{3} \mathrm{M}^{-1} \mathrm{~cm}^{-1}$.
(b) $\frac{\text { Absorbance of unknown }}{\text { Absorbance of reference }}$
$=\frac{0.592-0.140}{0.308-0.140}=\frac{\text { concentration of unknown }}{\text { concentration of reference }}$
$\Rightarrow$ concentration of $\mathrm{NH}_{3}$ in unknown
$=\left(\frac{0.452}{0.168}\right)\left(1.869 \times 10^{-4}\right)=5.028 \times 10^{-4} \mathrm{M}$
100.00 mL of unknown $=5.028 \times 10^{-5} \mathrm{~mol}$ of N
$=7.043 \times 10^{-4} \mathrm{~g}$ of N
$\Rightarrow \mathrm{wt} \% \mathrm{~N}=\left(7.043 \times 10^{-4} \mathrm{~g}\right) /\left(4.37 \times 10^{-3} \mathrm{~g}\right)=16.1 \%$
17-D. (a) Cu in flask $\mathrm{C}=(1.00 \mathrm{mg})\left(\frac{10}{250}\right)\left(\frac{15}{30}\right)=0.0200 \mathrm{mg}$.
This entire quantity is in the isoamyl alcohol ( 20.00 mL ), so the concentration is $\left(2.00 \times 10^{-5} \mathrm{~g}\right) /[(0.0200 \mathrm{~L})(63.546 \mathrm{~g} / \mathrm{mol})]=1.57_{4} \times 10^{-5} \mathrm{M}$.
(b) Observed absorbance

$$
\begin{aligned}
& =\text { absorbance due to } \mathrm{Cu} \text { in rock }+ \text { blank absorbance }=\varepsilon b c+0.056 \\
& =\left(7.90 \times 10^{3}\right)(1.00)\left(1.57_{4} \times 10^{-5}\right)+0.056=0.180
\end{aligned}
$$

Note that the observed absorbance is equal to the absorbance from Cu in the rock plus the blank absorbance. In the lab, we measure the observed absorbance and subtract the blank absorbance from it to find the absorbance due to copper.
(c) $\frac{\mathrm{Cu} \text { in unknown }}{\mathrm{Cu} \text { in known }}=\frac{A \text { of unknown }}{A \text { of known }}$
$\frac{x \mathrm{mg}}{1.00 \mathrm{mg}}=\frac{0.874-0.056}{0.180-0.056} \Rightarrow x=6.60 \mathrm{mg} \mathrm{Cu}$
17-E. Absorbance is corrected by multiplying observed absorbance by (total volume/initial volume). For example, at $36.0 \mu \mathrm{~L}$, $A($ corrected $)=(0.399)[2025+36) / 2025]=0.406$. A graph of corrected absorbance versus volume of $\mathrm{Pb}^{2+}(\mu \mathrm{L})$ is similar to Figure 17-10, with the end point at $46.7 \mu \mathrm{~L}$. The moles of $\mathrm{Pb}^{2+}$ in this volume are $\left(46.7 \times 10^{-6} \mathrm{~L}\right)\left(7.515 \times 10^{-4} \mathrm{M}\right)=3.510 \times 10^{-8} \mathrm{~mol}$. The concentration of semi-xylenol orange is $\left(3.510 \times 10^{-8} \mathrm{~mol}\right) /\left(2.025 \times 10^{-3} \mathrm{~L}\right)=$ $1.73 \times 10^{-5} \mathrm{M}$.

## Chapter 18

18-A. (a) $c=A / \varepsilon b=0.463 /[(4170)(1.00)]=1.110 \times 10^{-4} \mathrm{M}=$ $8.99 \mathrm{~g} / \mathrm{L}=8.99 \mathrm{mg}$ of transferrin $/ \mathrm{mL}$. The Fe concentration is $2.220 \times 10^{-4} \mathrm{M}=0.0124 \mathrm{~g} / \mathrm{L}=12.4 \mu \mathrm{~g} / \mathrm{mL}$.
(b) $A_{\lambda}=\Sigma \varepsilon b c$

At $470 \mathrm{~nm}: \quad 0.424=4170[\mathrm{~T}]+2290[\mathrm{D}]$
At $428 \mathrm{~nm}: \quad 0.401=3540[\mathrm{~T}]+2730[\mathrm{D}]$
where [T] and [D] are the concentrations of transferrin and desferrioxamine, respectively. Solving the simultaneous equations gives $[\mathrm{T}]=$ $7.30 \times 10^{-5} \mathrm{M}$ and $[\mathrm{D}]=5.22 \times 10^{-5} \mathrm{M}$. The fraction of iron in transferrin (which binds two ferric ions) is $2[\mathrm{~T}] /(2[\mathrm{~T}]+[\mathrm{D}])=73.7 \%$.
The fraction in desferrioxamine is $26.3 \%$. The spreadsheet solution looks like this:

|  | A | B | C | D | E | F | G |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

Spreadsheet for Exercise 18-B.

18-C. The Scatchard plot is a graph of $\Delta A /[\mathrm{X}]$ versus $\Delta A$ (Equation 18-16).

| Experiment | $\Delta A$ | $\Delta A /[\mathrm{X}]$ |
| :---: | :--- | ---: |
| 1 | 0.090 | 20360 |
| 2 | 0.181 | 19890 |
| 3 | 0.271 | 16940 |
| 4 | 0.361 | 14620 |
| 5 | 0.450 | 12610 |
| 6 | 0.539 | 9764 |
| 7 | 0.627 | 7646 |
| 8 | 0.713 | 5021 |
| 9 | 0.793 | 2948 |
| 10 | 0.853 | 1453 |
| 11 | 0.904 | 93.6 |

Points 2-11 lie on a reasonably straight line whose slope is $-2.72 \times 10^{4} \mathrm{M}^{-1}$, giving $K=2.72 \times 10^{4}$.
18-D.

## Chapter 19

19-A. (a) For $\lambda=10.00 \mu \mathrm{~m}$ and $\Delta \lambda=0.01 \mu \mathrm{~m}, \lambda / \Delta \lambda=10.00 / 0.01=10^{3}$. The resolution is $10^{4}$, so these lines will be resolved.
(b) $\lambda=\frac{1}{\tilde{v}}=\frac{1}{\left(1000 \mathrm{~cm}^{-1}\right)\left(10^{-4} \mathrm{~cm} / \mu \mathrm{m}\right)}=10 \mu \mathrm{~m}$
$\Delta \lambda=\frac{\lambda}{10^{4}}=10^{-3} \mu \mathrm{~m}$
$\Rightarrow 10.001 \mu \mathrm{~m}$ could be resolved from $10.000 \mu \mathrm{~m}$
$\left.\begin{array}{l}10.000 \mu \mathrm{~m}=1000.0 \mathrm{~cm}^{-1} \\ 10.001 \mu \mathrm{~m}=999.9 \mathrm{~cm}^{-1}\end{array}\right\} \quad$ Difference $=0.1 \mathrm{~cm}^{-1}$
(c) $5.0 \mathrm{~cm} \times 2500$ lines $/ \mathrm{cm}=12500$ lines

Resolution $=1 \cdot 12500=12500$ for $n=1$

$$
=10 \cdot 12500=125000 \text { for } n=10
$$

(d) $\frac{\Delta \phi}{\Delta \lambda}=\frac{n}{d \cos \phi}=\frac{2}{\left(\frac{1 \mathrm{~mm}}{250}\right) \cos 30^{\circ}}$

$$
=577 \frac{\text { radians }}{\mathrm{mm}}=0.577 \frac{\text { radians }}{\mu \mathrm{m}}
$$

Convert radians to degrees $=\frac{\text { radians }}{\pi} \times 180$
$\Rightarrow \frac{\Delta \phi}{\Delta \lambda}=33.1$ degrees $/ \mu \mathrm{m}$
The two wavelengths are $1000 \mathrm{~cm}^{-1}=10.00 \mu \mathrm{~m}$ and $1001 \mathrm{~cm}^{-1}=$ $9.99 \mu \mathrm{~m} \Rightarrow \Delta \lambda=0.01 \mu \mathrm{~m}$.

$$
\begin{aligned}
\Delta \phi & =0.577 \frac{\text { radians }}{\mu \mathrm{m}} \times 0.01 \mu \mathrm{~m} \\
& =6 \times 10^{-3} \text { radian }=0.3^{\circ}
\end{aligned}
$$

19-B. True transmittance $=10^{-1.000}=0.100$. With $1.0 \%$ stray light, the apparent transmittance is
Apparent transmittance $=\frac{P+S}{P_{0}+S}=\frac{0.100+0.010}{1+0.010}=0.109$
The apparent absorbance is $-\log T=-\log 0.109=0.963$.
Apparent concentration $=96.3 \%$ of true concentration $\Rightarrow$ error $=-3.7 \%$
19-C. (a) $\Delta \tilde{v}=1 / 2 \delta=1 /\left(2 \cdot 1.2660 \times 10^{-4} \mathrm{~cm}\right)$

$$
=3949 \mathrm{~cm}^{-1}
$$

(b) Each interval is $1.2660 \times 10^{-4} \mathrm{~cm} .4096$ intervals $=$ $(4096)\left(1.2660 \times 10^{-4} \mathrm{~cm}\right)=0.5186 \mathrm{~cm}$. This is a range of $\pm \Delta$, so $\Delta=0.2593 \mathrm{~cm}$.
(c) Resolution $\approx 1 / \Delta=1 /(0.2593 \mathrm{~cm})=3.86 \mathrm{~cm}^{-1}$
(d) Mirror velocity $=0.693 \mathrm{~cm} / \mathrm{s}$

Interval $=\frac{1.2660 \times 10^{-4} \mathrm{~cm}}{0.693 \mathrm{~cm} / \mathrm{s}}=183 \mu \mathrm{~s}$
(e) $(4096$ points) $(183 \mu \mathrm{~s} /$ point $)=0.748 \mathrm{~s}$
(f) The beamsplitter is germanium on $\mathrm{KBr} . \mathrm{KBr}$ absorbs light below $400 \mathrm{~cm}^{-1}$, which the background transform shows clearly.
19-D. The graphs show that signal-to-noise ratio is proportional to $\sqrt{n}$. The confidence interval is $\pm t s / \sqrt{n}$, where $s$ is the standard deviation, $n$ is the number of experiments, and $t$ is Student's $t$ from Table 4-2 for $95 \%$ confidence and $n-1$ degrees of freedom. For the first line of the table, $n=8, s=1.9$, and $t=2.365$ for 7 degrees of freedom. $95 \%$ confidence interval $= \pm(2.365)(1.9) / \sqrt{8}= \pm 1.6$. For remaining rows, $95 \%$ confidence interval $=3.9,5.1,5.9,9.0,11.2,14.0,24.0,23.9$, and 27.2.

## Chapter 20

20-A. A graph of intensity versus concentration of added standard has an $x$-intercept of $-0.164 \pm 0.005 \mu \mathrm{~g} / \mathrm{mL}$. Because the sample was diluted by a factor of 10 , the original concentration is $1.64 \pm 0.05 \mu \mathrm{~g} / \mathrm{mL}$.

|  | A | B | C | D |
| :---: | :---: | :---: | :---: | :---: |
| 1 | Standard Addition Constant Volume Least-Squares |  |  |  |
| 2 | x = Added Li | y |  |  |
| 3 | ( $\mathrm{g} / \mathrm{mL}$ ) | Signal |  |  |
| 4 | 0.000 | 309 |  |  |
| 5 | 0.081 | 452 |  |  |
| 6 | 0.162 | 600 |  |  |
| 7 | 0.243 | 765 |  |  |
| 8 | 0.324 | 906 |  |  |
| 9 | B11:C13 = LINEST(B4:B8,A4:A8,TRUE,TRUE) |  |  |  |
| 10 |  | LINEST output: |  |  |
| 11 | m | 1860.5 | 305.0 | b |
| 12 | $\mathrm{s}_{\mathrm{m}}$ | 26.3 | 5.2 | $\mathrm{s}_{\mathrm{b}}$ |
| 13 | $\mathrm{R}^{2}$ | 0.9994 | 6.7 | $\mathrm{S}_{\mathrm{y}}$ |
| 14 | x-intercept $=-\mathrm{b} / \mathrm{m}=$ | -0.164 |  |  |
| 15 | $\mathrm{n}=$ | 5 | = COUNT | (A4:A8) |
| 16 | Mean $\mathrm{y}=$ | 606.400 | = AVERAG | E(B4:B8) |
| 17 | $\Sigma\left(\mathrm{x}_{\mathrm{i}}-\text { mean } \mathrm{x}\right)^{2}=$ | 0.06561 | = DEVSQ( | (A4:A8) |
| 18 | Std deviation of |  |  |  |
| 19 | x-intercept = | 0.0049 |  |  |
| 20 | B19=(C13/ABS(B11))*SQRT((1/B15) + B16^2/(B11^2*B17)) |  |  |  |

20-B. The concentration of Mn in the unknown mixture is $(13.5 \mu \mathrm{~g} / \mathrm{mL})(1.00 / 6.00)=2.25 \mu \mathrm{~g} / \mathrm{mL}$.
Standard mixture:

$$
\begin{aligned}
& \frac{A_{\mathrm{X}}}{[\mathrm{X}]}=F\left(\frac{A_{\mathrm{S}}}{[\mathrm{~S}]}\right) \\
& \frac{1.05}{[2.50 \mu \mathrm{~g} / \mathrm{mL}]}=F\left(\frac{1.00}{[2.00 \mu \mathrm{~g} / \mathrm{mL}]}\right) \Rightarrow F=0.840
\end{aligned}
$$

Unknown mixture:
$\frac{A_{\mathrm{X}}}{[\mathrm{X}]}=F\left(\frac{A_{\mathrm{S}}}{[\mathrm{S}]}\right)$
$\frac{0.185}{[\mathrm{Fe}]}=0.840\left(\frac{0.128}{[2.25 \mu \mathrm{~g} / \mathrm{mL}]}\right) \Rightarrow[\mathrm{Fe}]=3.87 \mu \mathrm{~g} / \mathrm{mL}$
The original concentration of Fe must have been
$\frac{6.00}{5.00}(3.87 \mu \mathrm{~g} / \mathrm{mL})=4.65 \mu \mathrm{~g} / \mathrm{mL}=8.33 \times 10^{-5} \mathrm{M}$
20-C. (a) The ratio of signal to peak-to-peak noise level is measured to be 17 in the figure. The concentration of Fe needed to give a signal-to-noise ratio of 2 is $\left(\frac{2}{17}\right)(0.0485 \mu \mathrm{~g} / \mathrm{mL})=0.0057 \mu \mathrm{~g} / \mathrm{mL}(=5.7 \mathrm{ppb})$.
(b) Standard deviation of 7 standards $=0.22_{48} \mathrm{ng} / \mathrm{L} \equiv \mathrm{s} / \mathrm{m}$

Detection limit $=3 \mathrm{~s} / \mathrm{m}=0.67 \mathrm{ng} / \mathrm{L}$
Quantitation limit $=10 \mathrm{~s} / \mathrm{m}=2.2 \mathrm{ng} / \mathrm{L}$
20-D. (a) The higher result in experiment 2 compared with experiment 1 is probably the effect of diluting interfering species, so they do not interfere as much in experiment 2 as in experiment 1 . Dilution lowers the concentration of species that might react with Li or make smoke that scatters light. In experiment 3, interference is present to the same extent as in experiment 2 , but the standard addition procedure corrects for the interference. The whole point of standard addition is to measure the effect of the complex interfering matrix on the response to known quantities of analyte.
(b) Experiments 4-6 use a hotter flame than experiments 1-3. High temperature appears to eliminate most of the interference observed at lower temperature. Dilution has only a tiny effect on the results.
(c) Because it appears from experiments 1-3 that standard addition gives a true result, we surmise that experiments 3 and 6 , and possibly 5, are within experimental error of each other. I would probably report the "true" value as the mean of experiments 3 and $6(81.4 \mathrm{ppm})$. It might also be reasonable to take the average of experiments 3,5 , and $6(80.8 \mathrm{ppm})$.

## Chapter 21

21-A. (a) Resolving power $=\frac{m}{m_{1 / 2}}=\frac{53}{0.6_{0}} \approx 88$
We should be able to barely distinguish two peaks differing by 1 Da at a mass of 88 Da . We will probably not be able to distinguish two peaks at 100 and 101 Da .

$$
\begin{array}{lll}
\text { 21-B. } & \mathrm{C}_{2} \mathrm{H}_{5}^{+}: & 2 \times 12.00000 \\
& & +5 \times 1.007825 \\
& -\mathrm{e}^{-} \text {mass } & \frac{-1 \times 0.00055}{} \\
& \mathrm{HCO}^{+}: & 1 \times 129.03858 \\
& & 1 \times 1.00000 \\
& +1 \times 15.99491 \\
& -\mathrm{e}^{-} \text {mass } & \frac{-1 \times 0.00055}{29.00218}
\end{array}
$$

We need to distinguish a mass difference of $29.03858-29.00218=$ 0.036 40. The required resolving power is $m / \Delta m=29.0 /(0.03640) \approx 800$. 21-C. ${ }^{35} \mathrm{Cl}$ abundance $\equiv a=0.7578$
${ }^{37} \mathrm{Cl}$ abundance $\equiv b=0.2422$
Relative abundance of $\mathrm{C}_{6} \mathrm{H}_{4}{ }^{35} \mathrm{Cl}_{2}=a^{2}=0.5742_{6}$
Relative abundance of $\mathrm{C}_{6} \mathrm{H}_{4}{ }^{35} \mathrm{Cl}^{37} \mathrm{Cl}=2 a b=0.3670_{8}$
Relative abundance of $\mathrm{C}_{6} \mathrm{H}_{4}{ }^{37} \mathrm{Cl}_{2}=b^{2}=0.05866_{1}$
Relative abundances: ${ }^{35} \mathrm{Cl}_{2}:{ }^{35} \mathrm{Cl}^{37} \mathrm{Cl}:{ }^{37} \mathrm{Cl}_{2}=1: 0.6392: 0.1022$
Figure 21-7 shows the stick diagram.
21-D. (a) $\mathrm{C}_{14} \mathrm{H}_{12}$
$\mathrm{R}+\mathrm{DB}=c-h / 2+n / 2+1=14-12 / 2+0 / 2+1=9$

A molecule with two rings + seven double bonds is trans-stilbene:

(b) $\mathrm{C}_{4} \mathrm{H}_{10} \mathrm{NO}^{+}$
$\mathrm{R}+\mathrm{DB}=c-h / 2+n / 2+1=4-10 / 2+1 / 2+1=\frac{1}{2} \quad$ Huh?
We came out with a fraction because the species is an ion in which at least one atom does not make its usual number of bonds. In the following structure, N makes four bonds instead of three:

A fragment in a
mass spectrum

21-E. (a) The principal difference between the two spectra is the appearance of a significant peak at $m / z 72$ in A that is missing in B . This peak represents loss of a neutral molecule with an even mass of 28 Da from the molecular ion. The McLafferty rearrangement can split $\mathrm{C}_{2} \mathrm{H}_{4}$ from 3-methyl-2-pentanone but not from 3,3-dimethyl-2-butanone, which lacks a $\gamma$ - CH group.

Spectrum A must be from 3-methyl-2-pentanone and spectrum B is from 3,3-dimethyl-2-butanone.
(b) Expected intensity of $\mathrm{M}+1$ relative to $\mathrm{M}^{+\cdot}$ for $\mathrm{C}_{6} \mathrm{H}_{12} \mathrm{O}$ :

Intensity $=\underbrace{6 \times 1.08 \%}_{{ }^{13} \mathrm{C}}+\underbrace{12 \times 0.012 \%}_{{ }^{2} \mathrm{H}}+\underbrace{1 \times 0.038 \%}_{{ }^{17} \mathrm{O}}=6.7 \%$ of $\mathrm{M}^{+\cdot}$
21-F. (a)

$\mathrm{C}_{6} \mathrm{H}_{6} \mathrm{O}: \mathrm{M}^{+\bullet}=94$
Rings + double bonds $=c-h / 2+n / 2+1=6-6 / 2+0 / 2+1=4$
Expected intensity of $\mathrm{M}+1$ from Table 21-2:

$$
\underset{\text { Carbon }}{1.08(6)}+\underset{\text { Hydrogen }}{0.012(6)}+\underset{\text { Oxygen }}{0.038(1)}=6.59 \%
$$

Observed intensity of $\mathrm{M}+1=68 / 999=6.8 \%$
Expected intensity of $M+2=0.0058(6)(5)+0.205(1)=0.38 \%$
Observed intensity of $\mathrm{M}+2=0.3 \%$
(b)

$\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{Br}: \mathrm{M}^{+\bullet}=156$
The two nearly equal peaks at $m / z 156$ and 158 scream out "bromine!"
Rings + double bonds $=c-h / 2+n / 2+1=6-6 / 2+0 / 2+1=4$
$h$ includes $\mathrm{H}+\mathrm{Br}$
Expected intensity of $\mathrm{M}+1=\underset{\text { Carbon }}{1.08(6)}+\underset{\text { Hydrogen }}{0.012(5)}=6.54 \%$
Observed intensity of $M+1=46 / 566=8.1 \%$
Expected intensity of $\mathrm{M}+2=\underset{\text { Carbon }}{0.005(6)(5)}+\underset{\text { Bromine }}{97.3(1)}=97.5 \%$
Observed intensity of $\mathrm{M}+2=520 / 566=91.9 \%$
The $M+3$ peak is the isotopic partner of the $M+2$ peak $\left(\mathrm{C}_{6} \mathrm{H}_{5}{ }^{81} \mathrm{Br}\right)$. $\mathrm{M}+3$ contains ${ }^{81} \mathrm{Br}$ plus either $1{ }^{13} \mathrm{C}$ or $1{ }^{2} \mathrm{H}$. Therefore, the expected intensity of $\mathrm{M}+3$ (relative to $\mathrm{C}_{6} \mathrm{H}_{5}{ }^{81} \mathrm{Br}$ at $\mathrm{M}+2$ ) is $1.08(6)+0.012(5)=6.54 \%$ of predicted intensity of $\mathrm{C}_{6} \mathrm{H}_{5}{ }^{81} \mathrm{Br}$ at $\mathrm{M}+2=(0.0654)(97.3)=6.4 \%$ of $\mathrm{M}^{+\bullet}$. Observed intensity of $\mathrm{M}+3$ is $35 / 566=6.2 \%$

$\mathrm{C}_{7} \mathrm{H}_{3} \mathrm{O}_{2} \mathrm{Cl}_{3}: \mathrm{M}^{+\boldsymbol{\bullet}}=224$

From Figure 21-7, the $\mathrm{M}: \mathrm{M}+2: \mathrm{M}+4$ pattern looks like a molecule containing three chlorine atoms. The correct structure is shown here, but there is no way you could assign the isomeric structure from the data.
Rings + double bonds $=c-h / 2+n / 2+1=7-6 / 2+0 / 2+1=5$ Expected intensity of $\mathrm{M}+1$ from Table 21-2:

$$
\underset{\text { Carbon }}{1.08(7)}+\underset{\text { Hydrogen }}{0.012(3)}+\underset{\text { Oxygen }}{0.038(2)}=7.67 \%
$$

Observed intensity of $M+1=63 / 791=8.0 \%$
Expected intensity of $\mathrm{M}+2=0.0058(7)(6)+0.205(2)+32.0(3)=96.7 \%$ Observed intensity of $\mathrm{M}+2=754 / 791=95.4 \%$

The $\mathrm{M}+3$ peak is the isotopic partner of $\mathrm{C}_{7} \mathrm{H}_{3} \mathrm{O}_{2}{ }^{35} \mathrm{Cl}_{2}{ }^{37} \mathrm{Cl}$ at $\mathrm{M}+2$. $\mathrm{M}+3$ contains one ${ }^{37} \mathrm{Cl}$ plus either $1^{13} \mathrm{C}$ or $1^{2} \mathrm{H}$ or $1{ }^{17} \mathrm{O}$. Expected intensity of $\mathrm{M}+3$ (relative to $\mathrm{C}_{7} \mathrm{H}_{3} \mathrm{O}_{2}{ }^{35} \mathrm{Cl}_{2}{ }^{37} \mathrm{Cl}$ at $\left.\mathrm{M}+2\right)=1.08(7)+0.012(3)+$ $0.038(2)=7.67 \%$ of predicted intensity of $\mathrm{C}_{7} \mathrm{H}_{3} \mathrm{O}_{2}{ }^{35} \mathrm{Cl}_{2}{ }^{37} \mathrm{Cl}$ at $\mathrm{M}+2$. The predicted intensity of $\mathrm{C}_{7} \mathrm{H}_{3} \mathrm{O}_{2}{ }^{35} \mathrm{Cl}_{2}{ }^{37} \mathrm{Cl}$ is $32.0(3)=96.0 \%$ of $\mathrm{M}^{+}$. Expected intensity of $\mathrm{M}+3=7.67 \%$ of $96.0 \%=7.4 \%$ of $\mathrm{M}^{+}$ Observed intensity $=60 / 791=7.6 \%$.
$\mathrm{M}+4$ is composed mainly of $\mathrm{C}_{7} \mathrm{H}_{3} \mathrm{O}_{2}{ }^{35} \mathrm{Cl}^{37} \mathrm{Cl}_{2}$ plus a small amount of $\mathrm{C}_{7} \mathrm{H}_{3}{ }^{16} \mathrm{O}^{18} \mathrm{O}^{35} \mathrm{Cl}_{2}{ }^{37} \mathrm{Cl}$. Other formulas such as ${ }^{12} \mathrm{C}_{6}{ }^{13} \mathrm{CH}_{2}{ }^{16} \mathrm{O}^{17} \mathrm{O}^{35} \mathrm{Cl}_{2}{ }^{37} \mathrm{Cl}$ also add up to $\mathrm{M}+4$, but they are even less likely to occur because they have two minor isotopes ( ${ }^{13} \mathrm{C}$ and ${ }^{17} \mathrm{O}$ ). Expected intensity of $\mathrm{M}+4$ from $\mathrm{C}_{7} \mathrm{H}_{3} \mathrm{O}_{2}^{35} \mathrm{Cl}^{37} \mathrm{Cl}_{2}$ is $5.11(3)(2)=30.7 \%$ of $\mathrm{M}^{+\bullet}$. The contribution from $\mathrm{C}_{7} \mathrm{H}_{3}{ }^{16} \mathrm{O}^{18} \mathrm{O}^{35} \mathrm{Cl}_{2}{ }^{37} \mathrm{Cl}$ is based on the predicted intensity of $\mathrm{C}_{7} \mathrm{H}_{3} \mathrm{O}_{2}{ }^{35} \mathrm{Cl}_{2}{ }^{37} \mathrm{Cl}$ at $\mathrm{M}+2$. The predicted intensity of $\mathrm{C}_{7} \mathrm{H}_{3} \mathrm{O}_{2}{ }^{35} \mathrm{Cl}_{2}{ }^{37} \mathrm{Cl}$ is $32.0(3)=96.0 \%$ of $\mathrm{M}^{+\bullet}$. The predicted intensity from $\mathrm{C}_{7} \mathrm{H}_{3}{ }^{16} \mathrm{O}^{18} \mathrm{O}^{25} \mathrm{Cl}_{2}{ }^{37} \mathrm{Cl}$ at $\mathrm{M}+4$ is $0.205(2)$ $=0.410 \%$ of $96.0 \%=0.4 \%$. Total expected intensity of $\mathrm{M}+4$ is $30.7 \%+0.4 \%=31.1 \%$ of $\mathrm{M}^{+}$.
Observed intensity $=264 / 791=33.4 \%$
Expected intensity of $\mathrm{M}+5$ from ${ }^{12} \mathrm{C}_{6}{ }^{13} \mathrm{CH}_{3} \mathrm{O}_{2}{ }^{35} \mathrm{Cl}^{37} \mathrm{Cl}_{2}$ and
${ }^{12} \mathrm{C}_{7} \mathrm{H}_{2}{ }^{2} \mathrm{HO}_{2}{ }^{35} \mathrm{Cl}^{37} \mathrm{Cl}_{2}$ and $\mathrm{C}_{7} \mathrm{H}_{3}{ }^{16} \mathrm{O}^{17} \mathrm{O}^{35} \mathrm{Cl}^{37} \mathrm{Cl}_{2}$ is based on the predicted intensity of $\mathrm{C}_{7} \mathrm{H}_{3} \mathrm{O}_{2}{ }^{35} \mathrm{Cl}^{37} \mathrm{Cl}_{2}$ at $\mathrm{M}+4$. $\mathrm{M}+5$ should have $1.08(7)+0.012$ (3) $+0.038(2)=7.7 \%$ of $\mathrm{C}_{7} \mathrm{H}_{3} \mathrm{O}_{2}{ }^{35} \mathrm{Cl}^{37} \mathrm{Cl}_{2}$ at $\mathrm{M}+4=7.7 \%$ of $30.7 \%=2.4 \%$.
Observed intensity $=19 / 791=2.4 \%$
Expected intensity of $\mathrm{M}+6$ from $\mathrm{C}_{7} \mathrm{H}_{3} \mathrm{O}_{2}{ }^{37} \mathrm{Cl}_{3}$ is $0.544(3)(2)(1)=3.26 \%$ of $\mathrm{M}^{+\bullet}$. There will also be a small contribution from $\mathrm{C}_{7} \mathrm{H}_{3}{ }^{16} \mathrm{O}^{18} \mathrm{O}^{35} \mathrm{Cl}^{37} \mathrm{Cl}_{2}$, which will be $0.205(2)=0.410 \%$ of predicted intensity of $\mathrm{C}_{7} \mathrm{H}_{3}{ }^{16} \mathrm{O}^{35} \mathrm{Cl}^{37} \mathrm{Cl}_{2}$ $=0.410 \%$ of $30.7 \%$ of $\mathrm{M}^{+\cdot}=0.13 \%$ of $\mathrm{M}^{+\bullet}$. The total expected intensity at $\mathrm{M}+6$ is therefore $3.26+0.13=3.4 \%$ of $\mathrm{M}^{+}$.
Observed intensity $=29 / 791=3.7 \%$
(d) HS

$\mathrm{C}_{4} \mathrm{H}_{10} \mathrm{O}_{2} \mathrm{~S}_{2}: \mathrm{M}^{+\bullet}=154$

Sulfur gives a significant M+2 peak ( $4.52 \%$ of $M$ per sulfur). The observed $\mathrm{M}+2$ is $12 / 122=9.8 \%$, which could represent two sulfur atoms. The composition $\mathrm{C}_{4} \mathrm{H}_{10} \mathrm{O}_{2} \mathrm{~S}_{2}$ has two sulfur atoms and has a molecular mass of 154 . The known structure is shown here, but you could not deduce the structure from the composition.
Rings + double bonds $=c-h / 2+n / 2+1$

$$
=4-10 / 2+0 / 2+1=0
$$

Expected intensity of $\mathrm{M}+1$ :

$$
\underset{\text { Carbon }}{1.08(4)}+\underset{\text { Hydrogen }}{0.012(10)}+\underset{\text { Oxygen }}{0.038(2)}+\underset{\text { Sulfur }}{0.801(2)}=6.12 \%
$$

Observed intensity of $\mathrm{M}+1=9 / 122=7.4 \%$
Expected intensity of $\mathrm{M}+2=0.0058(4)(3)+0.205(2)+4.52(2)=9.52 \%$
Observed intensity of $\mathrm{M}+2=12 / 122=9.8 \%$

21-H. (a) To find the response factor, we insert values from the first line of the table into the equation:
$\frac{\text { Area of analyte signal }}{\text { Area of standard signal }}=F\left(\frac{\text { concentration of analyte }}{\text { concentration of standard }}\right)$
$\frac{11438}{2992}=F\left(\frac{13.60 \times 10^{2}}{3.70 \times 10^{2}}\right)=F=1.04_{0}$
For the next two sets of data, we find $F=1.02_{0}$ and $1.06_{4}$, giving a mean value $F=1.04_{1}$.
(b) The concentration of internal standard in the mixture of caffeine- $\mathrm{D}_{3}$ plus cola is
$(1.11 \mathrm{~g} / \mathrm{L}) \times \frac{0.0500 \mathrm{~mL}}{1.050 \mathrm{~mL}}=52.8_{6} \mathrm{mg} / \mathrm{L}$
The concentration of caffeine in the chromatography solution is
$\frac{\text { Area of analyte signal }}{\text { Area of standard signal }}=F\left(\frac{\text { concentration of analyte }}{\text { concentration of standard }}\right)$
$\frac{1733}{1144}=1.04_{1}\left(\frac{\text { [caffeine] }}{52.8_{6} \mathrm{mg} / L}\right) \Rightarrow[$ caffeine $]=76.9 \mathrm{mg} / \mathrm{L}$
The unknown beverage had been diluted from 1.000 to 1.050 mL when the standard was added, so the concentration of caffeine in the original beverage was $\left(\frac{1.0500 \mathrm{~mL}}{1.00 \mathrm{~mL}}\right)(76.9 \mathrm{mg} / \mathrm{L})=80.8 \mathrm{mg} / \mathrm{L}$.

## Chapter 22

22-A. (a) $k_{1}=\frac{t_{\mathrm{r} 1}-t_{\mathrm{m}}}{t_{\mathrm{m}}}$
$\Rightarrow t_{\mathrm{m}}=\frac{t_{\mathrm{r} 1}}{k_{1}+1}=\frac{10.0 \mathrm{~min}}{5.00}=2.00 \mathrm{~min}$
$t_{\mathrm{r} 2}=t_{\mathrm{m}}\left(k_{2}+1\right)=2.00 \min (5.00+1)=12.0 \mathrm{~min}$
$\sigma_{1}=\frac{t_{\mathrm{r} 1}}{\sqrt{N}}=\frac{10.0 \mathrm{~min}}{\sqrt{1000}}=0.316 \mathrm{~min}$
$\Rightarrow=w_{1 / 2}($ peak 1$)=2.35 \sigma_{1}=0.74 \mathrm{~min}$
$w_{1}=4 \sigma_{1}=1.26 \mathrm{~min}$
$\sigma_{2}=\frac{t_{\mathrm{r} 2}}{\sqrt{N}}=\frac{12.0 \mathrm{~min}}{\sqrt{1000}}=0.379 \mathrm{~min}$
$\Rightarrow=w_{1 / 2}($ peak 2$)=2.35 \sigma_{2}=0.89 \mathrm{~min}$
$w_{2}=4 \sigma_{2}=1.52 \mathrm{~min}$
(b)

(c) Resolution $=\frac{\Delta t_{\mathrm{r}}}{w_{\mathrm{av}}}=\frac{2 \mathrm{~min}}{(1.26 \mathrm{~min}+1.52 \mathrm{~min}) / 2}=1.44$

22-B. (a) Fraction remaining $=q=\frac{V_{1}}{V_{1}+K V_{2}}$
$0.01=\frac{10}{10+4.0 V_{2}} \Rightarrow V_{2}=248 \mathrm{~mL}$
(b) $q^{3}=0.01=\left(\frac{10}{10+4.0 V_{2}}\right)^{3} \Rightarrow V_{2}=9.1 \mathrm{~mL}$
and total volume $=27.3 \mathrm{~mL}$.
22-C. (a) Relative distances measured from Figure 22-7:
$t_{\mathrm{m}}=10.4$
$t_{\mathrm{r}}^{\prime}=39.8$ for octane
$t_{\mathrm{r}}^{\prime}=76.0$ for nonane
$k=t_{\mathrm{r}}^{\prime} t_{\mathrm{m}}=3.8_{3}$ for octane and $7.3_{1}$ for nonane
(b) Let $t_{\mathrm{s}}=$ time in stationary phase, $t_{\mathrm{m}}=$ time in mobile phase, and $t=$ total time on column. We know that $k=t_{\mathrm{s}} / t_{\mathrm{m}}$. But
$t=t_{\mathrm{s}}+t_{\mathrm{m}}=t_{\mathrm{s}}+\frac{t_{\mathrm{s}}}{k}=t_{\mathrm{s}}\left(1+\frac{1}{k}\right)=t_{\mathrm{s}}\left(\frac{k+1}{k}\right)$
Therefore, $t_{\mathrm{s}} / t=\frac{k}{k+1}=3.8_{3} / 4.8_{3}=0.79_{3}$
(c) $\alpha=t_{\mathrm{r}}^{\prime}($ nonane $) / t_{\mathrm{r}}^{\prime}($ octane $)=76 .{ }_{0} / 39 .{ }_{8}=1.9_{1}$
(d) $K=k V_{\mathrm{m}} / V_{\mathrm{s}}=3.8_{3}\left(V_{\mathrm{m}} / \frac{1}{2} V_{\mathrm{m}}\right)=7.6_{6}$

22-D. (a) For ethyl acetate, I measure $t_{\mathrm{r}}=11.3 \mathrm{~mm}$ and $w=1.5 \mathrm{~mm}$. (You will have different numbers depending on the size of the figure in your book.) Therefore, $N=16 t_{\mathrm{r}}^{2} / w^{2}=910$ plates. For toluene, the values are $t_{\mathrm{r}}=36.2 \mathrm{~mm}, w=4.2 \mathrm{~mm}$, and $N=1200$ plates.
(b) We expect $w_{1 / 2}=(2.35 / 4) w$. The measured value of $w_{1 / 2}$ is in good agreement with the calculated value.
22-E. The column is overloaded, causing a gradual rise and an abrupt fall of the peak. As the sample size is decreased, the overloading decreases and the peak becomes more symmetric.
22-F. (a) We know that $\alpha=1.068$ and $k_{1}=5.16$. For resolution, we need to find the unadjusted relative retention $\gamma=t_{2} / t_{1}$, where $t$ is retention time. The relation between retention factor and retention time is $k_{1}=\left(t_{1}-t_{\mathrm{m}}\right) / t_{\mathrm{m}}=$ $t_{1} / t_{\mathrm{m}}-1 \Rightarrow t_{1}=t_{\mathrm{m}}\left(k_{1}+1\right)=t_{\mathrm{m}}(6.16)$. Also, $k_{2}=\alpha k_{1}=(1.068)(5.16)=$ 5.51 . Therefore, $t_{2}=t_{\mathrm{m}}\left(k_{2}+1\right)=t_{\mathrm{m}}\left(6.51_{1}\right)$.
$\frac{t_{2}}{t_{1}}=\frac{t_{\mathrm{m}}\left(6.51_{1}\right)}{t_{\mathrm{m}}(6.16)}=1.057_{0}$
(b) Resolution $=\frac{\sqrt{N}}{4}(\gamma-1)$
$1.00=\frac{\sqrt{N}}{4}\left(1.057_{0}-1\right) \Rightarrow N=4.92 \times 10^{3}$ plates
Required length $=\left(4.92 \times 10^{3}\right.$ plates $)(0.520 \mathrm{~mm} /$ plate $)=2.56 \mathrm{~m}$
(c) From (a), $t_{\mathrm{r} 1}=t_{\mathrm{m}}(6.16)=(2.00 \mathrm{~min})(6.16)=12.32 \mathrm{~min}$
$t_{\mathrm{r} 2}=t_{\mathrm{m}}\left(6.51_{1}\right)=(2.00 \mathrm{~min})\left(6.51_{1}\right)=13.02 \mathrm{~min}$
$w_{1 / 2}=\sqrt{\frac{5.55}{N}} t_{\mathrm{r}}=\sqrt{\frac{5.55}{4.92 \times 10^{3}}}(12.32 \mathrm{~min})=0.41 \mathrm{~min}$ for component 1
$w_{1 / 2}=\sqrt{\frac{5.55}{4.92 \times 10^{3}}}(13.02 \mathrm{~min})=0.44 \mathrm{~min}$ for component 2
(d) $k=K V_{\mathrm{s}} / V_{\mathrm{m}}$
$5.16=K(0.30) \Rightarrow K=17.2$

## Chapter 23

23-A. (a) $\mathrm{S}=[$ butanol $]=\frac{234 \mathrm{mg} /(74.12 \mathrm{~g} / \mathrm{mol})}{10.0 \mathrm{~mL}}=0.315_{7} \mathrm{M}$
$\mathrm{X}=[$ hexanol $]=\frac{312 \mathrm{mg} /(102.17 \mathrm{~g} / \mathrm{mol})}{10.0 \mathrm{~mL}}=0.305_{4} \mathrm{M}$
$\frac{\mathrm{A}_{\mathrm{X}}}{[\mathrm{X}]}=F\left(\frac{\mathrm{~A}_{\mathrm{S}}}{[\mathrm{S}]}\right) \Rightarrow \frac{1.45}{\left[0.305_{4} \mathrm{M}\right]}=F\left(\frac{1.00}{\left[0.315_{7} \mathrm{M}\right]}\right) \Rightarrow F=1.49_{9}$
(b) I estimate the areas by measuring the height and $w_{1 / 2}$ in millimeters. Your answer will be different from mine if the figure size in your book is different from that in my manuscript. However, the relative peak areas should be the same.
Butanol: $\quad$ Height $=41.3 \mathrm{~mm} ; w_{1 / 2}=2.2 \mathrm{~mm}$;
Area $=1.064 \times$ peak height $\times w_{1 / 2}=96.7 \mathrm{~mm}^{2}$
Hexanol: $\quad$ Height $=21.9 \mathrm{~mm} ; w_{1 / 2}=6.9 \mathrm{~mm}$;
Area $=161 \mathrm{~mm}^{2}$
(c) The volume of solution is not stated, but the concentration is directly proportional to the number of moles. We can substitute moles for concentrations in the internal standard equation:
$\frac{\mathrm{A}_{\mathrm{X}}}{[\mathrm{X}]}=F\left(\frac{\mathrm{~A}_{\mathrm{S}}}{[\mathrm{S}]}\right) \Rightarrow \frac{161 \mathrm{~mm}^{2}}{\mathrm{mg} \text { hexanol } /(102.17 \mathrm{mg} / \mathrm{mmol})}$
$=1.49_{9}\left(\frac{96.7 \mathrm{~mm}^{2}}{112 \mathrm{mg} /(74.12 \mathrm{mg} / \mathrm{mmol})}\right)$
$\Rightarrow$ hexanol $=171 \mathrm{mg}$
(d) The greatest uncertainty is in the width of the fairly narrow butanol peak. The uncertainty in width is $\sim 5-10 \%$.
23-B. $\quad \mathrm{S}=$ [pentanol]; $\mathrm{X}=$ [hexanol]. We will substitute mmol for concentrations, because the volume is unknown and concentrations are proportional to mmol.
For the standard mixture, we can write
$\frac{\mathrm{A}_{\mathrm{X}}}{[\mathrm{X}]}=F\left(\frac{\mathrm{~A}_{\mathrm{S}}}{[\mathrm{S}]}\right) \Rightarrow \frac{1570}{[1.53]}=F\left(\frac{922}{[1.06]}\right) \Rightarrow F=1.18_{0}$
For the unknown mixture,
$\frac{816}{[X]}=1.18_{0}\left(\frac{843}{[0.57]}\right) \Rightarrow[\mathrm{X}]=0.47 \mathrm{mmol}$
23-C. (a) Between nonane $\left(\mathrm{C}_{9} \mathrm{H}_{20}\right)$ and decane $\left(\mathrm{C}_{10} \mathrm{H}_{22}\right)$.
(b) Adjusted retention times are $13.83\left(\mathrm{C}_{10}\right)$ and $15.42 \mathrm{~min}\left(\mathrm{C}_{11}\right)$
$1050=100\left[10+(11-10) \frac{\log t_{r}^{\prime}(\text { unknown })-\log 13.83}{\log 15.42-\log 13.83}\right]$
$\Rightarrow t_{\mathrm{r}}^{\prime}($ unknown $)=14.60 \mathrm{~min} \Rightarrow t_{\mathrm{r}}($ unknown $)=16.40 \mathrm{~min}$
23-D. (a) A plot of $\log t_{\mathrm{r}}^{\prime}$ versus (number of carbon atoms) should be a fairly straight line for a homologous series of compounds.

| Peak | $t_{\mathrm{r}}^{\prime}$ | $\log t_{\mathrm{r}}^{\prime}$ |
| :--- | ---: | ---: |
| $n=7$ | 2.9 | 0.46 |
| $n=8$ | 5.4 | 0.73 |
| $n=14$ | 85.8 | 1.93 |
| Unknown | 41.4 | 1.62 |

From a graph of $\log t_{\mathrm{r}}^{\prime}$ versus $n$, it appears that $n=12$ for the unknown.
(b) $k=t_{\mathrm{r}}^{\prime} / t_{\mathrm{m}}=41.4 / 1.1=38$

23-E. (a) Plate number is proportional to column length. If everything is the same except for length, we can say from Equation 22-30 that
$\frac{1.5}{1.0}=\frac{R_{2}}{R_{1}}=\frac{\sqrt{N_{2}}}{\sqrt{N_{1}}} \Rightarrow N_{2}=2.25 N_{1}$
The column must be 2.25 times longer to achieve the desired resolution, and the elution time will be 2.25 times longer.
(b) If everything is the same except for $\gamma$, we can say from Equation 22-30 that
$\frac{1.5}{1.0}=\frac{R_{2}}{R_{1}}=\frac{\gamma_{2}-1}{\gamma_{1}-1}=\frac{\gamma_{2}-1}{1.013-1} \Rightarrow \gamma_{2}=1.020$
Alcohols are polar, so we could probably increase the relative retention by choosing a more polar stationary phase. (Diphenyl) $)_{0.05}$ (dimethyl) $)_{0.95}$ polysiloxane is listed as nonpolar. We could try an intermediate polarity phase such as (diphenyl $)_{0.35}(\text { dimethyl })_{0.65}$ polysiloxane. The more polar phase will probably retain alcohols more strongly and increase the retention time. We have no way to predict how much the retention time will increase.

## Chapter 24

24-A. $\frac{\operatorname{Area}_{\mathrm{A}}}{[\mathrm{A}]}=F\left(\frac{\mathrm{Area}_{\mathrm{B}}}{[\mathrm{B}]}\right) \Rightarrow \frac{10.86}{[1.03]}=F\left(\frac{4.37}{[1.16]}\right) \Rightarrow F=2.79_{9}$
The concentration of internal standard (B) mixed with unknown (A) is $12.49 \mathrm{mg} / 25.00 \mathrm{~mL}=0.4996 \mathrm{mg} / \mathrm{mL}$.
$\frac{5.97}{[A]}=2.799\left(\frac{6.38}{[0.4996]}\right) \Rightarrow[\mathrm{A}]=0.167_{0} \mathrm{mg} / \mathrm{mL}$
[A] in original unknown $=\frac{25.00}{10.00}\left(0.167_{0} \mathrm{mg} / \mathrm{mL}\right)=0.418 \mathrm{mg} / \mathrm{mL}$
24-B. (a) Equation 22-17: $\quad k=\frac{t_{\mathrm{r}}-t_{\mathrm{m}}}{t_{\mathrm{m}}} \quad \Rightarrow \frac{t_{1}-1.00}{1.00}=1.35$
$\Rightarrow t_{1}=2.35 \mathrm{~min}$
Equation 22-15: $\quad \alpha=\frac{t_{\mathrm{r} 2}^{\prime}}{t_{\mathrm{r} 1}^{\prime}} \Rightarrow 4.53=\frac{t_{2}-1.00}{t_{1}-1.00} \Rightarrow t_{2}=7.12 \mathrm{~min}$
Equation 22-23: Resolution $=\frac{\Delta t_{\mathrm{r}}}{w_{\mathrm{av}}}$
$\Rightarrow 7.7=\frac{7.12-2.35}{w_{\mathrm{av}}} \Rightarrow w_{\mathrm{av}}=0.62 \mathrm{~min}$
(b) From Equation 22-28b, we know that $w_{1 / 2}$ is proportional to $t_{\mathrm{r}}$ if $N$ is constant. Therefore, $\frac{w_{1 / 2}(\text { peak 1) }}{w_{1 / 2}(\text { peak 2) }}=\frac{t_{1}}{t_{2}}=\frac{2.35}{7.12}=0.330$. We know that
$w_{\mathrm{av}}$, the average width at the base, is 0.62 min . For each peak, $\mathrm{w}=4 \sigma$ and $w_{1 / 2}=2.35 \sigma$, so $w=1.70 w_{1 / 2}$.
$w_{\mathrm{av}}=0.62=\frac{1}{2}\left(w_{1}+w_{2}\right)$

$$
=\frac{1}{2}\left[1.70 w_{1 / 2}(\text { peak 1) })+1.70 w_{1 / 2}(\text { peak } 2)\right]
$$

Substituting $w_{1 / 2}\left(\right.$ peak 1) $=0.330 w_{1 / 2}$ (peak 2) into the previous equation gives $w_{1 / 2}($ peak 2$)=0.54_{8} \min$. Then $w_{1 / 2}($ peak 1$)=0.330 w_{1 / 2}($ peak 2 $)=$ $0.18_{1}$ min.
(c) Because the areas are equal, we can say

Height $_{R} \times w_{R}=$ height $_{S} \times w_{S}$
$\Rightarrow \frac{\text { Height }_{\mathrm{R}}}{\text { Height }_{\mathrm{S}}}=\frac{w_{\mathrm{S}}}{w_{\mathrm{R}}}=\frac{0.54_{8}}{0.18_{1}}=3.0$
24-C.

[Adapted from L. R. Snyder, J. J. Kirkland, and J. L. Glajch, Practical HPLC Method Development (New York: Wiley, 1997).]

24-D

MelamineH ${ }^{+}$
$m / z 127$

[Cyanuric acid-H] ${ }^{-}$ $m / z 128$

When melamine $\mathrm{H}^{+}$decomposes to $\mathrm{m} / \mathrm{z} 85$, it loses a mass of 42 Da , which is probably $\mathrm{CN}_{2} \mathrm{H}_{2}$. The remaining cation is $\mathrm{C}_{2} \mathrm{~N}_{4} \mathrm{H}_{5}^{+}$, which might have the structure

[Cyanuric acid- H$]^{-}$decomposes to $m / z 42$, which is most likely cyanate, $\mathrm{N} \equiv \mathrm{C}-\mathrm{O}^{-}$.
(b) In selected reaction monitoring for melamine, the mass spectrometer isolates $\mathrm{m} / \mathrm{z} 127^{+}$from the milk, and this ion then undergoes collisionally activated dissociation to $\mathrm{m} / \mathrm{z} 85^{+}$. There are not many other molecular species in the milk that provide the same two ions. For cyanuric acid, the spectrometer isolates $m / z 128^{-}$, and this ion dissociates to $m / z 42^{-}$. Again, there are not many other species in the milk that provide the same two ions.

|  | Peaks |  |  |  |  |  |  |  |

(b) A: 30\% acetonitrile/70\% buffer

B: $40 \%$ methanol/60\% buffer
D: $14 \%$ acetonitrile/20\% methanol/65\% buffer
Between A and D: $22.5 \%$ acetonitrile/10\% methanol/67.5\% buffer Between D and B: 7.5\% acetonitrile/30\% methanol/62.5\% buffer

## Chapter 25

25-A. $\quad 13.03 \mathrm{~mL}$ of $0.02274 \mathrm{M} \mathrm{NaOH}=0.2963 \mathrm{mmol}^{2} \mathrm{OH}^{-}$, which must equal the total cation charge $\left(=2\left[\mathrm{VO}^{2+}\right]+2\left[\mathrm{H}_{2} \mathrm{SO}_{4}\right]\right)$ in the $5.00-\mathrm{mL}$ aliquot. 50.0 mL therefore contains 2.963 mmol of cation charge. The $\mathrm{VO}^{2+}$ content is $(50.0 \mathrm{~mL})(0.0243 \mathrm{M})=1.215 \mathrm{mmol}=2.43 \mathrm{mmol}$ of charge. The $\mathrm{H}_{2} \mathrm{SO}_{4}$ must therefore be $(2.963-2.43) / 2=0.266{ }_{5} \mathrm{mmol}$.
$1.215 \mathrm{mmol} \mathrm{VOSO}_{4}=0.198 \mathrm{~g} \mathrm{VOSO}_{4}$ in 0.2447 g sample $=80.9 \mathrm{wt} \%$
$0.266_{5} \mathrm{mmol} \mathrm{H}_{2} \mathrm{SO}_{4}=0.0261 \mathrm{~g} \mathrm{H}_{2} \mathrm{SO}_{4}$ in 0.2447 g sample $=10.7 \mathrm{wt} \%$ $\mathrm{H}_{2} \mathrm{O}$ (by difference) $=8.4 \mathrm{wt} \%$
25-B. (a) Fractionation range of Sephadex G-50 $=1500-30000$, so hemoglobin should not be retained and ought to be eluted in a volume of 36.4 mL .
(b) The elution volume of ${ }^{22} \mathrm{NaCl}$ is $V_{\mathrm{m}}$. Inserting $V_{\mathrm{o}}=36.4 \mathrm{~mL}$ into the elution equation gives
$K_{\mathrm{av}}=\frac{V_{\mathrm{r}}-V_{\mathrm{o}}}{V_{\mathrm{m}}-V_{\mathrm{o}}} \Rightarrow 0.65=\frac{V_{\mathrm{r}}-36.4}{109.8-36.4} \Rightarrow V_{\mathrm{r}}=84.1 \mathrm{~mL}$
25-C. (a) Injection
end
Detection
end

Net flow of cations and anions is to the right, because electroosmotic flow is stronger than electrophoretic flow at high pH
(b) $\mathrm{I}^{-}$has a greater mobility than $\mathrm{Cl}^{-}$. Therefore, $\mathrm{I}^{-}$swims upstream faster than $\mathrm{Cl}^{-}$(because electrophoresis opposes electroosmosis) and is eluted later than $\mathrm{Cl}^{-}$. The mobility of $\mathrm{Br}^{-}$is greater than that of $\mathrm{I}^{-}$in Table 14-1. Therefore, $\mathrm{Br}^{-}$will have a longer migration time than $\mathrm{I}^{-}$. (c) Bare $\mathrm{I}^{-}$is a larger ion than bare $\mathrm{Cl}^{-}$, so the charge density in $\mathrm{I}^{-}$is lower than the charge density in $\mathrm{Cl}^{-}$. Therefore, $\mathrm{I}^{-}$should have a smaller hydrated radius than $\mathrm{Cl}^{-}$. This means that $\mathrm{I}^{-}$has less friction than $\mathrm{Cl}^{-}$and a greater mobility than $\mathrm{Cl}^{-}$.

## Chapter 26

26-A. 1 mol ethoxyl groups produces 1 mol AgI. 29.03 mg $\mathrm{AgI}=0.1236_{5} \mathrm{mmol}$. The amount of compound analyzed is $25.42 \mathrm{mg} /(417 \mathrm{~g} / \mathrm{mol})=0.0609_{6} \mathrm{mmol}$. There are
$\frac{0.1236_{5} \mathrm{mmol} \text { ethoxyl groups }}{0.0609_{6} \mathrm{mmol} \text { compound }}=2.03(=2)$ ethoxyl groups $/ \mathrm{molec} u l$ e

26-B. There is $1 \mathrm{~mol} \mathrm{SO}_{4}^{2-}$ in each mole of each reactant and of the product. Let $x=\mathrm{g}$ of $\mathrm{K}_{2} \mathrm{SO}_{4}$ and $y=\mathrm{g}$ of $\left(\mathrm{NH}_{4}\right)_{2} \mathrm{SO}_{4}$.

$$
\begin{gather*}
x+y=0.649 \mathrm{~g}  \tag{1}\\
\underbrace{\frac{x}{174.27}}_{\begin{array}{c}
\text { Moles of } \\
\mathrm{K}_{2} \mathrm{SO}_{4}
\end{array}}+\underbrace{\frac{y}{132.14}}_{\begin{array}{c}
\text { Moles of } \\
\left(\mathrm{NH}_{4}\right)_{2} \mathrm{SO}_{4}
\end{array}}=\underbrace{\frac{0.977}{233.39}}_{\begin{array}{c}
\text { Moles of } \\
\text { BaSO}
\end{array}} \tag{2}
\end{gather*}
$$

Making the substitution $y=0.649-x$ in Equation 2 gives $x=0.397 \mathrm{~g}=$ $61.1 \%$ of the sample.
26-C. Formula and atomic masses: $\mathrm{Ba}(137.327), \mathrm{Cl}(35.453), \mathrm{K}(39.098)$, $\mathrm{H}_{2} \mathrm{O}(18.015), \mathrm{KCl}(74.551), \mathrm{BaCl}_{2} \cdot 2 \mathrm{H}_{2} \mathrm{O}(244.26), \mathrm{H}_{2} \mathrm{O}$ lost $=1.7839-$ $1.5623=0.2216 \mathrm{~g}=1.2301 \times 10^{-2} \mathrm{~mol}$ of $\mathrm{H}_{2} \mathrm{O}$. For $2 \mathrm{~mol} \mathrm{H} \mathrm{H}_{2} \mathrm{O}$ lost, 1 mol $\mathrm{BaCl}_{2} \cdot 2 \mathrm{H}_{2} \mathrm{O}$ must have been present. $\frac{1}{2}\left(1.2301 \times 10^{-2} \mathrm{~mol} \mathrm{H}_{2} \mathrm{O}\right.$ lost $)=$ $6.1504 \times 10^{-3} \mathrm{~mol} \mathrm{BaCl}_{2} \cdot 2 \mathrm{H}_{2} \mathrm{O}=1.5024 \mathrm{~g}$. The Ba and Cl contents of the $\mathrm{BaCl}_{2} \cdot 2 \mathrm{H}_{2} \mathrm{O}$ are
$\mathrm{Ba}=\left(\frac{137.33}{244.26}\right)(1.5024 \mathrm{~g})=0.84469 \mathrm{~g}$
$\mathrm{Cl}=\left(\frac{2(35.453)}{244.26}\right)(1.5024 \mathrm{~g})=0.43613 \mathrm{~g}$
Because the total sample weighs 1.7839 g and contains 1.5024 g of $\mathrm{BaCl}_{2} \cdot 2 \mathrm{H}_{2} \mathrm{O}$, the sample must contain $1.7839-1.5024=0.2815 \mathrm{~g}$ of KCl , which contains
$K=\left(\frac{39.098}{74.551}\right)\left(0.281_{5}\right)=0.14763 \mathrm{~g}$
$\mathrm{Cl}=\left(\frac{35.453}{74.551}\right)\left(0.281_{5}\right)=0.13387 \mathrm{~g}$
Weight percent of each element:
$\mathrm{Ba}=\frac{0.84469}{1.7839}=47.35 \%$
$K=\frac{0.14763}{1.7839}=8.28 \%$
$\mathrm{Cl}=\frac{0.43613+0.13387}{1.7839}=31.95 \%$
26-D. Let $x=$ mass of $\mathrm{Al}\left(\mathrm{BF}_{4}\right)_{3}$ and $y=$ mass of $\mathrm{Mg}\left(\mathrm{NO}_{3}\right)_{2}$. We can say that $x+y=0.2828 \mathrm{~g}$. We also know that

Moles of nitron tetrafluoroborate $=3\left(\right.$ moles of $\left.\mathrm{Al}\left(\mathrm{BF}_{4}\right)_{3}\right)=\frac{3 x}{287.39}$
Moles of nitron nitrate $=2\left(\right.$ moles of $\left.\operatorname{Mg}\left(\mathrm{NO}_{3}\right)_{2}\right)=\frac{2 y}{148.31}$
Equating the mass of product to the mass of nitron tetrafluoroborate plus the mass of nitron nitrate, we can write

$$
\underset{\begin{array}{c}
\text { Mass of } \\
\text { product }
\end{array}}{1.322}=\underset{\begin{array}{c}
\text { Mass of nitron } \\
\text { tetrafluoroborate }
\end{array}}{\left(\frac{3 x}{287.39}\right)(400.18)}+\left(\frac{2 y}{(148.31}\right)(375.39)
$$

Making the substitution $x=0.2828-y$ allows us to find $y=0.1589 \mathrm{~g}$ of $\mathrm{Mg}\left(\mathrm{NO}_{3}\right)_{2}=1.072 \mathrm{mmol}$ of $\mathrm{Mg}=0.02605 \mathrm{~g}$ of $\mathrm{Mg}=9.210 \%$ of the original solid sample.
26-E. Reaction: $\mathrm{SCN}^{-}+\mathrm{Cu}^{+} \rightarrow \mathrm{CuSCN}(s)$
At $V_{\mathrm{e}}, \mathrm{mol} \mathrm{Cu}^{+}=\mathrm{mol} \mathrm{SCN}{ }^{-} \Rightarrow V_{\mathrm{e}}=100.0 \mathrm{~mL}$.
Before $V_{\mathrm{e}}$, there is excess $\mathrm{SCN}^{-}$in the solution. We calculate the molarity of $\mathrm{SCN}^{-}$and then find $\left[\mathrm{Cu}^{+}\right]$from the relation $\left[\mathrm{Cu}^{+}\right]=K_{\mathrm{sp}} /\left[\mathrm{SCN}^{-}\right]$. For example, when 0.10 mL of $\mathrm{Cu}^{+}$has been added.
$\left[\mathrm{SCN}^{-}\right]=\left(\frac{100.0-0.10}{100.0}\right)(0.0800 \mathrm{M})\left(\frac{50.0}{50.1}\right)=7.98 \times 10^{-2} \mathrm{M}$
$\left[\mathrm{Cu}^{+}\right]=4.8 \times 10^{-15} / 7.98 \times 10^{-2}=6.0 \times 10^{-14} \mathrm{M}$
$\mathrm{pCu}^{+}=13.22$
At $V_{\mathrm{e}},\left[\mathrm{Cu}^{+}\right]\left[\mathrm{SCN}^{-}\right]=x^{2}=K_{\text {sp }}$
$\Rightarrow x=\left[\mathrm{Cu}^{+}\right]=6.9 \times 10^{-8} \mathrm{M} \Rightarrow \mathrm{pCu}^{+}=7.16$

Past $V_{\mathrm{e}}$, there is excess $\left[\mathrm{Cu}^{+}\right]$. For example, when $V=101.0 \mathrm{~mL}$,
$\left[\mathrm{Cu}^{+}\right]=(0.0400 \mathrm{M})\left(\frac{101.0-100.0}{151.0}\right)=2.6 \times 10^{-4} \mathrm{M}$
$\mathrm{pCu}^{+}=3.58$

| mL | pCu | mL | pCu | mL | pCu |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 0.10 | 13.22 | 75.0 | 12.22 | 100.0 | 7.16 |
| 10.0 | 13.10 | 95.0 | 11.46 | 100.1 | 4.57 |
| 25.0 | 12.92 | 99.0 | 10.75 | 101.0 | 3.58 |
| 50.0 | 12.62 | 99.9 | 9.75 | 110.0 | 2.60 |

26-F. (a) 12.6 mL of $\mathrm{Ag}^{+}$are required to precipitate $\mathrm{I}^{-}$.
$(27.7-12.6)=15.1 \mathrm{~mL}$ are required to precipitate $\mathrm{SCN}^{-}$.
$\left[\mathrm{SCN}^{-}\right]=\frac{\text { moles of } \mathrm{Ag}^{+} \text {needed to react with } \mathrm{SCN}^{-}}{\text {original volume of } \mathrm{SCN}^{-}}$

$$
\begin{aligned}
& =\frac{[27.7( \pm 0.3)-12.6( \pm 0.4)][0.0683( \pm 0.0001)]}{50.00( \pm 0.05)} \\
& =\frac{[15.1( \pm 0.5)][0.0683( \pm 0.0001)]}{50.00( \pm 0.05)} \\
& =\frac{[15.1( \pm 3.31 \%)][0.0683( \pm 0.146 \%)]}{50.00( \pm 0.100 \%)} \\
& =0.0206( \pm 0.0007) \mathrm{M}
\end{aligned}
$$

(b) $\left[\mathrm{SCN}^{-}\right]( \pm 4.0 \%)=\frac{[27.7( \pm 0.3)-12.6( \pm ?)][0.0683( \pm 0.0001)]}{50.00( \pm 0.05)}$
Let the error in 15.1 mL be $y \%$ :
$(4.0 \%)^{2}=(y \%)^{2}+(0.146 \%)^{2}+(0.100 \%)^{2}$
$\Rightarrow y=4.00 \%=0.603 \mathrm{~mL}$
$27.7( \pm 0.3)-12.6( \pm ?)=15.1( \pm 0.603)$
$\Rightarrow 0.3^{2}+?^{2}=0.603^{2} \Rightarrow ?=0.5 \mathrm{~mL}$

## Chapter 27

27-A. (a) Expected number of red marbles $=n p_{\text {red }}=(1000)(0.12)=120$. Expected number of yellow $=n q_{\text {yellow }}=(1000)(0.88)=880$.
(b) Absolute: $\sigma_{\text {red }}=\sigma_{\text {yellow }}=\sqrt{n p q}$
$=\sqrt{(1000)(0.12)(0.88)}=10.28$
Relative: $\sigma_{\text {red }} / n_{\text {red }}=10.28 / 120=8.56 \%$
$\sigma_{\text {yellow }} / n_{\text {yellow }}=10.28 / 880=1.17 \%$
(c) For 4000 marbles, $n_{\text {red }}=480$ and $n_{\text {yellow }}=3520$.
$\sigma_{\text {red }}=\sigma_{\text {yellow }}=\sqrt{n p q}=\sqrt{(4000)(0.12)(0.88)}=20.55$
$\sigma_{\text {red }} / n_{\text {red }}=4.28 \% \quad \sigma_{\text {yellow }} / n_{\text {yellow }}=0.58 \%$
(d) $2, \sqrt{n}$
(e) $\frac{\sigma_{\text {red }}}{n_{\text {red }}}=0.02=\frac{\sqrt{n(0.12)(0.88)}}{(0.12) n}$
$\Rightarrow n=1.83 \times 10^{4}$
27-B. (a) $m R^{2}=K_{\mathrm{s}} \Rightarrow m(10)^{2}=36 \Rightarrow m=0.36 \mathrm{~g}$
(b) An uncertainty of $\pm 20$ counts per second per gram is $100 \times 20 / 237=$ $8.4 \%$.
$n=\frac{t^{2} s_{\mathrm{s}}^{2}}{e^{2}}=\frac{(1.96)^{2}(0.10)^{2}}{(0.084)^{2}}=5.4 \approx 5$
$\Rightarrow t=2.776$ (4 degrees of freedom)
$n \approx \frac{(2.776)^{2}(0.10)^{2}}{(0.084)^{2}}=10.9 \approx 11 \Rightarrow t=2.228$
$n \approx \frac{(2.228)^{2}(0.10)^{2}}{(0.084)^{2}}=7.0 \approx 7 \Rightarrow t=2.447$
$n \approx \frac{(2.447)^{2}(0.10)^{2}}{(0.084)^{2}}=8.5 \approx 8 \Rightarrow t=2.365$
$n \approx \frac{(2.365)^{2}(0.10)^{2}}{(0.084)^{2}}=7.9 \approx 8$
27-C. The acid-soluble inorganic matter and the organic material can probably be dissolved (and oxidized) together by wet ashing with $\mathrm{HNO}_{3}+\mathrm{H}_{2} \mathrm{SO}_{4}$ in a Teflon-lined bomb in a microwave oven. The insoluble residue should be washed well with water and the washings combined with the acid solution. After the residue has been dried, it can be fused with one of the fluxes in Table 27-6, dissolved in dilute acid, and combined with the previous solution.

## Chapter 1

3. (a) milliwatt $=10^{-3}$ watt $\quad$ (b) picometer $=10^{-12}$ meter
(c) kiloohm $=10^{3} \mathrm{ohm} \quad$ (d) microfarad $=10^{-6}$ farad
(e) terajoule $=10^{12}$ joule (f) nanosecond $=10^{-9}$ second
(g) femtogram $=10^{-15}$ gram $\quad$ (h) decipascal $=10^{-1}$ pascal
4. (a) 100 fJ or 0.1 pJ
(b) 43.1728 nF
(c) 299.79 THz or
0.29979 PHz
(d) 0.1 nm
5. (a) $5.4 \times 10^{12} \mathrm{~kg}$ of $\mathrm{C} \quad$ (b) $2.0 \times 10^{13} \mathrm{~kg} \mathrm{CO}_{2}$
(c) $2.0 \times 10^{10}$ ton $\mathrm{CO}_{2}=4$ tons per person
6. $7.457 \times 10^{4} \mathrm{~J} / \mathrm{s}, 6.416 \times 10^{7} \mathrm{cal} / \mathrm{h}$
7. (a) $2.0 \mathrm{~W} / \mathrm{kg}$ and $3.0 \mathrm{~W} / \mathrm{kg} \quad$ (b) The person consumes $1.1 \times 10^{2} \mathrm{~W}$.
8. $1.47 \times 10^{3} \mathrm{~J} / \mathrm{s}, 1.47 \times 10^{3} \mathrm{~W}$
9. (a) $0.62137 \mathrm{miles} / \mathrm{km}$
(b) 51 miles per gallon
(c) diesel produces
5.38 metric tons and gasoline produces 6.42 metric tons of $\mathrm{CO}_{2}$
10. 6 tons/year
11. 1.10 M
12. 5.48 g
13. (a) $1.9 \times 10^{-7}$ bar
(b) 11 nM
14. $10^{-3} \mathrm{~g} / \mathrm{L}, 10^{3} \mu \mathrm{~g} / \mathrm{L}, 1 \mu \mathrm{~g} / \mathrm{mL}, 1 \mathrm{mg} / \mathrm{L}$
15. $7 \times 10^{-10} \mathrm{M}$
16. $26.5 \mathrm{~g} \mathrm{HClO}_{4}, 11.1 \mathrm{~g} \mathrm{H}_{2} \mathrm{O}$
17. (a) 1670 g solution
(b) $1.18 \times 10^{3} \mathrm{~g} \mathrm{HClO}_{4}$
(c) 11.7 mol
18. 1.51 m
19. (a) $6.0 \mathrm{amol} / \mathrm{vesicle}$
(b) $3.6 \times 10^{6}$ molecules
(c) $3.35 \times 10^{-20} \mathrm{~m}^{3}, 3.35 \times 10^{-17} \mathrm{~L}$
(d) 0.30 M
20. $4.4 \times 10^{-3} \mathrm{M}, 6.7 \times 10^{-3} \mathrm{M}$
21. (a) $1046 \mathrm{~g}, 376.6 \mathrm{~g} / \mathrm{L}$
(b) 9.07 m
22. $\mathrm{Cal} / \mathrm{g}, \mathrm{Cal} /$ ounce: Shredded Wheat $(3.6,102)$; doughnut $(3.9,111)$; hamburger $(2.8,79)$; apple $(0.48,14)$
23. $2.5 \times 10^{6} \mathrm{~g} \mathrm{~F}^{-}, 3.2 \times 10^{6} \mathrm{~g} \mathrm{H}_{2} \mathrm{SiF}_{6}$
24. $\begin{array}{ll}\text { (a) } 2.11 \times 10^{-7} \mathrm{M} & \text { (b) Ar: } 3.77 \times 10^{-4} \mathrm{M} \text {; Kr: } 4.60 \times 10^{-8} \mathrm{M} \text {; }\end{array}$

Xe: $3.5 \times 10^{-9} \mathrm{M}$
28. 6.18 g in a $2-\mathrm{L}$ volumetric flask
29. Dissolve $6.18 \mathrm{~g} \mathrm{~B}(\mathrm{OH})_{3}$ in $2.00 \mathrm{~kg} \mathrm{H}_{2} \mathrm{O}$.
30. 3.2 L
31. 8.0 g
32. $\begin{array}{ll}\text { (a) } 55.6 \mathrm{~mL} & \text { (b) } 1.80 \mathrm{~g} / \mathrm{mL}\end{array}$
33. $1.52 \mathrm{~g} / \mathrm{mL}$
34. 1.29 mL
35. 14.4 g
42. 32.0 mL
43. $43.20 \mathrm{~mL} \mathrm{KMnO} 4,270.0 \mathrm{~mL} \mathrm{H}_{2} \mathrm{C}_{2} \mathrm{O}_{4}$
44. 0.149 M
45. 0.1003 M
46. $92.0 \mathrm{wt} \%$

## Chapter 2

3. Reducing $\mathrm{Cr}(\mathrm{VI})$ to $\mathrm{Cr}(\mathrm{III})$ decreases toxicity. Converting $\mathrm{Cr}(\mathrm{III})(a q)$ to $\mathrm{Cr}(\mathrm{OH})_{3}(s)$ decreases solubility. Evaporation minimizes waste volume.
4. The upper " 0 " means that the reagent has no fire hazard. The right-hand " 0 " indicates that the reagent is stable. The " 3 " tells us that the reagent is corrosive or toxic and we should avoid skin contact or inhalation.
5. The lab notebook must (1) state what was done; (2) state what was observed; and (3) be understandable to a stranger.
6. The buoyancy correction is 1 when the substance being weighed has the same density as the weight used to calibrate the balance.
7. 14.85 g
8. smallest: $\mathrm{PbO}_{2}$; largest: Li
9. 4.2391 g , lower by $0.06 \%$
10. (a) $0.000164 \mathrm{~g} / \mathrm{mL} \quad$ (b) 0.823 g
11. (a) 979 Pa
(b) $0.0011 \mathrm{~g} / \mathrm{mL}$
(c) 1.0010 g
12. 99.9991 g
13. TD means "to deliver" and TC means "to contain."
14. Dissolve $(0.2500 \mathrm{~L})(0.1500 \mathrm{~mol} / \mathrm{L})=0.03750 \mathrm{~mol} \mathrm{~K}_{2} \mathrm{SO}_{4}(=6.535 \mathrm{~g}$,

FM $174.26 \mathrm{~g} / \mathrm{mol}$ ) in $<250 \mathrm{~mL} \mathrm{H}_{2} \mathrm{O}$ in a $250-\mathrm{mL}$ volumetric flask. Add $\mathrm{H}_{2} \mathrm{O}$ and mix. Dilute to mark and mix well by inverting flask many times.
16. Plastic flask is for trace analysis of ppb analytes that might be adsorbed on glass.
17. (a) See Section 2.6
(b) transfer pipet
18. (a) Use forward mode described in text.
(b) Use reverse mode described in text.
19. Trap prevents liquid from being sucked into vacuum system. Watchglass keeps dust out of the sample.
20. phosphorus pentoxide
21. 9.9799 mL
22. $0.2 \%, 0.4990 \mathrm{M}$
23. 49.947 g in vacuum, 49.892 g in air
24. true mass $=50.506 \mathrm{~g}$, mass in air $=50.484 \mathrm{~g}$
25. (b) 54 days
26. $0.70 \%$

16. recovery $=96 \%$; concentration detection limit $=0.064 \mu \mathrm{~g} / \mathrm{L}$
17. detection limit $=130$ counts; minimum detectable concentration $=$ $4.8 \times 10^{-8} \mathrm{M}$
18. detection limits: $0.086,0.102,0.096$, and $0.114 \mu \mathrm{~g} / \mathrm{mL}$; mean $=0.10 \mu \mathrm{~g} / \mathrm{mL}$
19. Testing 2 independent samples drawn at the same time from each athlete would reduce the rate of false positives to $0.01 \times 0.01=0.0001$.
20. Lab C vs. Lab A: $F_{\text {calculated }}=31 ._{0}>F_{\text {table }}=3.88(2$ degrees of freedom for $s_{\mathrm{C}}$ and 12 degrees of freedom for $\left.s_{\mathrm{A}}\right) \cdot t_{\text {calculated }}=2.4_{1}<t_{\text {table }}=$ 4.303 for $95 \%$ confidence and 2 degrees of freedom $\Rightarrow$ difference is not significant
Lab C vs. Lab B: $F_{\text {calculated }}=1.9_{4}<F_{\text {table }}=4.74$ (2 degrees of freedom for $s_{\mathrm{C}}$ and 7 degrees of freedom for $\left.s_{\mathrm{A}}\right) \cdot s_{\text {pooled }}=0.61_{6} \cdot t_{\text {calculated }}=2.4_{7}>$ $t_{\text {table }}=2.262$ for $95 \%$ confidence and 9 degrees of freedom $\Rightarrow$ difference is significant
The conclusion that C is greater than B but C is not greater than A makes no sense. The problem is $s_{\mathrm{C}} \gg s_{\mathrm{A}}$ and number of replicates for $\mathrm{C} \ll$ number of replicates for A. I suggest that $\mathrm{C}>\mathrm{A}$ and $\mathrm{C}>\mathrm{B}$. I would ask for more replicates from C.
21. Addition of small volume keeps matrix nearly constant by not diluting the sample.

43. (a) acetic acid (b) pyridine
44. (b) $K=0.279, \mathrm{pH}=4.16$
45. 0.139 M
46. 0.815

## Chapter 11

(a) $2.7 \times 10^{-10}$
(b) 0.57
(a) $2.5 \times 10^{7}$
(b) $4.5 \times 10^{-5} \mathrm{M}$
4. 5.60 g
5. Neutral $\mathrm{H}_{5}$ DTPA is DTPA $\left(\mathrm{CO}_{2} \mathrm{H}\right)_{2}\left(\mathrm{CO}_{2}^{-}\right)_{3}\left(\mathrm{NH}^{+}\right)_{3}$. The predominant species at pH 14 is DTPA $^{5-}$. By analogy with EDTA, all carboxyl groups are probably ionized at $\mathrm{pH} 3-4$, so the predominant species is $\mathrm{H}_{3}$ DTPA $^{2-}$, which is DTPA $\left(\mathrm{CO}_{2}^{-}\right)_{5}\left(\mathrm{NH}^{+}\right)_{3}$. At pH 14 and at pH 3 , sulfate is in the form $\mathrm{SO}_{4}^{2-} \cdot 10^{-3} \mathrm{M} \mathrm{H}^{+}$displaces $\mathrm{Ba}^{2+}$ from DTPA, but $10^{-14} \mathrm{M} \mathrm{H}^{+}$does not.
6. (a) 100.0 mL
(b) 0.0167 M
(c) 0.041
(d) $4.1 \times 10^{10}$
(e) $7.8 \times 10^{-7} \mathrm{M}$
(f) $2.4 \times 10^{-10} \mathrm{M}$
7. (a) 2.93
(b) 6.79
(c) 10.52
$\begin{array}{lllll}\text { 8. } & \text { (a) } 1.70 & \text { (b) } 2.18 & \text { (c) } 2.81 \\ \text { g) } 8.82 & \text { (h) } 10.51 & \text { (i) } 10.82\end{array}$
(d) 3.87
(e) 4.87
(f) 6.85
$\begin{array}{lll}\text { (g) } 8.82 & \text { (h) } 10.51 & \text { (i) } 10.82\end{array}$
9. $\infty, 10.30,9.52,8.44,7.43,6.15,4.88,3.20,2.93$
10. $4.6 \times 10^{-11} \mathrm{M}$
15. (a) $25 \quad$ (b) 0.017
16. $\begin{array}{lllll}\text { (a) } 15.03 & \text { (b) } 15.05 & \text { (c) } 16.30 & \text { (d) } 17.02 & \text { (e) } 17.69\end{array}$
17. (b) $\alpha_{\mathrm{ML}}=0.28, \alpha_{\mathrm{ML}_{2}}=0.70$
18. (d) $[\mathrm{T}]=0.27_{7} ;\left[\mathrm{Fe}_{\mathrm{a}} \mathrm{T}\right]=0.55_{3} ;\left[\mathrm{Fe}_{\mathrm{b}} \mathrm{T}\right]=0.09_{2} ;\left[\mathrm{Fe}_{2} \mathrm{~T}\right]=0.07_{7}$
20. (b) $1.34 \mathrm{~mL}, \mathrm{pNi}=7.00 ; 21.70 \mathrm{~mL}, \mathrm{pNi}=8.00 ; 26.23 \mathrm{~mL}$, $\mathrm{pNi}=17.00$
24. 1. with metal ion indicators; 2. with a mercury electrode; 3. with an ion-selective electrode; 4 . with a glass electrode
25. $\mathrm{HIn}^{2-}$, wine-red, blue
26. Buffer (a): yellow $\rightarrow$ blue; other buffers: violet $\rightarrow$ blue, which is harder to see
27. analyte precipitates without EDTA, reacts slowly with EDTA, or blocks the indicator
28. analyte displaces a metal ion from a complex
30. hardness $\approx\left[\mathrm{Ca}^{2+}\right]+\left[\mathrm{Mg}^{2+}\right]$. Temporary hardness, due to $\mathrm{Ca}\left(\mathrm{HCO}_{3}\right)_{2}$, is lost by heating. Permanent hardness is derived from other salts such as $\mathrm{CaSO}_{4}$ and is not affected by heat.
31. $10.0 \mathrm{~mL}, 10.0 \mathrm{~mL}$
32. 0.0200 M
33. 0.995 mg
34. 0.09254 M
35. 21.45 mL
36. $\left[\mathrm{Ni}^{2+}\right]=0.0124 \mathrm{M},\left[\mathrm{Zn}^{2+}\right]=0.00718 \mathrm{M}$
37. 0.02430 M
38. 0.09228 M
39. observed: $32.7 \mathrm{wt} \%$; theoretical: $32.90 \mathrm{wt} \%$

## Chapter 12

1. $\mathrm{PbS}(s)+\mathrm{H}^{+} \rightleftharpoons \mathrm{Pb}^{2+}+\mathrm{HS}^{-}$
$\mathrm{PbCO}_{3}(s)+\mathrm{H}^{+} \rightleftharpoons \mathrm{Pb}^{2+}+\mathrm{HCO}_{3}^{-}$
2. (a) $\mathrm{pH}=9.98$
(b) $\mathrm{pH}=10.00$
(c) $\mathrm{pH}=9.45$
3. $\mathrm{pH}=9.95$
4. predicted values: $\mathrm{p} K_{1}^{\prime}=2.350, \mathrm{p} K_{2}^{\prime}=9.562$
5. $\mathrm{pH}=10.194$ from spreadsheet and 10.197 by hand method
6. $\mathrm{pH}=4.52$
7. $\mathrm{pH}=5.00$
8. ionic strength $=0.025 \mathrm{M}, \mathrm{pH}=4.94$
. (a) $\mathrm{pH}=7.420$
(b) $\mathrm{pH}=7.403$
9. $\mathrm{pH}=4.44$
10. (d) $\left[\mathrm{Fe}^{3+}\right]=\frac{\mathrm{F}_{\mathrm{SCN}}-\left[\mathrm{SCN}^{-}\right]}{\beta_{1}^{\prime}\left[\mathrm{SCN}^{-}\right]+2 \beta_{2}^{\prime}\left[\mathrm{SCN}^{-}\right]^{2}}$
(e) $\left[\mathrm{H}^{+}\right]=\frac{K_{\mathrm{a}}^{\prime}\left[\mathrm{Fe}^{3+}\right]}{\mathrm{F}_{\mathrm{Fe}}-\left[\mathrm{Fe}^{3+}\right]-\beta_{1}^{\prime}\left[\mathrm{Fe}^{3+}\right]\left[\mathrm{SCN}^{-}\right]-\beta_{2}^{\prime}\left[\mathrm{Fe}^{3+}\right]\left[\mathrm{SCN}^{-}\right]^{2}}$
$(\mathbf{f}, \mathbf{g}, \mathbf{h}, \mathbf{i})\left[\mathrm{SCN}^{-}\right]=2.03 \mu \mathrm{M},\left[\mathrm{Fe}^{3+}\right]=4.20 \mathrm{mM},\left[\mathrm{H}^{+}\right]=15.8 \mathrm{mM}$,

$\left[\mathrm{La}\left(\mathrm{SO}_{4}\right)^{+}\right]=1.36 \mathrm{mM},\left[\mathrm{La}\left(\mathrm{SO}_{4}\right)_{2}^{-}\right]=67 \mu \mathrm{M},\left[\mathrm{LaOH}^{2+}\right]=1.13 \mu \mathrm{M}$,
ionic strength $=0.00629 \mathrm{M}, \mathrm{pH}=5.98 \quad$ (b) ionic strength of strong electrolyte $=15.0 \mathrm{mM}$; actual ionic strength $=6.3 \mathrm{mM} \quad$ (c) $28.5 \%$
(d) $\mathrm{p} K_{\mathrm{a}}$ for $\mathrm{HSO}_{4}^{-}$is 1.99 and we expect the solution to be near neutral pH .
(e) no; $\left[\mathrm{La}^{3+}\right]\left[\mathrm{OH}^{-}\right]^{3} \gamma_{\mathrm{La}^{3+}} \gamma_{\mathrm{OH}^{-}}^{3}=2.3 \times 10^{-28}<K_{\text {sp }}$ for $\mathrm{La}(\mathrm{OH})_{3}=$ $2 \times 10^{-21}$
12. $\mathrm{pH}=7.06$, ionic strength $=0.041 \mathrm{M} ;\left[\mathrm{Ca}^{2+}\right]=0.0102 \mathrm{M}$,
$\left[\mathrm{CaOH}^{+}\right]=1.4 \times 10^{-8} \mathrm{M},\left[\mathrm{SO}_{4}^{2-}\right]=0.0102 \mathrm{M},\left[\mathrm{HSO}_{4}^{-}\right]=$
$5.0 \times 10^{-8} \mathrm{M}$
13. $\left[\mathrm{CN}^{-}\right]=1.51 \mu \mathrm{M},\left[\mathrm{H}^{+}\right]=1.29 \times 10^{-12} \mathrm{M},\left[\mathrm{OH}^{-}\right]=0.0129 \mathrm{M}$,
$\left[\mathrm{Ag}^{+}\right]=0.241 \mathrm{nM},[\mathrm{AgOH}]=0.187 \mathrm{nM},\left[\mathrm{Ag}(\mathrm{OH})(\mathrm{CN})^{-}\right]=46.9 \mu \mathrm{M}$,
$\left[\mathrm{Ag}(\mathrm{CN})_{2}^{-}\right]=0.100 \mathrm{M},\left[\mathrm{Ag}(\mathrm{CN})_{3}^{2-}\right]=4.19 \mu \mathrm{M},[\mathrm{HCN}]=1.90 \mathrm{nM}$,
$\left[\mathrm{Na}^{+}\right]=0.0130 \mathrm{M},\left[\mathrm{K}^{+}\right]=0.100 \mathrm{M}$, ionic strength $=0.113 \mathrm{M}$
14. fraction of Fe in each form: $\left[\mathrm{Fe}^{2+}\right], 2.7 \%$; $\left[\mathrm{FeG}^{+}\right], 34.0 \%$; $\left[\mathrm{FeG}_{2}\right]$, $62.0 \%$; $\left[\mathrm{FeG}_{3}^{-}\right], 1.1 \%$; $\left[\mathrm{FeOH}^{+}\right], 0.2 \%$
fraction of glycine in each form: $\left[\mathrm{G}^{-}\right], 1.1 \% ;[\mathrm{HG}], 18.2 \% ;\left[\mathrm{H}_{2} \mathrm{G}^{+}\right]$, $0.000015 \% ;\left[\mathrm{FeG}^{+}\right], 17.0 \% ; 2\left[\mathrm{FeG}_{2}\right], 62.0 \% ; 3\left[\mathrm{FeG}_{3}^{-}\right], 1.7 \%$ HCl added $=18.1 \mathrm{mmol}$; ionic strength $=21.1 \mathrm{mM}$
chemistry: $\mathrm{FeG}_{2} \rightleftharpoons \mathrm{FeG}^{+}+\mathrm{G}^{-}$followed by $\mathrm{G}^{-}+\mathrm{H}^{+} \rightleftharpoons \mathrm{HG}$.
$\mathrm{G}^{-}$released when $\mathrm{FeG}_{2}$ dissolves requires HCl to lower the pH to 8.50.
15. (b) Fixing $\mathrm{p} K_{\mathrm{w}}^{\prime}$ at 13.797 causes $\bar{n}_{\mathrm{H}}$ (measured) to deviate systematically above $\bar{n}_{\mathrm{H}}$ (theoretical) at the end of the titration when $\bar{n}_{\mathrm{H}}$ should approach 0 .
16. (a) $\bar{n}_{\mathrm{H}}$ (experimental) $=3+\frac{\left[\mathrm{OH}^{-}\right]+\left[\mathrm{Cl}^{-}\right]_{\mathrm{HCl}}-\left[\mathrm{H}^{+}\right]-\left[\mathrm{Na}^{+}\right]}{\mathrm{F}_{\mathrm{H}_{3} \mathrm{~A}}}$ $\bar{n}_{\mathrm{H}}($ theoretical $)=3 \alpha_{\mathrm{H}_{3} \mathrm{~A}}+2 \alpha_{\mathrm{H}_{2} \mathrm{~A}}+\alpha_{\mathrm{HA}}$
(b) $\mathrm{p} K_{\mathrm{w}}^{\prime}=13.819, \mathrm{p} K_{1}=8.33, \mathrm{p} K_{2}=9.48, \mathrm{p} K_{3}=10.19$
17. (b) $\mathrm{pH}=4.61$. In the absence of precipitation, at pH 4.61 , the concentrations are $\left[\mathrm{Cu}^{2+}\right]=18.6 \mathrm{mM},\left[\mathrm{SO}_{4}^{2-}\right]=18.7 \mathrm{mM}$, $\left[\mathrm{CuSO}_{4}(a q)\right]=6.3 \mathrm{mM},\left[\mathrm{HSO}_{4}^{-}\right]=20 \mu \mathrm{M},\left[\mathrm{CuOH}^{+}\right]=12 \mu \mathrm{M}$, $\left[\mathrm{Cu}_{2}(\mathrm{OH})^{3+}\right]=28 \mu \mathrm{M}$, and $\left[\mathrm{Cu}_{2}(\mathrm{OH})_{2}^{2+}\right]=5.8 \mu \mathrm{M}$; the other species have lower concentrations. (c) The solubility of $\mathrm{Cu}(\mathrm{OH})_{1.5}\left(\mathrm{SO}_{4}\right)_{0.25}(s)$ is exceeded above $\mathrm{pH} \approx 4.5$. $\mathrm{CuO}(s)$ solubility is exceeded above $\mathrm{pH} \approx 5 . \mathrm{Cu}(\mathrm{OH})_{2}(s)$ solubility is exceeded above $\mathrm{pH} \approx 5.5$. At pH 4.61 , $\mathrm{Cu}(\mathrm{OH})_{1.5}\left(\mathrm{SO}_{4}\right)_{0.25}(s)$ will precipitate from $0.025 \mathrm{M} \mathrm{CuSO}_{4}$.
18. 

(b) $\left[\mathrm{T}^{2-}\right]=\frac{\mathrm{F}_{\mathrm{H}_{2} \mathrm{~T}}}{\frac{\left[\mathrm{H}^{+}\right]^{2}}{K_{1} K_{2}}+\frac{\left[\mathrm{H}^{+}\right]}{K_{2}}+1+K_{\mathrm{NaT}^{-}}\left[\mathrm{Na}^{+}\right]+K_{\mathrm{NaHT}}\left[\mathrm{Na}^{+}\right] \frac{\left[\mathrm{H}^{+}\right]}{K_{2}}}$
(c) $\left[\mathrm{HT}^{-}\right]=\frac{\mathrm{F}_{\mathrm{H}_{2} \mathrm{~T}}}{\frac{\left[\mathrm{H}^{+}\right]}{K_{1}}+1+\frac{K_{2}}{\left[\mathrm{H}^{+}\right]}+K_{\mathrm{NaT}^{-}}\left[\mathrm{Na}^{+}\right] \frac{K_{2}}{\left[\mathrm{H}^{+}\right]}+K_{\mathrm{NaHT}}\left[\mathrm{Na}^{+}\right]}$
$\left[\mathrm{H}_{2} \mathrm{~T}\right]=\frac{\mathrm{F}_{\mathrm{H}_{2} \mathrm{~T}}}{1+\frac{K_{1}}{\left[\mathrm{H}^{+}\right]}+\frac{K_{1} K_{2}}{\left[\mathrm{H}^{+}\right]^{2}}+K_{\mathrm{NaT}^{-}}\left[\mathrm{Na}^{+}\right] \frac{K_{1} K_{2}}{\left[\mathrm{H}^{+}\right]^{2}}+K_{\mathrm{NaHT}}\left[\mathrm{Na}^{+}\right] \frac{K_{1}}{\left[\mathrm{H}^{+}\right]}}$
(d) $\mathrm{pH}=4.264,\left[\mathrm{PyH}^{+}\right]=0.0134,\left[\mathrm{Na}^{+}\right]=0.0185,\left[\mathrm{~K}^{+}\right]=0.0100$,

## Chapter 23

8. (a) hexane $<$ butanol $<$ benzene $<$ 2-pentanone $<$ heptane $<$ octane
(b) hexane $<$ heptane $<$ butanol $<$ benzene $<2$-pentanone $<$ octane
(c) hexane $<$ heptane $<$ octane $<$ benzene $<2$-pentanone $<$ butanol
9. (a) $3,1,2,4,5,6$
(b) 3, 4, 1, 2, 5,6
(c) $3,4,5,6,2,1$
10. (a) $4.7 \mathrm{~min}, 1.3$
(b) 1.8
11. 836
12. $a=1.69 \times 10^{3} \mathrm{~K}, b=-3.36$, 27.1 min
13. (b) Injections: 0.16 ng (narrow bore), 56 ng (wide bore)
14. Use narrower or longer column or different stationary phase.
15. (b) air: $9.3 \mathrm{~cm} / \mathrm{s}, 0.036 \mathrm{~cm} ; \mathrm{H}_{2}: 17.6 \mathrm{~cm} / \mathrm{s}, 0.051$
$\begin{array}{lll}\text { (c) air: } 8300 ; \mathrm{H}_{2}: 5900 & \text { (d) air: } 32 \mathrm{~s} ; \mathrm{H}_{2}: 17 \mathrm{~s} & \text { (e) } C_{\mathrm{s}} \text { becomes }\end{array}$ negligible
16. (a) $1.25_{3}$
(c) 77.6 mM
17. $0.41 \mu \mathrm{M}$
18. 932
19. (d) nonsmoker: $78 \pm 5 \mu \mathrm{~g} / \mathrm{L}$; nonsmoker whose parents smoke: $192 \pm 6 \mu \mathrm{~g} / \mathrm{L}$
20. $\left[{ }^{14} \mathrm{NO}_{2}^{-}\right]=1.8 \mu \mathrm{M} ;\left[{ }^{14} \mathrm{NO}_{3}^{-}\right]=384 \mu \mathrm{M}$
21. (a) $A=0 \quad$ (b) $B=2 D_{\mathrm{m}}$
(c) $C=C_{\mathrm{s}}+C_{\mathrm{m}}=\frac{2 k}{3(k+1)^{2}} \frac{d^{2}}{D_{\mathrm{s}}}+\frac{1+6 k+11 k^{2}}{24(k+1)^{2}} \frac{r^{2}}{D_{\mathrm{m}}}$
(d) $u_{\mathrm{x}}($ optimum $)=\sqrt{\frac{B}{C}} ; H_{\text {min }}=2 \sqrt{B\left(C_{\mathrm{s}}+C_{\mathrm{m}}\right)}$
22. (a) $0.58,1.9$
(b) $0.058 \mathrm{~mm}, 0.19 \mathrm{~mm}$
(c) $3.0 \times 10^{5}$
(d) 4.0
23. $D_{\mathrm{m}}=3.0 \times 10^{-5} \mathrm{~m}^{2} / \mathrm{s}, D_{\mathrm{s}}=5.0 \times 10^{-10} \mathrm{~m}^{2} / \mathrm{s}$
24. (b) limiting $m=K V_{\mathrm{f}} C_{\mathrm{o}} \quad$ (c) $0.69 \%, 41 \%$
25. (a) 6 (b) 350 (c) $350,315,280,245,210=\mathrm{M}^{+},(\mathrm{M}-\mathrm{Cl})^{+}$, $(\mathrm{M}-2 \mathrm{Cl})^{+},(\mathrm{M}-3 \mathrm{Cl})^{+},(\mathrm{M}-4 \mathrm{Cl})^{+},(\mathrm{M}-5 \mathrm{Cl})^{+} \quad$ (d) For 5 Cl , predicted relative abundances $=62.5: 100: 64.0: 20.4: 3.3: 0.2$. For 4Cl, abundances $=$ $78.2: 100: 48.0: 10.2: 0.8$. For 3Cl, abundances $=100: 95.9: 30.7: 3.3$. For 2 Cl , abundances $=100: 64.0: 10.2$.

## Chapter 24

. (b) pressure gradient (= density gradient)
5. (a) $\mathrm{L}=33,17,10,5 \mathrm{~cm}$
6. $0.14 \mathrm{~min}, 0.30 \mathrm{~min}$
11. (a) 1560 for L enantiomer and 1310 for D enantiomer $\quad$ (b) 1.25
(c) 1.35
12. (a) 18
(b) 10
13. (a) bonded reversed-phase chromatography
(b) bonded normal-phase chromatography (c) ion-exchange or ion chromatography (d) molecular exclusion chromatography
(e) ion-exchange chromatography (f) molecular exclusion chromatography
14. $0.27 \mathrm{~m}^{2}$
15. (a) shorter
(b) amine
16. (a) $1.76 \mathrm{~mm} / \mathrm{s}$
(b) 3.51
(c) $192000,22.9 \mu \mathrm{~m}$
(d) 0.59 $\begin{array}{lll}\text { (e) } \alpha=1.006_{6}, \gamma=1.005_{2} & \text { (f) } 5.9_{2} \times 10^{5}, 13.6 \mathrm{~m} & \text { (g) decrease }\end{array}$ flow or change solvent (h) 0.91
17. (a) $(R)$-Gimatecan would be eluted at 6.96 min from $(R, R)$-stationary phase and 6.10 min from $(S, S)$-stationary phase. (b) ( $R$ )-Gimatecan at 6.96 min is lost beneath tail of $(S)$-gimatecan $\quad$ (c) $\alpha=1.25_{8}, \gamma=1.14_{1}$
(d) 2.91 (better than baseline separation)
18. 126 mm
20. (a) $t_{\mathrm{m}}=0.38 \mathrm{~min}$ for column A and 0.26 min for column B
(d) $k^{\prime}=1.3$ for morphine 3- $\beta$-D-glucuronide and 3.3 for morphine
(e) 6.2
21. (b) 5.8 W
22. (a) $m / z 304$ is $\mathrm{BH}^{+}$(cocaine protonated at N )
(b) loss of $\mathrm{C}_{6} \mathrm{H}_{5} \mathrm{CO}_{2} \mathrm{H}$
(e) phenyl group
23.
(a) $m / z 234$ is $\mathrm{MH}^{+}, m / z 84$ is $\mathrm{C}_{5} \mathrm{H}_{10} \mathrm{~N}^{+}$
(b) $237 \rightarrow 84$
24. (c) 1.1 min for both
32. 27.8 min predicted, 20.2 min observed
33. (a) $\sim 36 \mathrm{~min}$
(b) 43.0 min using points from $\Phi=0.35$ to 0.6
34. (b) between B and $\mathrm{F}: 30 \%$ methanol/8\% tetrahydrofuran/62\% buffer; between F and C : $10 \%$ methanol/24\% tetrahydrofuran/66\% buffer
35. D: $25 \%$ acetonitrile $/ 30 \%$ methanol/45\% buffer; E: $25 \%$ acetonitrile $/ 20 \%$ tetrahydrofuran/55\% buffer; F: $30 \%$ methanol/20\% tetrahydrofuran/ $50 \%$ buffer; G: $16.7 \%$ acetonitrile/20\% methanol/13.3\% tetrahydrofuran/50\% buffer 36. $38 \%$
37. (a) lower
(b) higher
38. (a) $\Delta t / t_{\mathrm{G}}=0.32>0.25 \Rightarrow$ gradient elution
(b) 40 to $70 \%$ acetonitrile in 60 min
39. (a) Change solvent strength, temperature, or pH . Use a different solvent or a different kind of stationary phase. (b) slower flow rate, different temperature, longer column, smaller particle size
40. (a) $\sim 29 \mathrm{~min}$
(b) $k^{*}=12.9, F=4.7 \mathrm{~mL} / \mathrm{min}, m=4.7 \mathrm{mg}$,
$t_{\mathrm{G}}=11.5 \mathrm{~min}$

## Chapter 25

6. $38-75 \mu \mathrm{~m} ; 200 / 400 \mathrm{mesh}$
7. (a) 30
(b) 3.3
(c) increase
8. cation charge $=0.00202 \mathrm{M}$, anion charge $=-0.00159 \mathrm{M}$. Either some concentrations are inaccurate or some ionic material was not detected.
9. (b) $29 \mathrm{ng} / \mathrm{mL}$
10. (a) $3.8 \times 10^{2} \mathrm{~h}$
(b) $8.0 \mathrm{~mA}, 0.16 \mathrm{~A}$
11. (b) $10 \mu \mathrm{~m}$
12. (a) 40.2 mL
(b) 0.53
13. 0.16
14. (a) 2000 Da
(b) 300 Da
15. (a) 5.7 mL
(b) 11.5 mL
(c) Solutes must be adsorbed.
16. 320000
17. 

(a) 0.167 mm
(b) 0.016 s
(c) 0.00040 s
(d) 0.064 s
31. (a) $1.15 \times 10^{4} \mathrm{~Pa} \quad$ (b) 1.17 m height (not possible), so use pressure of $11.5 \mathrm{kPa}=0.114 \mathrm{~atm}$.
32. (a) 29.5 fmol
(b) $3.00 \times 10^{3} \mathrm{~V}$
33. $9.2 \times 10^{4}$ plates, $4.1 \times 10^{3}$ plates (My measurements are about $1 / 3$ lower than the values labeled in the figure from the original source.)
34. (a) maleate
(b) Fumarate is eluted first
(c) Maleate is eluted first.
35.
(a) $\mathrm{pH} 2: 920 \mathrm{~s} ; \mathrm{pH} 12: 150 \mathrm{~s}$
(b) pH 2: never; $\mathrm{pH} 12: 180 \mathrm{~s}$
36. (a) $t_{120 \mathrm{kV}} / t_{28 \mathrm{kV}}=4.3$ (observed ratio $=3.9$ )
(b) $N_{120 \mathrm{kV}} /$
$N_{28 \mathrm{kV}}=4.3$ (c) $\sigma_{120 \mathrm{kV}} / \sigma_{28 \mathrm{kV}}=0.48 \quad$ (d) Increasing voltage decreases migration time, giving bands less time to spread apart by diffusion.
38. $1.3_{5} \times 10^{4}$ plates, $30 \mu \mathrm{~m}$
39. 20.5 min
40. light chain $=17300 \mathrm{Da}$, heavy chain $=23500 \mathrm{Da}$
41. $z_{0}=-3.28$
42. $2.0 \times 10^{5}$ plates
43. thiamine $<$ (niacinamide + riboflavin) $<$ niacin. Thiamine is most soluble.
44. Cyclobarbital and thiopental each separate into two peaks because each has a chiral carbon atom.
46. 5.55
48. (d) $N_{\text {obs }}=1.45 \times 10^{5}, N_{\text {theory }}=2.06 \times 10^{5}$
(e) 1.6

## Chapter 26

${ }^{\dagger}$ Commercial lithium compounds are artificially depleted of ${ }^{6} \mathrm{Li}$. The atomic mass of commercial Li is in the range 6.939 to 6.996 . If a more accurate value is required, it must be determined for the specific material.

[^20]

[^0]:    *P. R. Griffiths, "Whither 'Quant'? An Examination of the Curriculum and Testing Methods for Quantitative Analysis Courses Taught in Universities and Colleges in the Western USA," Anal. Bioanal. Chem. 2008, 391, 875.

[^1]:    Frequency is the number of cycles per unit time for a repetitive event. Force is the product mass $\times$ acceleration. Pressure is force per unit area. Energy or work is force $\times$ distance $=$ mass $\times$

[^2]:    a. Corrected for buoyancy with Equation 2-1.
    b. Corrected for buoyancy and expansion of borosilicate glass $\left(0.0010 \% K^{-1}\right)$.

[^3]:    In calculating confidence intervals, $\sigma$ may be substituted for sin Equation 4-6 if you have a great deal of experience with a particular method and have therefore determined its "true" population standard deviation. If $\sigma$ is used instead of $s$, the value of $t$ to use in Equation 4-6 comes from the bottom row of Table 4-2.
    Values of t in this table apply to two-tailed tests illustrated in Figure 4-9a. The 95\% confidence level specifies the regions containing $2.5 \%$ of the area in each wing of the curve. For a one-tailed test, we use values of t listed for $90 \%$ confidence. Each wing outside of t for $90 \%$ confidence contains $5 \%$ of the area of the curve.

[^4]:    The dilution factor $\frac{\text { initial volume }}{\text { final volume }}$ converts initial concentration into final concentration.

[^5]:    The volume of solution injected into the column was different in all three runs.

[^6]:    ${ }^{\dagger}$ The definition of the standard state contains subtleties beyond the scope of this book. For Reaction 6-3, the standard state of $\mathrm{H}^{+}$or $\mathrm{Cl}^{-}$is the hypothetical state in which each ion is present at a concentration of 1 M but behaves as if it were in an infinitely dilute solution. That is, the standard concentration is 1 M , but the standard behavior is what would be observed in a very dilute solution in which each ion is unaffected by surrounding ions.

[^7]:    ${ }^{\dagger}$ In this text, we use $K_{\mathrm{w}}=10^{-14.00}=1.0 \times 10^{-14}$ at $25^{\circ} \mathrm{C}$. The more accurate value from Table 6-1 is $K_{\mathrm{w}}=10^{-13.995}$. For acetic acid with $K_{\mathrm{a}}=10^{-4.756}$, the accurate value of $K_{\mathrm{b}}$ is $10^{-(13.995-4.756)}=10^{-9.239}=$ $5.77 \times 10^{-10}$.

[^8]:    $10^{\log z}=z$

[^9]:    ${ }^{\dagger}$ These problems are based on Beer's law in Section 17-2.

[^10]:    *Asterisk indicates that equilibrium constant was estimated for $\mu=0.1 \mathrm{M}$ from data reported for a different ionic strength.

[^11]:    a. A. E. Fischer, Y. Show, and G. M. Swain, "Electrochemical Performance of Diamond Thin-Film Electrodes from Different Commercial Sources," Anal. Chem. 2004, 76, 2553; Y. Dai, G. M. Swain, M. D. Porter, and J. Zak, "Optically Transparent Carbon Electrodes," Anal. Chem. 2008, 80, 14; J. Stotter, Y. Show, S. Wang, and G. Swain, "Comparison of Electrical, Optical, and Electrochemical Properties of Diamond and Indium Tin Oxide Thin-Film Electrodes," Chem. Mater. 2005, 17, 4880.
    b. S. Ferro and A. De Battisti, "The 5-V Window of Polarizability of Fluorinated Diamond Electrodes in Aqueous Solution," Anal. Chem. 2003, 75, 7040.

[^12]:    Variation in ${ }^{13} \mathrm{C}$ from natural sources. $\mathrm{C}_{3}, \mathrm{C}_{4}$, and CAM are types of plants with distinct metabolic pathways leading to different ${ }^{13} \mathrm{C}$ incorporation. [Adapted from W. Meier-Augenstein, LCGC 1997, 15, 244.]

[^13]:    ${ }^{\dagger}$ Whenever a choice exists between $\mathrm{CHCl}_{3}$ and $\mathrm{CCl}_{4}$, the less toxic $\mathrm{CHCl}_{3}$ should be chosen. Hexane and toluene are greatly preferred over benzene, which is a carcinogen.

[^14]:    a. Methyl stearate $\left(\mathrm{CH}_{3}\left(\mathrm{CH}_{2}\right)_{16} \mathrm{CO}_{2} \mathrm{CH}_{3}\right)$ and methyl oleate $\left(\right.$ cis- $\left.\mathrm{CH}_{3}\left(\mathrm{CH}_{2}\right)_{7} \mathrm{CH}=\mathrm{CH}\left(\mathrm{CH}_{2}\right)_{7} \mathrm{CO}_{2} \mathrm{CH}_{3}\right)$ were separated on columns with poly(diethylene glycol succinate) stationary phase at $180^{\circ} \mathrm{C}$.

[^15]:    a. Buffer is 25 mM phosphate/pH 2-3 made by treating $\mathrm{H}_{3} \mathrm{PO}_{4}$ with $\mathrm{KOH} . \mathrm{K}^{+}$is more soluble than $\mathrm{Na}^{+}$in organic solvents and leads to less tailing. This concentration of phosphate is suitable for ultraviolet detection. Add 0.2 g sodium azide per liter as a preservative if buffer will not be consumed quickly.
    Adapted and modified from L. R. Synder, J. J Kirkland, and J. L. Glajch, Practical HPLC Method Development (New York: Wiley, 1997) and S. Needham, "HPLC Method Development for LC/MS," short course presented at Pittcon 2009.
